THE CORE PAPERS

Realization Calculus

Projectors, Transfer and Arithmetic

Komorebi P.

A mathematical monograph in twelve chapters.

INTRODUCTION

Objects, operators and arithmetic

Realization Calculus studies how mathematical objects are generated from seeds, resolved into packets and related by operators. Projectors specify the components retained in a description. Transfer records their interaction and the passage from one resolution to another.

The first four chapters develop the Projector Resolved Seed Calculus. The argument then moves through multiresolution signals, evolution and memory, quantum dynamics and packet operator algorithms. The final chapters examine congruences, residual seeds, packet geometry and patching support.

Three questions recur. Which objects can be generated from the available seeds? Which relations survive a change of resolution? What additional hypotheses permit a compatible description to be realized in the intended analytic or arithmetic setting? Each construction is read with its own domain and assumptions.

The arithmetic conclusions retain their conditional character. Conjecture 66 in Chapter XI remains open. Chapter XII requires suitable residual and deformation data, patching and full support, a compatible Hecke point over the same coefficient field, classicality and an attached representation. A universal supply of these inputs is not a conclusion of the chapter.

The mathematical text and visual studies form the main sequence. The formal companions and glossary follow, with sources and references collected at the end.

READING MAP

Following the argument

The main sequence

Read Chapters I-XII in order for the development from seed constructions to conditional arithmetic realization. Each chapter opening connects its subject to the surrounding chapters and identifies the mathematical text and visual studies that follow.

Visual studies

The visual material stays with the chapter whose objects it illustrates. Figures and examples retain their stated inputs and ranges. A chapter identifier accompanies a global plate reference, as in Plate VIII.32.

Formal companions

The Lean guides are collected at the back. They identify the statements, hypotheses and source correspondences in their own formal scope. The machine-native treatment of Chapter I appears with its formal companion.

The back matter

Further studies retain their own hypotheses and open questions. The glossary gives short definitions with links to the relevant treatment. Sources and references are grouped by chapter and treatment at the end of the book.

Begin with Chapter I 1

NOTATION AND REFERENCES

Conventions across the book

Local notation

Each chapter specifies its ambient spaces, scalar fields, domains and index sets. A symbol reused elsewhere need not denote the same object. Read every operator with its stated domain and codomain.

Finite and infinite settings

Finite algebra, limits and infinite-dimensional constructions have different assumptions. A formal identity does not by itself extend an operator to a larger space or supply continuity. The passage between settings is made where the text provides it.

Exact and numerical statements

Exact identities and numerical examples retain their stated roles. Numerical illustrations support the specified comparisons within their parameter ranges.

References within the volume

Continuous page numbers and PDF bookmarks navigate this book. Theorem, equation, figure and section numbers remain local to their named treatment unless a chapter prefix is given. Cite the chapter and treatment with the local number.

Citation labels

Bibliographies and source registers are collected at the end of the book. Their citation labels retain the numbering or short names used in the corresponding chapter and treatment. The accompanying electronic material preserves the supporting sources.

CONTENTS

Chapters I-VI

I Projector Resolved Seed Calculus I 1
Typed operator systems, seed rank, and exact packet coordinates

II Projector Resolved Seed Calculus II 98
Refinement towers, weighted transfer, and integral separation of operator packets

III Projector Resolved Seed Calculus III 177
Typed transfer, nonlinear packets, and obstruction theory

IV Projector Resolved Seed Calculus IV 279
Cyclic analytic functions, reciprocal families, and spectral zero data

V Multiresolution Signal Calculus 382
Exact coordinates, singular packets, and stable reconstruction

VI Transfer Semigroups and Memory 510
Probabilistic refinement, fractional operators, and exact hidden-state elimination

CONTENTS

Chapters VII-XII

VII Quantum Seeds and Effective Dynamics 659
Symmetry, geometric transport, quantum channels, and bounded refinement towers

VIII Packet Operator Algorithms 813
Exact compilation and GPU realization

IX Euler Congruences 930
Completion, factorial strengthening, and sharp dyadic geometry

X Universal Residual Seeds 1169
Deformation forests, transport categories, and conditional system completion

XI Tame and Wild Packet Geometry 1259
For local Langlands

XII Patching Support and Hecke Packets 1417
Conditional automorphic completion

Glossary 2647

Sources and references 2665

The scope of the companions

A written proof, a formal declaration and a finite computation answer different questions. The companions state their own coverage and the assumptions on which it depends.

Using the glossary

The glossary is a navigation aid. Its definitions are intentionally brief, and its references lead to the fuller statements and hypotheses in the text.

CHAPTER I

Projector Resolved Seed Calculus I

Typed operator systems, seed rank, and exact packet coordinates

The opening chapter introduces the seed and operator language used throughout the book.

Seeds, operators and projectors provide the linear language of the series. Exact packet coordinates make the generated objects and the maps between them visible.

IN THIS CHAPTER

Mathematical text 2

Formal companion 1588

Sources and references 2666

Scope

The correspondence concerns the stated proof-level constructions. Noncomputable existence results do not provide executable solvers.

The next chapter compares these descriptions across refinement levels and asks which structures survive that passage.

Overview

This chapter begins with a practical mathematical question. Once a family of operators has been fixed, what can we generate from a few starting vectors, and how can we keep track of the resulting object? The answer has two parts. Seed rank measures how many starting vectors are needed. Packet coordinates describe the components of vectors and the transfers between them.

The construction starts with a typed operator grammar and a concrete realization of that grammar. From there we study generated hulls, presentations by seeds and relations, and the number of generators required by a module. The generator results include reduction modulo the Jacobson radical, the semisimple multiplicity formula over division rings, and the formula for a single operator over an arbitrary field.

We then resolve vectors and operators using complete families of idempotents. Finite packet reconstruction is exact. Countable reconstruction requires the stated convergence assumptions. Transfer blocks record the action from each input packet to each output packet, and their multiplication exposes both admissible paths and cancellation. Later sections develop quotient descent, coordinate changes, completion, and transport through realization functors.

Worked quiver, coordinate ring, matrix, graph, and shift models show how the same language is used in different settings. The visual atlas follows these models through complete calculations. Stable statement identifiers connect this text to the existing machine companion, while the separate Lean guide specifies the scope of the formal certificates. The written proofs and the imported classical results retain their stated hypotheses.

Reader's orientation

Status class	Meaning
Definition	Introduced structure or notation.
Theorem, proposition, corollary, lemma	Proved in this manuscript under the printed hypotheses.
Classical input	Imported standard theorem, stated explicitly because later proofs depend on it.
Boundary	A limitation, counterexample, or failure of an implication that is part of the formal scope.

Formal and computational companions. The formal companion explains the Lean development, its build procedure, theorem mapping, and the hypotheses of each verified statement. It distinguishes the 35-row foundational contract from the correspondence for the 108-record mathematical inventory. The computational companion presents those stable records, dependencies, and executable interfaces. Both companions are collected in the back matter. The mathematics below retains the full scope of its stated classical inputs and written proofs.

A route through this section

The argument has four stages. Reading them in order makes the later examples easier to follow.

1. **Grammar and realization.** Specify which compositions of operators are legal, then distinguish that abstract syntax from the operators that actually act on a chosen space.
2. **Generation.** Choose one or more seeds and ask which part of the realization is generated by their operator orbits. The minimal number of required seeds is the seed rank.
3. **Packet coordinates.** Resolve the space by a complete family of idempotents. Every vector and every operator then has exact packet coordinates.
4. **Transport.** Study how those coordinates behave under products, graphs, morphisms, quotients, completion, and realization functors.

The first two layers describe what can be generated. The last two describe how the generated object is resolved and transported.

The basic conceptual chain

$$\begin{aligned} &\text{typed grammar} \longrightarrow \text{realized algebra} \longrightarrow \text{seed hull} \\ &\longrightarrow \text{seed rank} \longrightarrow \text{packet coordinates} \\ &\longrightarrow \text{transfer blocks} \longrightarrow \text{functorial realization.} \end{aligned}$$

Each object in this chain has a different role. A grammar is a presentation of allowed operator words. A realized algebra is the image of that grammar in an endomorphism algebra. A seed hull is an orbit span inside one particular module. A packet system is an exact coordinate decomposition and need not be orthogonal. A realization functor is required to preserve a declared mathematical profile, not merely the vocabulary.

Four questions answered by Chapter I

Question	Formal object	Principal answer
What operations are legal?	Quiver with relations or a unital operator algebra	Typed realizations are modules over the quotient path algebra.
What can a finite seed family generate?	Evaluation map $A^{\oplus r} \to M$	The generated hull is a quotient of a finite free module.
How many seeds are required?	$\operatorname{srank}_A(M)$	For a finitely generated module, pass to $M/\operatorname{Jac}(A)M$. When the quotient algebra is semisimple Artinian, compute its simple multiplicities.
How are vectors and operators resolved?	Complete idempotents (P_α)	$X \cong \bigoplus_\alpha P_\alpha X$ and $T \leftrightarrow (P_\beta T P_\alpha)$.

Notation map

Symbol	Name	Meaning
$\mathfrak{G} = (Q, I)$	Typed grammar	A quiver with finite vertex set and a two-sided ideal of source and target compatible relations.
$\Lambda_{\mathfrak{G}}$	Grammar algebra	The quotient path algebra $\Bbbk Q/I$.
$\mathcal{A}_X$	Realized algebra	The image of the grammar algebra in $\operatorname{End}_\Bbbk(\lvert X\rvert)$.
$S \subseteq M$	Seed family	The vectors from which the operator orbit is generated.
$\operatorname{Hull}_A(S)$	Generated hull	The submodule AS, or its declared topological closure.
$\operatorname{srank}_A(M)$	Seed rank	The smallest cardinality of a generating family. A finite value is the minimum number of seeds.
$\mathcal{P} = (P_\alpha)$	Packet system	Pairwise annihilating idempotents summing to the identity.
X_α	Packet space	The range $P_\alpha X$.
$\mathcal{A}_\mathcal{P}$	Analysis	The map $x \mapsto (P_\alpha x)_\alpha$.
$\mathcal{S}_\mathcal{P}$	Synthesis	The map $(x_\alpha) \mapsto \sum_\alpha x_\alpha$.
$T_{\beta\alpha}$	Transfer block	The source and target block $P_\beta T P_\alpha : X_\alpha \to X_\beta$.
$\operatorname{Supp}_\mathcal{P}(x)$	Packet support	The packet indices on which x has a nonzero coordinate.
psrank	Rank for seeds confined to individual packets	The minimal number of generating seeds each supported in a single packet.

Small examples to keep in view

The following small systems recur throughout the explanatory boxes. The worked models and visual atlas later develop these ideas in complete calculations.

R1: one operator with several primary blocks

Let T act on a finite dimensional vector space. Regard X as a $\Bbbk[t]$-module by $t \cdot x = Tx$. If T has three Jordan blocks for the same eigenvalue, then three seeds are necessary and sufficient for that primary component. The largest number of blocks over any irreducible polynomial is the seed rank.

R2: a matrix algebra with multiplicity

Let $A = M_2(\Bbbk)$ act diagonally on $M = (\Bbbk^2)^{\oplus 3}$. One seed can contribute at most two independent multiplicity directions, because the regular module contains two copies of the simple module. Hence

$$\operatorname{srank}_A(M) = \left\lceil \frac{3}{2} \right\rceil = 2.$$

This is the simplest nontrivial instance of the semisimple multiplicity formula.

R3: an exact but oblique packet split

On $X = \Bbbk^2$, set

$$P_1 = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}, \qquad P_2 = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}.$$

Then $P_i^2 = P_i$, $P_1P_2 = P_2P_1 = 0$, and $P_1 + P_2 = I$. The ranges form a direct sum, but over $\mathbb{R}$ the projectors are not orthogonal in the Euclidean inner product. Exact reconstruction and numerical conditioning are therefore separate questions.

R4: a directed packet system

Let $X = X_1 \oplus X_2 \oplus X_3$. Suppose the generating operators permit transfers $1 \to 2$ and $2 \to 3$, with no path entering packet 1. Packet 1 is the unique source component. If the corner action on X_1 is cyclic and the propagation hypotheses of theorem 9.7 hold, one seed in X_1 can generate all three packets.

Suggested reading paths

- For the minimal algebraic foundation, read Sections 1 to 5, then Sections 7 and 8.
- For finite dimensional representation theory, concentrate on Sections 4 to 6.
- For signal, wavelet, or quantum applications, read Sections 7 and 8 and the results on tensor products carefully.
- For graphs and applications involving residual transport, read Sections 8 to 10.
- For later categorical claims, read Sections 10 and 11 together with the final semantic realization criterion.

Scope of the argument

The chapter does not claim that every useful decomposition is automatically discovered, that every packet split is numerically stable, or that exact coordinates solve a nonlinear problem. Chapter I establishes the linear language and its exact transport laws. Refinement, obstruction theory, nonlinear trees, arithmetic valuations, and continuum limits belong to later chapters.

1 Coefficient conventions, logical status, and scope

A route through this section

This section sets out the conventions used throughout the chapter. It explains when a statement concerns algebra, when topology enters the argument, which results are taken as classical input, and how the stable record IDs connect this chapter to later work. Keeping these settings distinct makes the hypotheses of each result easier to follow.

1.1 Ambient regimes and theorem records

Definition 1.1 (Coefficient and module regimes)**.** All modules are left modules unless stated otherwise. The algebraic regime consists of a unital ring A and a unital left module M over A. When linear dimensions, tensor products, quivers, or operator blocks are used, A is a unital algebra over $\Bbbk$, where $\Bbbk$ is a field, and M is a vector space over $\Bbbk$. The topological regime consists of a Hausdorff topological vector space over a complete valued field, together with a unital algebra of continuous linear operators. Every infinite sum, completion, quotient topology, and closure below is interpreted only in the regime explicitly declared in its statement.

Conventions for empty families. For finite families of nonnegative integers we use $\max \emptyset = 0$. The height of an empty finite partially ordered set is 0, as is the height of a nonempty poset with no strict comparable pair. Thus the height in the theorem for the support preorder counts strict steps.

Definition 1.2 (Canonical theorem record)**.** A canonical theorem record is the tuple

$$(\mathrm{ID}, \mathrm{status}, \mathrm{hypotheses}, \mathrm{statement}, \mathrm{dependencies}, \mathrm{proof}, \mathrm{exports}, \mathrm{boundary}).$$

A later chapter cites the stable record ID. A domain specialization may add domain hypotheses, but it does not repeat a generic proof from this chapter.

Boundary 1.3 (Symbolic scope). This chapter proves the algebraic and topological statements printed below. It does not assert historical novelty, independent external certification, automatic discovery of useful packet systems, nonlinear obstruction theory, multilevel refinement, arithmetic congruences, quantum gravity, automorphy, or local or global Langlands reciprocity.

2 Typed operator grammars, realizations, and seed systems

A route through this section

An operator grammar describes which compositions are allowed and which relations they satisfy. A realization gives this syntax a concrete action on vector spaces. Its realized algebra consists of the operators that actually occur in that action. We can then ask which vectors serve as seeds.

2.1 Typed syntax and module realizations

Definition 2.1 (Typed operator grammar)**.** Let $Q = (Q_0, Q_1, s, t)$ be a quiver with finite vertex set. A typed operator grammar over $\Bbbk$ is a pair

$$\mathfrak{G} = (Q, I),$$

where $I \lhd \Bbbk Q$ is an ideal on both sides generated by linear combinations over $\Bbbk$ of paths having common source and common target. Write

$$\Lambda_{\mathfrak{G}} := \Bbbk Q / I.$$

A realization of $\mathfrak{G}$ is a family $(X_v)_{v \in Q_0}$ and linear maps

$$X_a : X_{s(a)} \longrightarrow X_{t(a)} \qquad (a \in Q_1)$$

that annihilate every relation in I. A morphism $f : X \to Y$ of realizations is a family of linear maps $f_v : X_v \to Y_v$ satisfying

$$f_{t(a)} X_a = Y_a f_{s(a)} \qquad (a \in Q_1).$$

Definition 2.2 (Realization on a single space)**.** For a typed realization X, define its realization on a single space by

$$|X| := \bigoplus_{v \in Q_0} X_v.$$

Every vertex idempotent acts as a coordinate projector on $|X|$, and every path acts as a block operator from its source space to its target space.

Theorem 2.3 (Typed realization and module equivalence)**.** *The category of realizations of $\mathfrak{G}$ is equivalent to the category of unital left modules over $\Lambda_{\mathfrak{G}}$. Explicitly, a realization X determines the collapsed space $|X|$ of definition 2.2 with the vertex idempotent e_v acting as the coordinate projector onto X_v and each arrow acting in the block between its declared source and target. Conversely, a unital module M over $\Lambda_{\mathfrak{G}}$ determines the realization*

$$M_v = e_v M, \qquad M_a(x) = ax.$$

The two constructions are inverse up to canonical natural isomorphism.

Proof. Because Q_0 is finite, $1 = \sum_{v \in Q_0} e_v$ in $\Bbbk Q$, the e_v are pairwise orthogonal, and the same identities hold in $\Lambda_{\mathfrak{G}}$. Given a realization, define the action of a path by composition of its arrow maps and extend linearly. Every element of I acts as zero, so the action factors through $\Lambda_{\mathfrak{G}}$. The vertex idempotents give

$$|X| = \bigoplus_v e_v |X| = \bigoplus_v X_v.$$

Conversely, if M is unital, then

$$M = 1M = \sum_v e_v M.$$

Orthogonality makes the sum direct. For an arrow $a : v \to w$, the identities $a = e_w a e_v$ imply

$$a(e_v M) \subseteq e_w M.$$

The relations in I act as zero because M is a module over $\Lambda_{\mathfrak{G}}$. Applying both constructions returns the original vertex spaces and arrow maps, or the original module decomposition, through the evident identity maps. These identifications commute with morphisms, giving an equivalence of categories. □

How to read the result

The equivalence does not claim that a quiver presentation is unique. It says that once a grammar is fixed, working with typed arrows and working with a module over the quotient path algebra carry the same information. The typed description is often easier for constructing an operator system. The module description is often easier for proving generation and quotient theorems.

A grammar with two vertices

Take two vertices and one arrow $a : 1 \to 2$. A realization is a pair of spaces and a linear map

$$X_1 \xrightarrow{X_a} X_2.$$

After collapse, $|X| = X_1 \oplus X_2$, the vertex idempotents are the two coordinate projectors, and a is a single block outside the diagonal. This elementary case already contains the viewpoint of packets and transfer blocks used later.

2.2 The realized action and faithful reduction

Definition 2.4 (Realized operator algebra)**.** For a realization X, the realized operator algebra is

$$\mathcal{A}_X := \mathrm{im}(\Lambda_{\mathfrak{G}} \longrightarrow \mathrm{End}_{\Bbbk}(|X|)) .$$

It records the actual operators in the realization and may be a proper quotient of the abstract grammar algebra.

Proposition 2.5 (Action factorization and hull invariance)**.** *Let $S \subseteq |X|$. The generated submodule under the grammar algebra equals the generated submodule under the realized operator algebra:*

$$\Lambda_{\mathfrak{G}} S = \mathcal{A}_X S.$$

Consequently, every statement about seed rank depends only on the realized action, not on redundant relations in a chosen presentation of the grammar.

Proof. The action map $\rho : \Lambda_{\mathfrak{G}} \twoheadrightarrow \mathcal{A}_X$ is surjective by definition and satisfies $\lambda s = \rho(\lambda) s$. Hence every grammar orbit vector lies in $\mathcal{A}_X S$. The reverse inclusion holds because every element of $\mathcal{A}_X$ is $\rho(\lambda)$ for some λ. □

The central idea

Replacing the abstract grammar algebra by its image $\mathcal{A}_X$ removes syntax that acts as zero. This is a faithful reduction of the action. It does not change any orbit, hull, or computation of seed rank.

2.3 Seeds, addressed hulls, and natural presentations

Definition 2.6 (Linear seed system)**.** A linear seed system is a tuple

$$\mathfrak{S} = (X, \mathcal{A}, S, \mathcal{P}, \tau),$$

where X is a unital left module over $\mathcal{A}$, $\mathcal{A}$ is fixed independently of the target element, $S = (s_1, \dots, s_r)$ is a finite distinguished seed family, $\mathcal{P}$ is either empty or a declared packet system, and τ is either the algebraic convention or a specified Hausdorff topology in which the declared operator action is continuous.

Definition 2.7 (Generated hull)**.** For $S \subseteq X$, define

$$\mathrm{Hull}_{\mathcal{A}}(S) := \sum_{s \in S} \mathcal{A}s.$$

In the topological regime define

$$\mathrm{Hull}_{\mathcal{A},\tau}(S) := \overline{\mathrm{Hull}_{\mathcal{A}}(S)}^{\tau}.$$

For a singleton $S = \{s\}$, write $\mathrm{Hull}_{\mathcal{A}}(s)$.

The algebraic hull uses finite sums of addressed seed vectors. In the topological setting, taking its closure may add limits that no finite expression reaches. Thus algebraic generation and dense generation answer different questions, even when they use the same seeds and operators.

Definition 2.8 (Natural presentation)**.** A seed presentation is natural relative to a declared grammar when the primitive operators and relations are fixed independently of the target, the relation system is finite or effectively enumerable, the topology is intrinsic to the realization, no primitive operator directly stores the complete target, and the presentation exposes a reusable invariant, theorem, or computation not encoded by a primitive chosen for the target.

Proposition 2.9 (Algebra generation and module generation are distinct)**.** *Every nonzero unital algebra A, regarded as a left module over itself, has*

$$\mathrm{srank}_A(A) = 1,$$

with cyclic seed 1_A. This conclusion is independent of the number of algebra generators required to present A as an algebra.

Proof. For every $a \in A$, one has $a = a1_A$. Hence $A1_A = A$. The number of operations needed to generate A as an algebra is a different invariant and does not enter the module calculation. □

Boundary 2.10 (Operators chosen for a target). For a fixed seed s and target x, the existence of a specially defined operator A_x satisfying $A_x s = x$ does not establish a natural seed calculus unless A_x belongs to a grammar that is fixed independently of the target and satisfies definition 2.8.

Scope of the argument

An operator may be chosen because it sends the current seed to a desired target. Such a choice proves only an existence statement for that one target unless the operator already belongs to the fixed algebra. The algebra must be declared before the question of seed rank is asked. Otherwise the acting system changes with the answer one wants to obtain.

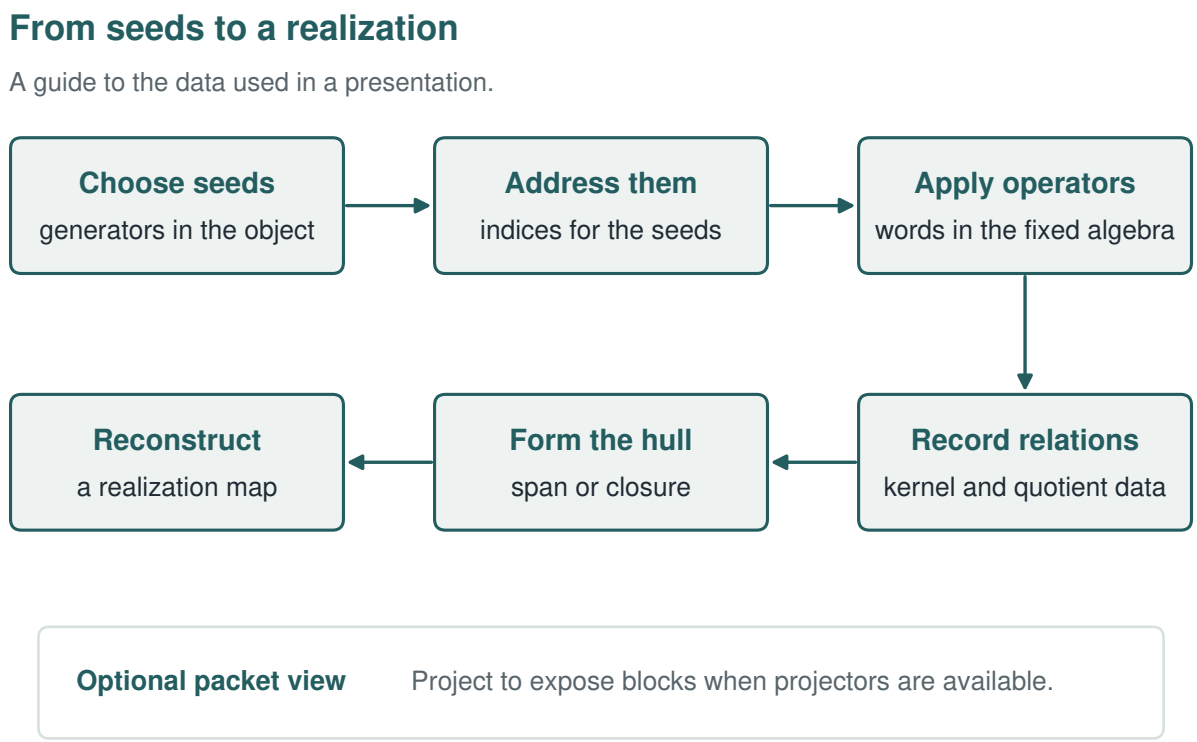

Figure 1. Schematic organization of the seed, operator, relation, and reconstruction data. This is a guide to the presentation, not an additional formal theorem.

3 Free presentations by seeds and relations

A route through this section

A seed family gives a canonical map from a finite free module. The generated hull is exactly its image, and the relations among addressed seeds form the kernel. This converts orbit generation into a presentation problem.

3.1 Finite free covers

Definition 3.1 (Seed evaluation map)**.** Let A be a unital ring, let M be a left module over A, and let $S = (s_1, \dots, s_r) \in M^r$. Define the linear map over A

$$\varepsilon_S : A^{\oplus r} \longrightarrow M, \qquad (a_1, \dots, a_r) \longmapsto \sum_{j=1}^{r} a_j s_j.$$

Theorem 3.2 (Finite free presentation)**.** *For the map in definition 3.1,*

$$\operatorname{im} \varepsilon_S = \operatorname{Hull}_A(S), \qquad N_S := \operatorname{Ker} \varepsilon_S \leq A^{\oplus r},$$

and the induced map is an isomorphism of left modules over A

$$\boxed{A^{\oplus r}/N_S \cong \operatorname{Hull}_A(S).}$$

Consequently, S generates M if and only if ε_S is surjective.

Proof. The image consists exactly of finite sums $\sum_j a_j s_j$, which is $\operatorname{Hull}_A(S)$. Because ε_S is linear over A, its kernel is a left submodule. The first isomorphism theorem gives

$$A^{\oplus r}/N_S \cong \operatorname{im} \varepsilon_S = \operatorname{Hull}_A(S).$$

The final equivalence is the equality $\operatorname{im} \varepsilon_S = M$. □

How to read the result

The theorem converts the geometric language of addressed seed orbits into the algebraic language of generators and relations. A word in the operators is represented by an element of the free module. Two addressed expressions represent the same vector exactly when their difference lies in the kernel. The generated hull is therefore not merely spanned by the free module. It is its canonical quotient.

A cyclic nilpotent chain

Let $A = \Bbbk[t]$ and $M = \Bbbk[t]/(t^3)$. The residue class $s = [1]$ is one seed and

$$\varepsilon_s : A \to M, \qquad f(t) \mapsto f(t)[1]$$

has kernel (t^3). Hence $M \cong A/(t^3)$, and the addressed vectors $s, ts, t^2 s$ are the visible orbit chain.

Corollary 3.3 (Characterization by minimal free covers)**.** *For every finitely generated left module M over A,*

$$\boxed{\operatorname{srank}_A(M) = \min\{r \geq 0 : \textit{there exists a surjection } A^{\oplus r} \twoheadrightarrow M\}.}$$

Proof. A seed family of size r gives a surjection by theorem 3.2. Conversely, the images of the standard basis vectors under any surjection $A^{\oplus r} \twoheadrightarrow M$ form a generating family of size at most r. □

Corollary 3.4 (Presentation with one seed). *For $s \in M$, the annihilator*

$$\mathrm{Ann}_A(s) := \{a \in A : as = 0\}$$

is a left ideal and

$$\boxed{A/\mathrm{Ann}_A(s) \cong \mathrm{Hull}_A(s).}$$

Proof. The evaluation map for one seed is $a \mapsto as$. Its kernel is $\mathrm{Ann}_A(s)$, which is therefore a left ideal, and theorem 3.2 gives the quotient isomorphism. □

3.2 One seed and the distinction between module and algebra relations

Proposition 3.5 (Criterion for the annihilator to be an ideal on both sides). *For $s \in M$, the left ideal $L = \mathrm{Ann}_A(s)$ is an ideal on both sides if and only if*

$$L\ \mathrm{Hull}_A(s) = 0.$$

If s is cyclic, these conditions are equivalent to

$$\mathrm{Ann}_A(s) = \mathrm{Ann}_A(M).$$

Proof. The left ideal L is an ideal on both sides exactly when $ab \in L$ for every $a \in L$ and $b \in A$. This is equivalent to

$$0 = (ab)s = a(bs) \qquad (a \in L,\ b \in A).$$

By additivity, the last identity is equivalent to $L\,\mathrm{Hull}_A(s) = 0$.

If s is cyclic, then $\mathrm{Hull}_A(s) = M$. Hence the preceding condition is $L \subseteq \mathrm{Ann}_A(M)$. The reverse inclusion always holds because an operator annihilating all of M annihilates s. Thus equality follows. Conversely, $\mathrm{Ann}_A(M)$ is an ideal on both sides, so equality implies that L is an ideal on both sides. □

Why a seed annihilator need not be an ideal on both sides

Let $A = M_2(\Bbbk)$ act on $M = \Bbbk^2$, and let $s = e_1$. Then $\mathrm{Ann}_A(s)$ consists of matrices whose first column is zero. It is a left ideal because left multiplication preserves a zero first column. It is not generally a right ideal. Thus the natural quotient for one seed is a quotient of the left regular module, not automatically a quotient algebra.

3.3 Topological completion of a presentation

Theorem 3.6 (Completion of a dense free presentation). *Let X be a complete Hausdorff locally convex space, let $\mathcal{A} \subseteq \mathrm{End}(X)$ act continuously, and let $S = (s_1, \dots, s_r)$. Put*

$$E := \mathcal{A}^{\oplus r}/N_S$$

algebraically and let $j : E \to X$ be the injective map induced by ε_S. Give E the locally convex topology transported from $j(E)$, equivalently the topology generated by

$$\tilde{p}(e) := p(j(e))$$

for the continuous seminorms p on X. Every $a \in \mathcal{A}$ acts continuously on E in the transported topology and therefore extends to $\widehat{E}$. If $\mathrm{Hull}_{\mathcal{A}}(S)$ is dense in X, then j extends uniquely to a topological isomorphism of modules over $\mathcal{A}$

$$\boxed{\widehat{E} \cong X.}$$

Proof. By theorem 3.2, j is an algebraic isomorphism of modules over $\mathcal{A}$ from E onto $\mathrm{Hull}_{\mathcal{A}}(S)$. The transported seminorms make it a topological isomorphism onto that subspace. For $a \in \mathcal{A}$ and a continuous seminorm p on X, continuity of $a : X \to X$ supplies continuous seminorms controlling $p(aj(e))$, so the induced action on E is continuous and extends uniquely to $\widehat{E}$. The subspace is dense by hypothesis. A Cauchy net in E is mapped to a Cauchy net in X, which converges because X is complete. This defines a continuous extension $\hat{j} : \widehat{E} \to X$. For any $x \in X$, choose a net (e_λ) in E with $j(e_\lambda) \to x$. The transported topology makes (e_λ) Cauchy, so it converges to some $\xi \in \widehat{E}$, and continuity gives $\hat{j}(\xi) = x$. Thus $\hat{j}$ is surjective. If $\hat{j}(\xi) = 0$, represent ξ by a Cauchy net (e_λ). Then $j(e_\lambda) \to 0$, so every defining seminorm $\tilde{p}(e_\lambda)$ tends to zero. Thus $e_\lambda \to 0$ in the completion and $\xi = 0$. Hence $\hat{j}$ is bijective. Its inverse is continuous by the universal property of completion, or directly because the topology on E was transported from X. □

The topology in this completion theorem comes from the realized image. It is not an independently chosen topology on the free algebra. This choice ensures that the completion recovers the given space, while leaving separate the question of whether another natural topology on the grammar produces the same completion.

What we have established

A seed family always gives a free presentation of its hull. The kernel stores all linear relations among addressed seed words. One seed gives a cyclic module, but only special annihilators permit an algebra quotient. Dense generation is handled by completing the presented image rather than by silently replacing algebraic span with closure.

4 Seed rank and functorial calculus

A route through this section

For a finitely generated module, seed rank is the smallest number of seeds needed to generate it. We first examine how this number behaves when the acting algebra changes or the module is replaced by a quotient. We then give bounds for exact sequences, direct sums, and tensor products. Quotients with simple actions provide useful witnesses for lower bounds.

4.1 Definition, cyclicity, and monotonicity

Definition 4.1 (Seed rank)**.** For a unital left module M over A, define

$$\operatorname{srank}_A(M) := \min\{|S| : AS = M\}.$$

For a topological module (X, τ), define

$$\operatorname{srank}_{\mathcal{A},\tau}(X) := \min\{|S| : \overline{\mathcal{A}S}^{\tau} = X\}.$$

Set $\operatorname{srank}_A(0) = 0$. When the value is finite, it is the minimal number of module generators.

Proposition 4.2 (Cyclic characterization)**.** *For $M \neq 0$,*

$$\operatorname{srank}_A(M) = 1 \quad \Longleftrightarrow \quad M \text{ contains a cyclic vector}.$$

Proof. Both conditions say that there is $m \in M$ with $Am = M$. □

Proposition 4.3 (Monotonicity under enlargement of the acting algebra)**.** *Let $B \subseteq A \subseteq \operatorname{End}_{\Bbbk}(X)$ be unital operator algebras with the same identity. Then*

$$\boxed{\operatorname{srank}_A(X) \leq \operatorname{srank}_B(X).}$$

The same statement holds for topological seed rank when both algebras act continuously.

Proof. For every $S \subseteq X$, one has $BS \subseteq AS$. Hence every generating family over B is also a generating family over A. Taking closures gives the topological statement. □

How to read the result

Enlarging the acting algebra can only create more orbit directions, so it can only lower the number of seeds required. This is why every statement about seed rank must name the acting algebra. The same vector space may be cyclic for a large algebra and require many seeds for a smaller one.

4.2 Quotients, isomorphisms, and exact sequences

Theorem 4.4 (Quotient monotonicity)**.** *Let $\varphi : A \to B$ be a unital ring homomorphism and let*

$$\Phi : M \twoheadrightarrow N$$

be a surjective additive map satisfying

$$\Phi(am) = \varphi(a)\Phi(m) \qquad (a \in A,\ m \in M).$$

Then

$$\boxed{\operatorname{srank}_B(N) \leq \operatorname{srank}_A(M).}$$

If M and N are topological modules, Φ is continuous and surjective, and the actions are continuous, then

$$\operatorname{srank}_{B,\tau_N}(N) \leq \operatorname{srank}_{A,\tau_M}(M).$$

Proof. Let S generate M. For every $n \in N$, choose $m \in M$ with $\Phi(m) = n$ and write $m = \sum_i a_i s_i$. Then

$$n = \sum_i \varphi(a_i)\Phi(s_i),$$

so $\Phi(S)$ generates N.

For the topological statement, let S generate M densely. Given $n = \Phi(m)$, choose a net $m_\lambda \in AS$ converging to m. Continuity gives

$$\Phi(m_\lambda) \longrightarrow n,$$

and every $\Phi(m_\lambda)$ lies in $B\Phi(S)$. Thus $B\Phi(S)$ is dense in N. □

A quotient can strictly lower seed rank

Let $A = \Bbbk$ act by scalars on $M = \Bbbk^3$. Then $\operatorname{srank}_A(M) = 3$. Quotienting by a subspace of dimension one gives a scalar module of dimension two, whose seed rank is 2. Quotient monotonicity is therefore often strict.

Corollary 4.5 (Isomorphism invariance)**.** *An intertwining module isomorphism preserves algebraic seed rank. A topological intertwining isomorphism preserves topological seed rank.*

Proof. Apply theorem 4.4 to the isomorphism and its inverse. □

Theorem 4.6 (Short exact sequence bounds)**.** *Let*

$$0 \longrightarrow L \xrightarrow{\iota} M \xrightarrow{\pi} N \longrightarrow 0$$

be a short exact sequence of left modules over A. Then

$$\boxed{\operatorname{srank}_A(N) \leq \operatorname{srank}_A(M) \leq \operatorname{srank}_A(L) + \operatorname{srank}_A(N).}$$

Proof. The lower inequality is quotient monotonicity. For the upper inequality, choose generating families $(\ell_i)_{i\in I}$ of L and $(n_j)_{j\in J}$ of N with the least possible cardinalities. Choose a lift $m_j \in M$ of each n_j. For any $m \in M$, a finite subset $F \subseteq J$ and coefficients $a_j \in A$ give

$$\pi(m) = \sum_{j\in F} a_j n_j.$$

The vector $m - \sum_{j\in F} a_j m_j$ belongs to $\iota(L)$, so it is a finite linear combination of the $\iota(\ell_i)$. The union of the lifted family and the image of the generating family of L therefore generates M. Its cardinality is at most $|I| + |J|$, giving the upper bound. This argument uses finite sums for each vector even when either generating family is infinite. □

Why the hypotheses matter

For a short exact sequence, a generating family for M always maps to a generating family for the quotient. It need not generate the submodule L. For the upper bound, choose generators of L separately and combine them with lifts of quotient generators.

4.3 Direct sums under shared and independent actions

Proposition 4.7 (Direct sum bounds for a shared action)**.** *If one algebra A acts diagonally on $M \oplus N$, then*

$$\boxed{\max\{\operatorname{srank}_A(M), \operatorname{srank}_A(N)\} \le \operatorname{srank}_A(M \oplus N) \le \operatorname{srank}_A(M) + \operatorname{srank}_A(N).}$$

Proof. The coordinate projections are intertwining quotients and give the lower bound. For the upper bound, embed minimal generating families of M as $(m_i, 0)$ and of N as $(0, n_j)$. Their union generates by finite sums and has cardinality at most the sum of the two seed ranks. □

Theorem 4.8 (Direct sum formula for independent actions)**.** *Let M be a left module over A and N a left module over B. Under the action of the product algebra*

$$(a, b)(m, n) = (am, bn),$$

one has

$$\boxed{\operatorname{srank}_{A\times B}(M \oplus N) = \max\{\operatorname{srank}_A(M), \operatorname{srank}_B(N)\}.}$$

Proof. The coordinate projections give the lower bound. Let r be the maximum on the right, regarded as a cardinal, and choose an index set I of cardinality r. Choose minimal generating families for M and N, index them by subsets of I, and fill any unused positions with zeros. Write the resulting families as $(m_i)_{i\in I}$ and $(n_i)_{i\in I}$. For any $m \in M$ and $n \in N$, their finite expressions involve a common finite subset $F \subseteq I$ after zero coefficients have been added. Thus

$$m = \sum_{i\in F} a_i m_i, \qquad n = \sum_{i\in F} b_i n_i,$$

and

$$(m, n) = \sum_{i\in F} (a_i, b_i)(m_i, n_i).$$

The family of paired vectors generates and has cardinality at most r. The empty family handles the case in which both modules are zero. □

4.4 Tensor generation and witnesses for lower bounds

Proposition 4.9 (Tensor product bound)**.** *Let A and B be unital algebras over $\Bbbk$, let M be a left module over A, and let N be a left module over B. Under the natural $A \otimes_\Bbbk B$ action,*

$$\boxed{\operatorname{srank}_{A\otimes B}(M \otimes_\Bbbk N) \le \operatorname{srank}_A(M) \operatorname{srank}_B(N).}$$

Proof. Choose minimal generating families $(m_i)_{i\in I}$ for M and $(n_j)_{j\in J}$ for N. Each vector in either module is a finite linear combination of its generators. Bilinearity therefore expresses every simple tensor as a finite sum of terms

$$(am_i) \otimes (bn_j) = (a \otimes b)(m_i \otimes n_j).$$

Simple tensors span the algebraic tensor product, so the family $(m_i \otimes n_j)_{(i,j)\in I\times J}$ generates it. This family has cardinality at most $|I||J|$, which is the claimed bound. The proof also covers an empty generating family, when the corresponding module and tensor product are zero. □

> **How to read the result**
>
> The tensor product bound is constructive. Tensor the chosen seed families and act independently in the two factors. Equality can fail because a single tensor seed may contain several useful components, or because the tensor product algebra acquires additional relations. Later quantum applications should therefore cite the bound, not assume multiplicativity.

Boundary 4.10 (Tensor rank is not generally multiplicative). The inequality in proposition 4.9 can be strict. Equality requires additional hypotheses on the acting algebras and their module multiplicities and is not exported as a universal law.

Proposition 4.11 (Monotonicity under extension of scalars)**.** *Let $K/\Bbbk$ be a field extension, let A be a unital algebra over $\Bbbk$, and let M be a finitely generated left module over A. Set*

$$A_K := K \otimes_{\Bbbk} A, \qquad M_K := K \otimes_{\Bbbk} M.$$

Then

$$\boxed{\operatorname{srank}_{A_K}(M_K) \le \operatorname{srank}_A(M).}$$

Every generating family $S \subseteq M$ extends to the generating family $1 \otimes S \subseteq M_K$.

Proof. Let $S = \{s_1, \dots, s_r\}$ generate M. Every pure tensor $\lambda \otimes m \in M_K$ has an expression

$$m = \sum_{i=1}^{r} a_i s_i,$$

so

$$\lambda \otimes m = \sum_{i=1}^{r} (\lambda \otimes a_i)(1 \otimes s_i).$$

Pure tensors span M_K, hence $1 \otimes S$ generates M_K over A_K. Taking the minimum over S proves the inequality. □

> **Why the hypotheses matter**
>
> The proposition gives an inequality in one direction. A smaller generating family found after extending scalars need not descend to the original field. Descent requires additional structure. The chapter therefore exports monotonicity, not an unconditional equality.

4.5 Quotient witnesses for lower bounds

Definition 4.12 (Witness for seed rank)**.** A surjective intertwiner $\Phi : M \twoheadrightarrow N$ is a witness for seed rank of order r when $\mathrm{srank}(N) = r$. It certifies $\mathrm{srank}(M) \geq r$.

Proposition 4.13 (Scalar quotient witness)**.** *Let M be a module over A with coefficient field $\Bbbk$. Suppose M has a quotient N of dimension r on which A acts through a character*

$$\chi : A \longrightarrow \Bbbk.$$

Then

$$\boxed{\mathrm{srank}_A(M) \geq r.}$$

Proof. For every $n \in N$, the cyclic submodule An is contained in the scalar span $\Bbbk n$. Therefore q seed images span a subspace of dimension at most q. Generating the quotient of dimension r requires at least r seeds. Quotient monotonicity transfers the lower bound to M. □

What we have established

Seed rank is functorial under quotients and isomorphisms, subadditive across extensions, given by the maximum for independent product actions, and bounded above under tensor products. Lower bounds come from quotients on which the action simplifies. Scalar extension cannot increase seed rank, but descent of a reduced seed family is a separate problem.

5 Generator number modulo the Jacobson radical

A route through this section

For a finitely generated module, Nakayama's lemma allows us to count generators after passing to the quotient by the Jacobson radical. When the algebra has finite dimension, this quotient is semisimple and its multiplicities give an explicit answer. We begin with the radical reduction and then calculate those multiplicities.

5.1 Reduction to the module top

Classical Input 5.1 (Nakayama lemma)**.** Let A be a unital ring, let $J \subseteq \mathrm{Jac}(A)$, and let M be a finitely generated left module over A. If $M = N + JM$ for a submodule $N \leq M$, then $M = N$.

Theorem 5.2 (Generator number is detected modulo the Jacobson radical)**.** *Let A be a unital ring, let $J = \mathrm{Jac}(A)$, and let M be a finitely generated left module over A. A family $S \subseteq M$ generates M if and only if its image generates M/JM as a module over A/J. When A/J is semisimple Artinian, this quotient is the usual semisimple top. No semisimplicity of A/J is required for the general equality. Consequently,*

$$\boxed{\mathrm{srank}_A(M) = \mathrm{srank}_{A/J}(M/JM).}$$

Proof. If S generates M, its image generates every quotient. Conversely, suppose the image of S generates M/JM and put $N = AS$. Then

$$M = N + JM.$$

Nakayama's lemma gives $M = N$. Thus the same finite families generate before and after passage to the top, and the minimal cardinalities agree. □

How to read the result

The theorem says that nilpotent or radical directions can lengthen orbit chains but cannot reduce the number of independent directions in the module top that must be seeded. Once the images of the seeds generate M/JM, Nakayama's lemma forces the entire module to be generated.

A local nilpotent algebra

Let $A = \Bbbk[\varepsilon]/(\varepsilon^3)$ and $M = A^{\oplus 2}$. The radical is $J = (\varepsilon)$, and

$$M/JM \cong \Bbbk^2.$$

Therefore two seeds are necessary and sufficient. The extra nilpotent layers εM and $\varepsilon^2 M$ are generated automatically once the two top directions are seeded.

Corollary 5.3 (Local algebra formula)**.** *Let A be a local ring with Jacobson radical J and residue division ring $D = A/J$. For every finitely generated left module M over A,*

$$\boxed{\operatorname{srank}_A(M) = \dim_D(M/JM),}$$

where the dimension is that of a left vector space over D.

Proof. The module M/JM over A/J is a left vector space over D. Its minimal number of generators is its dimension over D. □

5.2 Semisimple multiplicity calculus

Classical Input 5.4 (Wedderburn and Artin decomposition)**.** Every semisimple Artinian ring is isomorphic to a finite product

$$A \cong \prod_{i=1}^{q} M_{d_i}(D_i)$$

of full matrix rings over division rings.

Lemma 5.5 (Multiplicities in the regular module)**.** *Let*

$$A = \prod_{i=1}^{q} M_{d_i}(D_i)$$

and let $S_i = D_i^{d_i}$ denote the natural simple left module for the ith factor, extended by zero across the other factors. Then, as a left module over A,

$$\boxed{A \cong \bigoplus_{i=1}^{q} S_i^{\oplus d_i}.}$$

Proof. For one factor $M_d(D)$, let e_{jj} be the diagonal matrix units. The left regular module decomposes as

$$M_d(D) = \bigoplus_{j=1}^{d} M_d(D)e_{jj}.$$

Each minimal left ideal $M_d(D)e_{jj}$ is isomorphic to the natural column module D^d. Taking the direct product of factors gives the stated decomposition. □

Theorem 5.6 (Semisimple seed rank formula over arbitrary division rings)**.** *Let*

$$A \cong \prod_{i=1}^{q} M_{d_i}(D_i)$$

be semisimple Artinian and let

$$M \cong \bigoplus_{i=1}^{q} S_i^{\oplus m_i}$$

be a finitely generated left module over A. Then

$$\boxed{\operatorname{srank}_A(M) = \max_{1 \le i \le q} \left\lceil \frac{m_i}{d_i} \right\rceil.}$$

If A is any algebra of finite dimension over a field, the same formula applied to the decomposition of $M/\operatorname{Jac}(A)M$ over $A/\operatorname{Jac}(A)$ computes $\operatorname{srank}_A(M)$.

Proof. By corollary 3.3, M is generated by r elements exactly when it is a quotient of $A^{\oplus r}$. By lemma 5.5,

$$A^{\oplus r} \cong \bigoplus_{i} S_i^{\oplus r d_i}.$$

Every short exact sequence of modules over a semisimple ring splits. Therefore a quotient isomorphic to M exists if and only if

$$m_i \le r d_i \qquad \text{for every } i.$$

The smallest such r is the displayed maximum. For a nonsemisimple algebra of finite dimension, theorem 5.2 reduces the calculation to the semisimple module $M/\operatorname{Jac}(A)M$ over $A/\operatorname{Jac}(A)$. □

How to read the result

For the factor $M_{d_i}(D_i)$, one free generator contributes d_i copies of the corresponding simple module. If the top of M contains m_i copies, at least $\lceil m_i/d_i \rceil$ free generators are required. The worst simple type controls the global answer.
This count concerns copies of a simple module, rather than the number of coordinates in a chosen basis. A single seed can reach several copies through the matrix action. The regular module records precisely how many copies one free generator can supply.

Multiplicity consumes seed capacity

For $A = M_2(\Bbbk)$ acting on $(\Bbbk^2)^{\oplus 3}$, the regular module contributes two copies of the natural simple module per generator. One generator cannot cover all three multiplicity directions. Two can, giving seed rank 2.

Corollary 5.7 (Algebraically closed multiplicity formula)**.** *Let $\Bbbk$ be algebraically closed, let A be a unital algebra of finite dimension over $\Bbbk$, put $J = \mathrm{Jac}(A)$, and let M be a finitely generated left module over A. Assume compatible decompositions indexed by an integer $q \geq 0$:*

$$A/J \cong \prod_{i=1}^{q} M_{d_i}(\Bbbk), \qquad M/JM \cong \bigoplus_{i=1}^{q} (\Bbbk^{d_i})^{\oplus m_i},$$

where the d_i are positive integers and the m_i are nonnegative integers. The first isomorphism is an isomorphism of algebras over $\Bbbk$. The second is an isomorphism of left modules over A/J, using the natural column module for each matrix factor and zero action from the other factors. Then

$$\mathrm{srank}_A(M) = \max_{1 \leq i \leq q} \left\lceil \frac{m_i}{d_i} \right\rceil,$$

with $\max \emptyset = 0$ when $q = 0$.

Proof. By theorem 5.2, $\mathrm{srank}_A(M) = \mathrm{srank}_{A/J}(M/JM)$. Apply theorem 5.6 to the displayed decompositions of A/J and M/JM, with every $D_i = \Bbbk$. This gives the stated maximum. If $q = 0$, the unital A/J-module M/JM is zero, and theorem 5.2 gives seed rank zero. □

Corollary 5.8 (Full matrix algebra)**.** *For the natural module $S = D^d$ over $M_d(D)$,*

$$\mathrm{srank}_{M_d(D)}(S) = 1.$$

More strongly, every nonzero vector of S is cyclic.

Proof. The formula gives $\lceil 1/d \rceil = 1$. Directly, let $v \neq 0$ and choose a coordinate $v_j \neq 0$. For any target $w = (w_i)$, the matrix whose jth column has entries $w_i v_j^{-1}$ and whose other columns vanish sends v to w. □

Corollary 5.9 (Multiplicity obstruction)**.** *For the diagonal action of $M_d(D)$ on $S^{\oplus m}$,*

$$\boxed{\mathrm{srank}_{M_d(D)}(S^{\oplus m}) = \left\lceil \frac{m}{d} \right\rceil.}$$

Proof. Apply theorem 5.6 to the single simple type with multiplicity m. □

What we have established

For finitely generated modules, the minimal number of seeds is detected on the quotient by the Jacobson radical. In the semisimple top, each generator has a fixed multiplicity capacity d_i in simple type i, and the largest capacity ratio determines the exact seed rank.

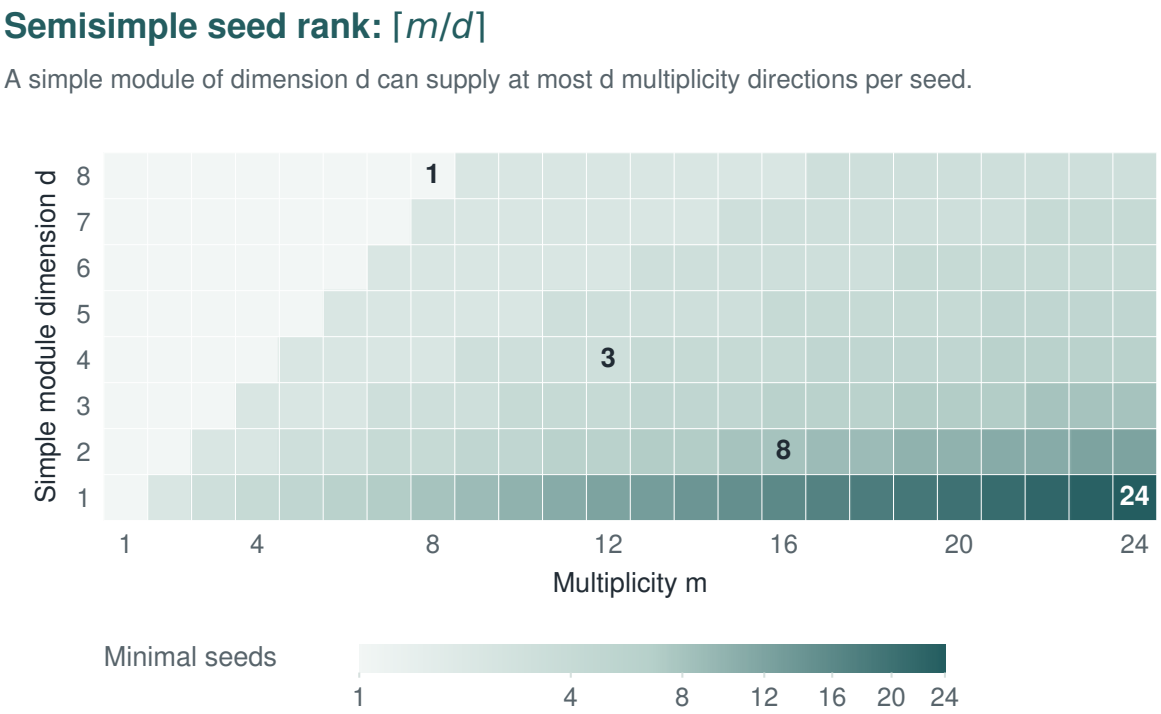

Figure 2. The semisimple multiplicity formula for one simple block. A seed can expose at most d independent multiplicity directions, so m copies require $\lceil m/d \rceil$ seeds.

6 Modules for a single operator over arbitrary fields

A route through this section

One operator is equivalent to a module over $\Bbbk[t]$. Primary decomposition isolates the irreducible polynomial sectors, and the quotient by $p(T)$ counts how many cyclic chains begin in each sector.

6.1 Primary components and generator counts

Classical Input 6.1 (Primary decomposition for polynomial modules)**.** Every module X over $\Bbbk[t]$ with finite dimension over the coefficient field decomposes as

$$X = \bigoplus_{p \in \mathrm{Irr}(\Bbbk[t])} X_p,$$

where $\mathrm{Irr}(\Bbbk[t])$ denotes the monic irreducible polynomials, only finitely many components are nonzero, and every nonzero X_p is a finite direct sum of modules $\Bbbk[t]/(p^e)$.

Theorem 6.2 (Seed rank for a single operator). *Let X have finite dimension over $\Bbbk$ and let $T \in \mathrm{End}_{\Bbbk}(X)$. Regard X as a module over $\Bbbk[t]$ by $t \cdot x = Tx$. For every monic irreducible p, let X_p be the primary component for p and set*

$$\mu_p(T) := \dim_{\Bbbk[t]/(p)}(X_p/p(T)X_p).$$

Then

$$\boxed{\mathrm{srank}_{\Bbbk[T]}(X) = \max_p \mu_p(T).}$$

Moreover, $\mu_p(T)$ is the number of cyclic primary summands for p in the decomposition into elementary divisors of X_p.

Proof. Let the minimal polynomial be

$$m_T(t) = \prod_p p(t)^{e_p}.$$

The acting algebra is

$$\Bbbk[T] \cong \Bbbk[t]/(m_T) \cong \prod_p R_p, \qquad R_p := \Bbbk[t]/(p^{e_p}),$$

by the Chinese remainder theorem. The factor R_p acts on X_p and annihilates every other primary component. Hence the formula for a direct sum with independent actions gives

$$\mathrm{srank}_{\Bbbk[T]}(X) = \max_p \mathrm{srank}_{R_p}(X_p).$$

Each R_p is local with maximal ideal generated by the class of p and residue division field $K_p = \Bbbk[t]/(p)$. By corollary 5.3,

$$\mathrm{srank}_{R_p}(X_p) = \dim_{K_p} X_p/p(T)X_p = \mu_p(T).$$

Finally, every summand $\Bbbk[t]/(p^e)$ contributes one copy of K_p after quotienting by p, so the dimension equals the number of summands in the elementary divisor decomposition. □

How to read the result

For one operator, the quotient $X_p/p(T)X_p$ counts the number of independent primary chains for the irreducible polynomial p. Over an algebraic closure these become Jordan chains. The seed rank is the largest chain count among the primary sectors, not the largest chain length.

Block count versus block size

A nilpotent operator with Jordan block sizes $(5, 1, 1)$ has seed rank 3, even though its largest block has length 5. Three seeds are needed because there are three independent chains. Once their initial vectors are chosen, repeated application of T generates every position in those chains.

6.2 Invariant factors, Jordan blocks, and cyclicity

Corollary 6.3 (Invariant factor count)**.** *If $X \neq 0$ and the rational canonical decomposition is written with nonconstant invariant factors*

$$X \cong \bigoplus_{j=1}^{r} \mathbb{k}[t]/(f_j), \qquad f_1 \mid f_2 \mid \cdots \mid f_r,$$

then

$$\boxed{\operatorname{srank}_{\mathbb{k}[T]}(X) = r.}$$

Proof. For each irreducible p, the number of invariant factors divisible by p equals the number of elementary divisors for p. Because $f_1 \mid \cdots \mid f_r$ and $f_1 \neq 1$ after zero summands are removed, some irreducible divisor of f_1 divides all r invariant factors. Hence $\max_p \mu_p(T) = r$. □

Corollary 6.4 (Formula for geometric multiplicity)**.** *If $\mathbb{k}$ is algebraically closed, then*

$$\boxed{\operatorname{srank}_{\mathbb{k}[T]}(X) = \max_{\lambda \in \operatorname{Spec}(T)} \dim_{\mathbb{k}} \operatorname{Ker}(T - \lambda I).}$$

Proof. The irreducibles are $p = t - \lambda$. On the primary component for λ, the quotient by $(T - \lambda I)X_\lambda$ has dimension equal to the number of Jordan blocks, which is also $\dim \operatorname{Ker}(T - \lambda I)$. □

Corollary 6.5 (Criterion for a cyclic matrix)**.** *For $X \neq 0$ of finite dimension, the following are equivalent:*

(i) *T has a cyclic vector.*

(ii) $\operatorname{srank}_{\mathbb{k}[T]}(X) = 1$.

(iii) *Every nonzero primary component for p is cyclic.*

(iv) *The rational canonical form has one invariant factor.*

(v) *The minimal polynomial equals the characteristic polynomial.*

(vi) *After scalar extension to an algebraic closure, every eigenvalue has geometric multiplicity one.*

Proof. The equivalence of (i) and (ii) is proposition 4.2. By theorem 6.2, (ii) holds exactly when every $\mu_p(T)$ belonging to a nonzero primary component equals one, which is (iii). Relatively prime primary cyclic modules combine into one cyclic module by the Chinese remainder theorem, so (iii) is equivalent to (iv). In rational canonical form, one invariant factor means that the unique invariant factor is both the minimal and characteristic polynomial, proving (iv)⇔(v). Scalar extension preserves the equality of minimal and characteristic polynomials. Over an algebraic closure, that equality is equivalent to one Jordan block for each eigenvalue, which is (vi). □

> **What we have established**
>
> A single operator is cyclic exactly when each primary sector has one cyclic chain. Over an algebraic closure this is equivalent to one Jordan block per eigenvalue and to equality of the minimal and characteristic polynomials.

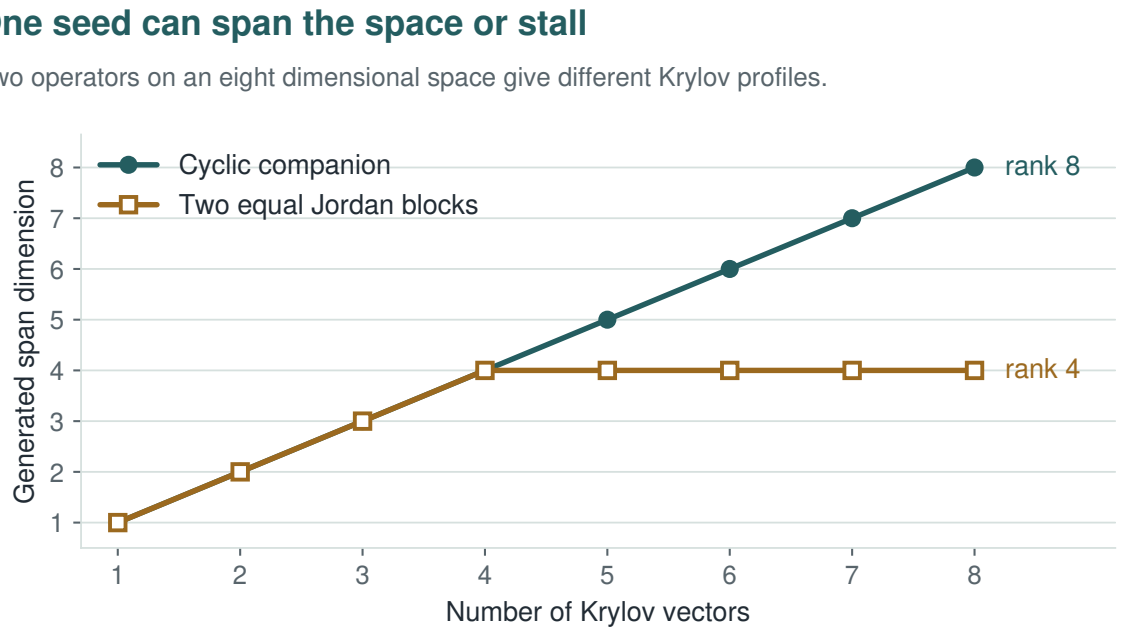

Figure 3. Krylov rank profiles for a cyclic companion operator and for two equal primary blocks. The second orbit stalls before reaching the ambient dimension because one seed cannot separate the repeated blocks.

7 Exact finite and countable packet coordinates

A route through this section

Packets give exact coordinates through idempotent maps. For finitely many packets, the reconstruction is algebraic. For countably many packets, we must also specify how the series converges and bound the coordinate maps. We begin with finite reconstruction, then consider packet support, tensor products, duality, and the universal mapping property before turning to convergence.

7.1 Finite exact packets

Definition 7.1 (Finite packet system)**.** A finite packet system on a vector space X over $\mathbb{k}$ is a family

$$\mathcal{P} = (P_\alpha)_{\alpha \in I} \subseteq \mathrm{End}_{\mathbb{k}}(X)$$

satisfying

$$P_\alpha^2 = P_\alpha, \qquad P_\alpha P_\beta = 0 \quad (\alpha \neq \beta), \qquad \sum_{\alpha \in I} P_\alpha = I_X.$$

Set $X_\alpha = P_\alpha X$. Zero packet spaces may be removed without changing any identity. No orthogonality is assumed unless stated.

Definition 7.2 (Packet support and packet pure vectors)**.** For a finite packet system $\mathcal{P} = (P_\alpha)_{\alpha\in I}$ and $x \in X$, define

$$\operatorname{Supp}_{\mathcal{P}}(x) := \{\alpha \in I : P_\alpha x \neq 0\}.$$

The vector x is *packet pure* if $|\operatorname{Supp}_{\mathcal{P}}(x)| \leq 1$. A finite family is packet pure if each of its members is packet pure, although different members may lie in different packets.

How to read the result

Packet support records which packet coordinates are present. A seed may lie in one packet, have coordinates in several packets, or be zero. Later, when we count the seeds needed for generation, this distinction matters because a seed with several nonzero coordinates can meet several graph sources at once.

Lemma 7.3 (Finite packet aggregation)**.** *Let $\sigma : I \twoheadrightarrow J$ be a surjection and define*

$$Q_j := \sum_{\sigma(\alpha)=j} P_\alpha.$$

Then $(Q_j)_{j\in J}$ is a finite packet system and

$$Q_j X = \bigoplus_{\sigma(\alpha)=j} X_\alpha.$$

Proof. Pairwise annihilation of the P_α gives

$$Q_j^2 = Q_j, \qquad Q_j Q_k = 0 \quad (j \neq k).$$

Summing over j recovers $\sum_\alpha P_\alpha = I$. The range statement follows from the directness forced by pairwise annihilation. □

Definition 7.4 (Packet analysis and synthesis)**.** For a finite packet system, define

$$\mathcal{A}_{\mathcal{P}} : X \longrightarrow \bigoplus_{\alpha\in I} X_\alpha, \qquad x \longmapsto (P_\alpha x)_\alpha,$$

and

$$\mathcal{S}_{\mathcal{P}} : \bigoplus_{\alpha\in I} X_\alpha \longrightarrow X, \qquad (x_\alpha)_\alpha \longmapsto \sum_\alpha x_\alpha.$$

Theorem 7.5 (Exact packet coordinate isomorphism)**.** *For every finite packet system,*

$$\boxed{\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}} = I_X, \qquad \mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{P}} = I_{\oplus X_\alpha}.}$$

Hence

$$\boxed{X \cong \bigoplus_{\alpha\in I} X_\alpha.}$$

Proof. For $x \in X$,

$$\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}}x = \sum_{\alpha} P_\alpha x = x.$$

If $x_\alpha \in X_\alpha$, then $P_\beta x_\alpha = \delta_{\alpha\beta} x_\alpha$, so

$$\mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{P}}(x_\alpha)_\alpha = \left(P_\beta \sum_{\alpha} x_\alpha\right)_\beta = (x_\beta)_\beta.$$

Thus analysis and synthesis are inverse linear maps. □

The central idea

Analysis records every packet coordinate and synthesis adds them back. The theorem gives an exact change of coordinates. Its proof uses the idempotent identities and does not require orthogonality. Questions about norms, energy, and conditioning require further structure.

Corollary 7.6 (Packetwise equality)**.** *For $x, y \in X$,*

$$x = y \quad \Longleftrightarrow \quad P_\alpha x = P_\alpha y \text{ for every } \alpha.$$

Proof. The forward implication is immediate. For the reverse implication, sum the packet equalities and use $\sum_\alpha P_\alpha = I$. □

Corollary 7.7 (Universal mapping property of finite packet coordinates)**.** *Let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ be a finite packet system on X, and let Y be a vector space over $\Bbbk$.*

1. *Every family of linear maps $f_\alpha : X_\alpha \to Y$ determines a unique linear map $f : X \to Y$ with $f|_{X_\alpha} = f_\alpha$, namely*
$$f = \sum_{\alpha} f_\alpha P_\alpha.$$
2. *Every family of linear maps $g_\alpha : Y \to X_\alpha$ determines a unique linear map $g : Y \to X$ with $P_\alpha g = g_\alpha$, namely*
$$g = \sum_{\alpha} g_\alpha.$$

Equivalently,

$$\mathrm{Hom}(X, Y) \cong \prod_{\alpha} \mathrm{Hom}(X_\alpha, Y), \qquad \mathrm{Hom}(Y, X) \cong \prod_{\alpha} \mathrm{Hom}(Y, X_\alpha),$$

where the products are finite.

Proof. For $x = \sum_\alpha P_\alpha x$, any extension of the f_α must satisfy

$$f(x) = \sum_{\alpha} f_\alpha(P_\alpha x),$$

which proves both existence and uniqueness of the first formula. For the second, the sum $g = \sum_\alpha g_\alpha$ satisfies

$$P_\beta g = \sum_{\alpha} P_\beta g_\alpha = g_\beta$$

because $g_\alpha(Y) \subseteq X_\alpha$. Uniqueness follows from $\sum_\alpha P_\alpha = I$. □

7.2 Tensor products and dual packets

Theorem 7.8 (Tensor product packet systems). *Let $\mathcal{P} = (P_\alpha)_{\alpha\in I}$ be a finite packet system on X, and let $\mathcal{Q} = (Q_\gamma)_{\gamma\in J}$ be a finite packet system on Y. Then*

$$\mathcal{P} \boxtimes \mathcal{Q} := (P_\alpha \otimes Q_\gamma)_{(\alpha,\gamma)\in I\times J}$$

is a finite packet system on the algebraic tensor product $X \otimes_{\mathbb{k}} Y$, with packet spaces

$$(P_\alpha \otimes Q_\gamma)(X \otimes Y) = X_\alpha \otimes Y_\gamma.$$

Hence

$$\boxed{X \otimes Y \cong \bigoplus_{(\alpha,\gamma)\in I\times J} X_\alpha \otimes Y_\gamma.}$$

Proof. For every pair of packet indices,

$$(P_\alpha \otimes Q_\gamma)^2 = P_\alpha^2 \otimes Q_\gamma^2 = P_\alpha \otimes Q_\gamma.$$

If $(\alpha,\gamma) \neq (\beta,\delta)$, then either $P_\alpha P_\beta = 0$ or $Q_\gamma Q_\delta = 0$, so the corresponding tensor idempotents annihilate each other. Finally,

$$\sum_{\alpha,\gamma} P_\alpha \otimes Q_\gamma = \left(\sum_\alpha P_\alpha\right) \otimes \left(\sum_\gamma Q_\gamma\right) = I_X \otimes I_Y.$$

The range is generated by pure tensors $P_\alpha x \otimes Q_\gamma y$, hence equals $X_\alpha \otimes Y_\gamma$. Exact reconstruction follows from theorem 7.5. □

Proposition 7.9 (Dual packet systems). *Let X be finite dimensional and let $\mathcal{P} = (P_\alpha)$ be a finite packet system. The algebraic dual maps*

$$P_\alpha^* : X^* \to X^*, \qquad P_\alpha^*(\varphi) = \varphi \circ P_\alpha,$$

form a finite packet system on X^*. Its packet with index α is canonically isomorphic to X_α^*, and

$$X^* \cong \bigoplus_\alpha X_\alpha^*.$$

Proof. Because dualization reverses products,

$$P_\alpha^* P_\beta^* = (P_\beta P_\alpha)^* = \delta_{\alpha\beta} P_\alpha^*.$$

Also $\sum_\alpha P_\alpha^* = I_{X^*}$. Thus the dual maps form a packet system. Restriction gives a map from $P_\alpha^* X^*$ to X_α^*. It is injective because a covector in the range of P_α^* vanishes on every other packet, and it is surjective because any covector on X_α extends to X through the direct sum decomposition. □

Tensoring the oblique packet split

Tensor the two oblique packets in Running Example R3 with the coordinate packets of $\mathbb{k}^3$. The result has six exact packets. No orthogonality is created by tensoring, but the analysis and synthesis identities remain exact because they are idempotent identities.

7.3 Banach stability and coordinate conditioning

Exact reconstruction answers whether the coordinates retain the whole vector. Stability asks how errors in those coordinates affect the reconstructed vector. A finite packet system answers the first question through its idempotent identities. On a Banach space, boundedness of analysis and synthesis answers the second. The chosen norm on the coordinate space matters, so we fix it before comparing operator sizes.

Theorem 7.10 (Finite Banach packet isomorphism)**.** *Let X be Banach and let $(P_\alpha)_{\alpha\in I}$ be a finite family of bounded pairwise annihilating idempotents with sum I_X. Then every range $X_\alpha = P_\alpha X$ is closed. For any finite product norm equivalent to the maximum norm on $\bigoplus_\alpha X_\alpha$, packet analysis and synthesis are bounded inverse operators.*

Proof. The range of a bounded idempotent is its space of fixed points,

$$P_\alpha X = \operatorname{Ker}(I - P_\alpha),$$

which is closed. Because I is finite, analysis and synthesis are bounded for the maximum and sum norms, respectively, and therefore for every equivalent finite product norm. Their inverse identities are algebraic and were proved in theorem 7.5. □

Definition 7.11 (Packet coordinate condition number)**.** Fix a finite product norm on $\bigoplus_\alpha X_\alpha$ equivalent to the maximum norm, as in theorem 7.10. Define

$$\kappa(\mathcal{P}) := \|\mathcal{A}_\mathcal{P}\|\,\|\mathcal{S}_\mathcal{P}\|.$$

Proposition 7.12 (Conditioned coordinate transport)**.** *For a finite Banach packet system with $X \neq 0$,*

$$\kappa(\mathcal{P}) \geq 1.$$

If $T \in \mathcal{B}(X)$ and

$$[T]_\mathcal{P} := \mathcal{A}_\mathcal{P} T \mathcal{S}_\mathcal{P},$$

then

$$\boxed{\|[T]_\mathcal{P}\| \leq \kappa(\mathcal{P})\|T\|, \qquad \|T\| \leq \kappa(\mathcal{P})\|[T]_\mathcal{P}\|.}$$

Proof. Since $I = \mathcal{S}_\mathcal{P}\mathcal{A}_\mathcal{P}$,

$$1 = \|I\| \leq \|\mathcal{S}_\mathcal{P}\|\|\mathcal{A}_\mathcal{P}\|.$$

The first displayed estimate follows from submultiplicativity. The inverse identity

$$T = \mathcal{S}_\mathcal{P}[T]_\mathcal{P}\mathcal{A}_\mathcal{P}$$

gives the second estimate. □

How to read the result

The quantity $\kappa(\mathcal{P})$ measures how strongly the chosen packet coordinates can amplify perturbations. An orthogonal Hilbert decomposition has the best possible behavior in the natural ℓ^2 sum norm. An oblique packet system can reconstruct every vector exactly and still have a large condition number.

Corollary 7.13 (Completion preserves a finite packet split)**.** *Let M be a dense normed subspace of a Banach space X. Suppose every bounded P_α leaves M invariant and the restricted projectors form a packet system on M. Then*

$$P_\alpha X = \overline{P_\alpha M}$$

and the packet decomposition of M extends uniquely to the completion X.

Proof. For $x \in X$, choose $m_n \in M$ with $m_n \to x$. Continuity gives $P_\alpha m_n \to P_\alpha x$, so $P_\alpha X \subseteq \overline{P_\alpha M}$. The reverse inclusion follows because $P_\alpha X$ is closed and contains $P_\alpha M$. The bounded extensions remain pairwise annihilating idempotents whose finite sum is the identity. □

7.4 Countable packets and unconditional convergence

For a finite family, synthesis adds a fixed number of coordinates. For a countable family, it must also take a limit. The algebraic idempotent identities still separate the coordinates, but they do not by themselves guarantee that the sum converges. The next definition includes unconditional convergence in the coordinate space itself, so synthesis is defined on precisely the sequences whose packet sums can be assembled in this way.

Definition 7.14 (Unconditional packet sum space)**.** Let $(X_n)_{n\ge1}$ be closed subspaces of a real or complex Banach space X. Define

$$\bigoplus_{n\ge1}^{u} X_n$$

to be the space of sequences $x = (x_n)$ with $x_n \in X_n$ for which $\sum_n x_n$ converges unconditionally in X. Equip it with

$$\|x\|_u := \sup_{F\Subset\mathbb{N}} \sup_{|a_n|\le1} \left\| \sum_{n\in F} a_n x_n \right\|.$$

Lemma 7.15 (Completeness of the unconditional packet sum)**.** *The normed space $\bigoplus_{n\ge1}^{u} X_n$ in definition 7.14 is Banach.*

Proof. Let $x^{(k)} = (x_n^{(k)})$ be Cauchy in $\|\cdot\|_u$. For every fixed n,

$$\|x_n^{(k)} - x_n^{(\ell)}\| \le \|x^{(k)} - x^{(\ell)}\|_u,$$

so $x_n^{(k)}$ converges to some $x_n \in X_n$ because X_n is closed. Given $\varepsilon > 0$, choose k_0 such that

$$\|x^{(k)} - x^{(\ell)}\|_u < \varepsilon \qquad (k, \ell \ge k_0).$$

For finite F and $|a_n| \le 1$, pass $\ell \to \infty$ in the finite sum to obtain

$$\left\| \sum_{n \in F} a_n (x_n^{(k)} - x_n) \right\| \le \varepsilon \qquad (k \ge k_0).$$

Hence $\|x^{(k)} - x\|_u \le \varepsilon$ once x is known to be unconditionally summable.

Choose such a $k \ge k_0$. Since $x^{(k)}$ is unconditionally summable, there is a finite F_0 such that every finite $F \subseteq \mathbb{N} \setminus F_0$ and every $|a_n| \le 1$ satisfy

$$\left\| \sum_{n \in F} a_n x_n^{(k)} \right\| < \varepsilon.$$

The preceding uniform estimate then gives

$$\left\| \sum_{n \in F} a_n x_n \right\| < 2\varepsilon.$$

Thus the tails of $\sum_n x_n$ are uniformly small under bounded scalar changes, which is the unconditional Cauchy criterion. Therefore $x \in \bigoplus^u X_n$, and the earlier estimate proves $x^{(k)} \to x$ in $\|\cdot\|_u$. □

Theorem 7.16 (Countable unconditional packet isomorphism)**.** *Let X be a real or complex Banach space and let $(P_n)_{n \ge 1} \subseteq \mathcal{B}(X)$ satisfy*

$$P_n P_m = \delta_{nm} P_n$$

and

$$x = \sum_{n \ge 1} P_n x$$

unconditionally for every $x \in X$. Assume

$$K := \sup_{F \in \mathbb{N}} \sup_{|a_n| \le 1} \left\| \sum_{n \in F} a_n P_n \right\| < \infty.$$

Then analysis and synthesis define inverse Banach space isomorphisms

$$\boxed{X \cong \bigoplus_{n \ge 1}^{u} P_n X.}$$

More precisely,

$$\|\mathcal{A}_{\mathcal{P}}\| \le K, \qquad \|\mathcal{S}_{\mathcal{P}}\| \le 1.$$

Proof. Each $P_n X = \operatorname{Ker}(I - P_n)$ is closed. For $x \in X$,

$$\|\mathcal{A}_{\mathcal{P}} x\|_u = \sup_{F, a} \left\| \sum_{n \in F} a_n P_n x \right\| \le K \|x\|.$$

For $y = (y_n) \in \bigoplus^u P_n X$, define

$$\mathcal{S}_{\mathcal{P}} y = \sum_n y_n.$$

Since the finite partial sums with every coefficient equal to one are among those used in $\|y\|_u$,

$$\|\mathcal{S}_{\mathcal{P}} y\| \le \|y\|_u.$$

The assumed expansion gives $\mathcal{S}_{\mathcal{P}} \mathcal{A}_{\mathcal{P}} x = x$. Conversely, boundedness of P_m permits termwise application to the unconditionally convergent series:

$$P_m \mathcal{S}_{\mathcal{P}} y = \sum_n P_m y_n = y_m.$$

Thus $\mathcal{A}_{\mathcal{P}} \mathcal{S}_{\mathcal{P}} = I$. Completeness of the coordinate space is lemma 7.15. □

Remark 7.17 (Uniform boundedness). If every expansion $\sum_n P_n x$ is unconditional, the operators obtained from finite partial sums with signs form a pointwise bounded family. The uniform boundedness principle therefore yields a finite constant K. We retain this constant explicitly in theorem 7.16 because later estimates use it to bound the coordinate map.

Boundary 7.18 (Infinite packet sums). For an infinite family, an identity such as $\sum_\alpha P_\alpha = I$ requires a declared convergence mode and the corresponding uniform boundedness statement. Pointwise, strong, norm, weak, and unconditional convergence are not interchangeable.

What we have established

Finite packet systems give exact coordinates in a direct sum, with no orthogonality requirement. Their universal property assembles arbitrary packetwise linear maps uniquely. Tensor products and duals preserve packet structure. In Banach spaces, the analysis and synthesis norms control conditioning. The countable theory developed here uses unconditional convergence and a uniform bound on finite partial sums with signs.

8 Transfer block algebra and support patterns

A route through this section

Once vectors are resolved into packets, every operator becomes a matrix of maps between packet spaces. To multiply operators, we sum over the possible intermediate packets. The blocks permitted to be nonzero define a relation on the packet indices. When that relation is a preorder, the resulting algebra has a triangular structure and a nilpotent ideal of strict transfers.

8.1 Exact operator coordinates

Definition 8.1 (Transfer block). For $T \in \mathrm{End}_{\Bbbk}(X)$ and a finite packet system $\mathcal{P}$, define

$$T_{\beta\alpha} := P_\beta T P_\alpha \in \mathrm{Hom}_{\Bbbk}(X_\alpha, X_\beta).$$

Theorem 8.2 (Exact operator reconstruction). *Every $T \in \mathrm{End}_{\Bbbk}(X)$ satisfies*

$$\boxed{T = \sum_{\alpha,\beta \in I} T_{\beta\alpha}.}$$

Proof. Insert the finite packet identity on both sides:

$$T = \left(\sum_{\beta} P_\beta\right) T \left(\sum_{\alpha} P_\alpha\right) = \sum_{\alpha,\beta} P_\beta T P_\alpha.$$

□

How to read the result

Operator reconstruction inserts the identity on both sides of T. The source index α records where a vector begins, and the target index β records where its image lands. The resulting matrix is exact, and each entry is itself a linear map.

Theorem 8.3 (Packet matrix multiplication). *For $S, T \in \mathrm{End}_{\Bbbk}(X)$,*

$$\boxed{(ST)_{\gamma\alpha} = \sum_{\beta \in I} S_{\gamma\beta} T_{\beta\alpha}.}$$

Proof. Insert $I = \sum_\beta P_\beta$ between S and T:

$$P_\gamma S T P_\alpha = \sum_{\beta} P_\gamma S P_\beta T P_\alpha.$$

□

The central idea

The intermediate packet index in block multiplication plays the role of a summed matrix index. Repeated multiplication therefore becomes a sum over packet paths. Chapter II adds weights and filtrations to this path expansion. Chapter III adds nonlinear trees.

Corollary 8.4 (Packet powers and paths). *For $m \geq 1$,*

$$(T^m)_{\beta_m \beta_0} = \sum_{\beta_1, \ldots, \beta_{m-1}} T_{\beta_m \beta_{m-1}} \cdots T_{\beta_1 \beta_0}.$$

The same formula holds for a product of nonidentical operators with the corresponding blocks in temporal order.

Proof. Induct on m using theorem 8.3. For a product of different operators, use the same induction with the specified operator at each step. □

Corollary 8.5 (Adjoint reversal). *If X is Hilbert, every P_α is orthogonal, and $T \in \mathcal{B}(X)$, then*

$$\boxed{(T_{\beta\alpha})^* = (T^*)_{\alpha\beta}.}$$

Proof. Because $P_\alpha^* = P_\alpha$,

$$(P_\beta T P_\alpha)^* = P_\alpha T^* P_\beta.$$

□

8.2 The full block algebra and intertwining equations

Corollary 8.6 (Tensor product transfer blocks). *Let $S \in \mathrm{End}(X)$ and $T \in \mathrm{End}(Y)$, with packet systems $\mathcal{P}$ and $\mathcal{Q}$. Relative to the tensor product packet system of theorem 7.8,*

$$\boxed{(S \otimes T)_{(\beta,\delta),(\alpha,\gamma)} = S_{\beta\alpha} \otimes T_{\delta\gamma}.}$$

Proof. By definition,

$$\begin{aligned}(S \otimes T)_{(\beta,\delta),(\alpha,\gamma)} &= (P_\beta \otimes Q_\delta)(S \otimes T)(P_\alpha \otimes Q_\gamma) \\ &= (P_\beta S P_\alpha) \otimes (Q_\delta T Q_\gamma) \\ &= S_{\beta\alpha} \otimes T_{\delta\gamma}.\end{aligned}$$

□

Theorem 8.7 (Blockwise intertwining equations). *Let $T \in \mathrm{End}(X)$, $S \in \mathrm{End}(Y)$, let $\mathcal{P} = (P_\alpha)_{\alpha\in I}$ and $\mathcal{Q} = (Q_\gamma)_{\gamma\in J}$ be finite packet systems, and let $U : X \to Y$ be linear. Define*

$$T_{\beta\alpha} = P_\beta T P_\alpha, \qquad S_{\gamma\delta} = Q_\gamma S Q_\delta, \qquad U_{\gamma\alpha} = Q_\gamma U P_\alpha.$$

Then

$$\boxed{UT = SU}$$

if and only if, for every $\gamma \in J$ and $\alpha \in I$,

$$\boxed{\sum_{\beta\in I} U_{\gamma\beta} T_{\beta\alpha} = \sum_{\delta\in J} S_{\gamma\delta} U_{\delta\alpha}.}$$

Proof. Apply Q_γ on the left and P_α on the right. Inserting $I_X = \sum_\beta P_\beta$ gives

$$Q_\gamma U T P_\alpha = \sum_\beta Q_\gamma U P_\beta T P_\alpha = \sum_\beta U_{\gamma\beta} T_{\beta\alpha}.$$

Inserting $I_Y = \sum_\delta Q_\delta$ gives

$$Q_\gamma S U P_\alpha = \sum_\delta Q_\gamma S Q_\delta U P_\alpha = \sum_\delta S_{\gamma\delta} U_{\delta\alpha}.$$

Thus $UT = SU$ implies every block equation. Conversely, if every block equation holds, then all blocks of $UT - SU$ vanish. Exact operator reconstruction yields $UT - SU = 0$. □

How to read the result

A global intertwiner is equivalent to a coupled finite system of packet equations. Later arguments about holonomy and representations use this theorem after the local blocks have been constructed. The equations state the exact compatibility those blocks must satisfy.

Theorem 8.8 (Full block algebra representation)**.** *The map*

$$\Theta_{\mathcal{P}} : \mathrm{End}_{\Bbbk}(X) \longrightarrow \prod_{\beta,\alpha\in I} \mathrm{Hom}_{\Bbbk}(X_\alpha, X_\beta), \qquad T \longmapsto (T_{\beta\alpha})_{\beta,\alpha},$$

is an algebra isomorphism when the codomain is equipped with matrix multiplication whose entries are operators.

Proof. Injectivity follows from exact reconstruction. Given arbitrary linear maps $B_{\beta\alpha} : X_\alpha \to X_\beta$, define

$$T\left(\sum_\alpha x_\alpha\right) := \sum_{\alpha,\beta} B_{\beta\alpha} x_\alpha.$$

The packet decomposition is unique and the index set is finite, so this defines a linear operator whose blocks are the prescribed maps. Thus $\Theta_{\mathcal{P}}$ is surjective. Compatibility with multiplication is theorem 8.3. □

Corollary 8.9 (Propagation of packet support)**.** *Let $T \in \mathrm{End}(X)$ and $x \in X$. Then*

$$\boxed{\mathrm{Supp}_{\mathcal{P}}(Tx) \subseteq \left\{\beta : \exists \alpha \in \mathrm{Supp}_{\mathcal{P}}(x) \text{ with } T_{\beta\alpha} \neq 0\right\}.}$$

Equality holds whenever, for every target β in the set on the right, the active contributions

$$(T_{\beta\alpha} P_\alpha x : \alpha \in \mathrm{Supp}_{\mathcal{P}}(x),\ T_{\beta\alpha} \neq 0)$$

have nonzero sum. In particular, equality holds if at most one active source packet feeds each such β and that source coordinate does not lie in the kernel of the corresponding block.

Proof. For every target packet β,

$$P_\beta T x = \sum_{\alpha\in\mathrm{Supp}_{\mathcal{P}}(x)} T_{\beta\alpha} P_\alpha x.$$

If every block in this sum is zero, then the coordinate with index β vanishes. This proves the inclusion. Equality is exactly the assertion that the displayed active sum is nonzero for every target in the set on the right. The final sufficient condition leaves at most one nonzero summand at each target, and kernel avoidance makes that summand nonzero. □

Corollary 8.10 (Dimension count)**.** *If X is finite dimensional and $d_\alpha = \dim X_\alpha$, then*

$$\dim \mathrm{End}_{\Bbbk}(X) = \sum_{\alpha,\beta} d_\alpha d_\beta = \left(\sum_{\alpha} d_\alpha \right)^2 .$$

Proof. Take dimensions in the block algebra isomorphism and use $\dim \mathrm{Hom}(X_\alpha, X_\beta) = d_\alpha d_\beta$. □

Proposition 8.11 (Block diagonal projection and packet commutant)**.** *Define*

$$\Delta_{\mathcal{P}}(T) := \sum_{\alpha} P_\alpha T P_\alpha .$$

Then $\Delta_{\mathcal{P}}$ is a linear idempotent on $\mathrm{End}(X)$ whose range is the block diagonal subalgebra. For $T \in \mathrm{End}(X)$, the following are equivalent:

(i) $TP_\alpha = P_\alpha T$ *for every* α.

(ii) $T_{\beta\alpha} = 0$ *whenever* $\beta \neq \alpha$.

(iii) $\Delta_{\mathcal{P}}(T) = T$.

Proof. Pairwise annihilation gives $\Delta_{\mathcal{P}}^2 = \Delta_{\mathcal{P}}$ and identifies its range with diagonal block families. If T commutes with all P_α, then for $\beta \neq \alpha$,

$$P_\beta T P_\alpha = P_\beta P_\alpha T = 0.$$

Thus (i) implies (ii). Exact reconstruction shows (ii) implies (iii). If $T = \sum_\alpha P_\alpha T P_\alpha$, then

$$TP_\gamma = P_\gamma T P_\gamma = P_\gamma T,$$

so (iii) implies (i). □

Lower triangular support

Take three packets of dimension one. Permit the diagonal blocks and transfers from a source with a lower index to a target with a higher index. The support relation is a total preorder. The blocks outside the diagonal form a nilpotent ideal, and every product of three strict transfers vanishes. This finite algebraic example anticipates the weighted triangular inverses developed in Chapter II.

8.3 Support patterns, preorders, and triangular structure

Definition 8.12 (Support relation and support space)**.** For a relation $R \subseteq I \times I$, with (β, α) interpreted as an allowed transfer $\alpha \to \beta$, define

$$\mathfrak{M}_R := \{T \in \mathrm{End}(X) : T_{\beta\alpha} = 0 \text{ whenever } (\beta,\alpha) \notin R\}.$$

Theorem 8.13 (Support pattern algebra criterion)**.** *Assume $X_\alpha \neq 0$ for every $\alpha \in I$. Then:*

(i) $I_X \in \mathfrak{M}_R$ *if and only if R is reflexive.*

(ii) $\mathfrak{M}_R\mathfrak{M}_R \subseteq \mathfrak{M}_R$ *if and only if R is transitive.*

(iii) $\mathfrak{M}_R$ *is a unital subalgebra if and only if R is a preorder.*

Proof. The identity has diagonal blocks I_{X_α} and no blocks outside the diagonal, so it belongs to $\mathfrak{M}_R$ exactly when $(\alpha, \alpha) \in R$ for every α.

Assume R is transitive. If a summand

$$S_{\gamma\beta}T_{\beta\alpha}$$

in the (γ, α) block of ST is nonzero, then (γ, β) and (β, α) lie in R. Transitivity gives $(\gamma, \alpha) \in R$, so every forbidden block of ST vanishes.

Conversely, suppose transitivity fails. Choose α, β, γ with

$$(\beta, \alpha) \in R, \qquad (\gamma, \beta) \in R, \qquad (\gamma, \alpha) \notin R.$$

Choose nonzero vectors $u \in X_\alpha$, $v \in X_\beta$, and $w \in X_\gamma$. Choose linear functionals $f \in X_\alpha^*$ and $g \in X_\beta^*$ with $f(u) = g(v) = 1$. Let T have the sole block $x \mapsto f(x)v$ from X_α to X_β, and let S have the sole block $y \mapsto g(y)w$ from X_β to X_γ. Then $S, T \in \mathfrak{M}_R$, but ST has a nonzero forbidden (γ, α) block. This proves necessity. Combining reflexivity and transitivity gives (iii). □

Corollary 8.14 (Bounded support patterns closed under $*$)**.** *Let X be Hilbert, let the packet projectors be orthogonal, assume $X_\alpha \neq 0$ for every $\alpha \in I$, and put*

$$\mathfrak{M}_R^{\mathrm{b}} := \mathfrak{M}_R \cap \mathcal{B}(X).$$

Then $\mathfrak{M}_R^{\mathrm{b}}$ is closed under adjoints if and only if R is symmetric. Hence $\mathfrak{M}_R^{\mathrm{b}}$ is a unital $*$ subalgebra of $\mathcal{B}(X)$ if and only if R is an equivalence relation.

Proof. Adjoint reversal sends an allowed (β, α) block to an (α, β) block. Symmetry is therefore sufficient. If symmetry fails, choose a nonzero map of rank one in an allowed nonsymmetric block. Its adjoint occupies the forbidden reverse block, proving necessity. A reflexive, transitive, symmetric relation is an equivalence relation. □

Theorem 8.15 (Preorder support algebra decomposition)**.** *Let R be a preorder on the finite set I. Define*

$$\alpha \sim \beta \quad \Longleftrightarrow \quad (\beta, \alpha) \in R \text{ and } (\alpha, \beta) \in R.$$

Let $\overline{I} = I/\!\sim$, which carries the induced partial order, and put

$$X_C := \bigoplus_{\alpha \in C} X_\alpha.$$

Let $\mathfrak{N}_R \subseteq \mathfrak{M}_R$ consist of operators whose blocks vanish whenever source and target belong to the same equivalence class. Then:

(i) $\mathfrak{N}_R$ *is a nilpotent ideal on both sides.*

(ii) If h is the maximal number of strict steps in a chain of $\overline{I}$, then

$$\mathfrak{N}_R^{h+1} = 0.$$

(iii) The map to the diagonal classes induces an algebra isomorphism

$$\boxed{\mathfrak{M}_R/\mathfrak{N}_R \cong \prod_{C\in\overline{I}} \mathrm{End}_{\Bbbk}(X_C).}$$

Proof. A nonzero block in $\mathfrak{N}_R$ moves from one equivalence class to a strictly larger class in the quotient partial order. The block multiplication law shows that products concatenate such moves. Therefore left or right multiplication by an element of $\mathfrak{M}_R$ preserves the property of having no blocks within a single class, so $\mathfrak{N}_R$ is an ideal on both sides. A product of $h+1$ elements of $\mathfrak{N}_R$ would require a strict chain of $h+1$ steps in $\overline{I}$, which does not exist. This proves nilpotence.

Let $P_C = \sum_{\alpha\in C} P_\alpha$. Define

$$\rho : \mathfrak{M}_R \longrightarrow \prod_C \mathrm{End}(X_C), \qquad \rho(T) = (P_C T P_C)_C.$$

If an intermediate class D contributes to $P_C S T P_C$, then the preorder contains transfers $C \to D$ and $D \to C$, forcing $C = D$ in the quotient poset. Hence

$$P_C S T P_C = (P_C S P_C)(P_C T P_C),$$

so ρ is an algebra homomorphism. Every collection of endomorphisms of the X_C defines an allowed operator that is block diagonal with respect to the classes, so ρ is surjective. Its kernel is exactly $\mathfrak{N}_R$. The first isomorphism theorem gives the quotient formula. □

What we have established

Every operator has an exact packet matrix. Products sum over intermediate packet indices, tensor products factor blockwise, and global intertwiners are equivalent to coupled block equations. A support pattern is closed under multiplication precisely when its relation is transitive. For a preorder pattern, the quotient is block diagonal and the ideal of strict transfers is nilpotent.

9 Transfer graphs and directed packet generation

A route through this section

The transfer graph records which blocks between packets occur in a declared generating family. Reachability constrains every word in that family. To obtain an exact seed count from the graph, we also need hypotheses that let generation propagate along its edges.

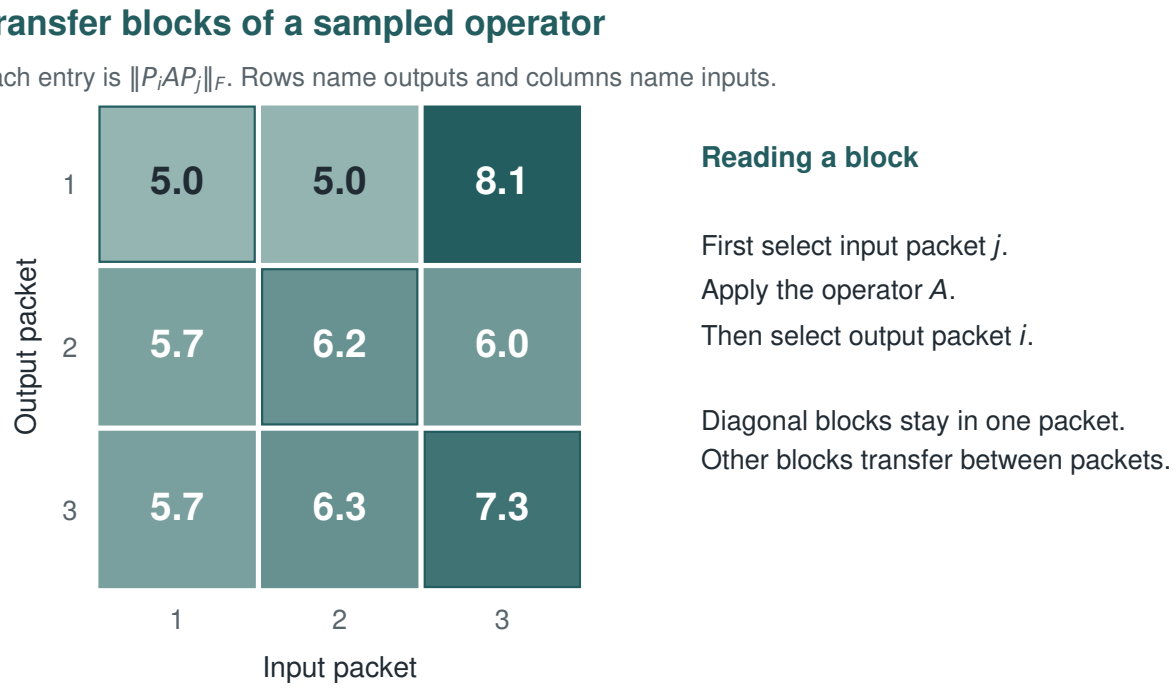

Figure 4. An operator represented by the norms of its blocks between packets. The diagonal entries preserve packets. Entries outside the diagonal describe transfers between packets.

9.1 Graphs generated by declared operators

Definition 9.1 (Transfer graph of a family generating the algebra)**.** Let $\mathcal{P} = (P_\alpha)_{\alpha\in I}$ be a finite packet system on X with every $P_\alpha \in \mathcal{A}$. Let $\mathcal{G} \subseteq \mathcal{A}$ satisfy

$$\mathcal{A} = \mathrm{alg}_{\Bbbk}(\{P_\alpha : \alpha \in I\} \cup \mathcal{G}),$$

where $\mathrm{alg}_{\Bbbk}(E)$ denotes the unital subalgebra over $\Bbbk$ generated by E. The transfer graph $\Gamma(\mathcal{G}, \mathcal{P})$ has vertex set I and an arrow

$$\alpha \longrightarrow \beta$$

when

$$P_\beta G P_\alpha \neq 0$$

for at least one $G \in \mathcal{G}$. Reachability includes paths of length zero.

Theorem 9.2 (Reachability support of the generated algebra)**.** *For every $A \in \mathcal{A}$,*

$$P_\beta A P_\alpha = 0 \qquad \textit{whenever } \beta \notin \mathrm{Reach}(\alpha).$$

Equivalently,

$$\mathcal{A} \subseteq \mathfrak{M}_{R_\Gamma}, \qquad R_\Gamma := \{(\beta, \alpha) : \beta \in \mathrm{Reach}(\alpha)\}.$$

Proof. It is enough to treat a word in the generators and packet projectors. Insert

$$I = \sum_{\gamma \in I} P_\gamma$$

between consecutive nonprojector generators. Every resulting (β, α) block is a finite sum of products

$$P_\beta G_m P_{\gamma_{m-1}} G_{m-1} \cdots P_{\gamma_1} G_1 P_\alpha.$$

A nonzero product requires every consecutive block to be nonzero, hence gives a directed path

$$\alpha \to \gamma_1 \to \cdots \to \gamma_{m-1} \to \beta.$$

Packet projectors only insert stationary steps. Thus a word has no block from α to an unreachable β. Linear combinations preserve the same zero pattern. □

How to read the result

The graph belongs to the declared generating family within $\mathrm{End}(X)$. Multiplying its generators concatenates paths, so a word in them cannot create a block outside graph reachability. Reachability alone gives less information in the other direction. A nonzero edge block may reach only a proper subspace of its target packet.

A path records a possible sequence of transfers. It does not guarantee that the composed transfer is nonzero. The image of one block may lie in the kernel of the next, and different path contributions may cancel when they are added. The reachability theorem therefore gives a restriction on support. To prove that a target packet is generated, we must also examine what the blocks do to vectors. Surjectivity along edges will provide that additional information below.

9.2 Reachability obstructions for seeds

Proposition 9.3 (Reachability obstruction for generated hulls)**.** *Let $I_0 \subseteq I$ and let*

$$S \subseteq \bigoplus_{\alpha \in I_0} X_\alpha.$$

Then

$$\boxed{\mathrm{Hull}_{\mathcal{A}}(S) \subseteq \bigoplus_{\beta \in \mathrm{Reach}(I_0)} X_\beta.}$$

In particular, no seed supported outside a source strongly connected component can generate a nonzero vector in that source component.

Proof. For $s \in S$, write $s = \sum_{\alpha \in I_0} P_\alpha s$. If β is unreachable from I_0, then for every $A \in \mathcal{A}$,

$$P_\beta A s = \sum_{\alpha \in I_0} P_\beta A P_\alpha s = 0$$

by theorem 9.2. The same holds for every finite linear combination of orbit vectors. □

9.3 Packet pure generation and source components

A strongly connected component groups packets that can reach one another. The condensation graph replaces each such group by a single vertex. It has no directed cycles between distinct components. A source component has no incoming edge from another component, so generation there must begin with seed coordinates already present in that component. The rank below records the effect of requiring each seed to lie in a single packet.

Definition 9.4 (Packet pure seed rank)**.** A vector is packet pure when it is zero or lies in one packet space X_α, equivalently when its packet support has cardinality at most one. Define

$$\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) := \min\{|S| : S \text{ is packet-pure and } \mathcal{A}S = X\}.$$

For $C \subseteq I$, put

$$P_C := \sum_{\alpha \in C} P_\alpha, \qquad X_C := P_C X, \qquad \mathcal{A}_C := P_C \mathcal{A} P_C,$$

and define the local packet pure rank

$$r_C := \operatorname{psrank}_{\mathcal{A}_C,\mathcal{P}|_C}(X_C).$$

Proposition 9.5 (Basic packet pure rank bounds)**.** *For every A module resolved into packets with $P_\alpha \in A$,*

$$\boxed{\operatorname{srank}_A(X) \le \operatorname{psrank}_{A,\mathcal{P}}(X) \le \sum_{\alpha \in I} \operatorname{srank}_{P_\alpha A P_\alpha}(X_\alpha).}$$

The corner algebra on the right is unital on X_α with identity P_α.

Proof. Every packet pure generating family is an unrestricted generating family, which gives the first inequality. For each α, choose a minimal generating family $S_\alpha \subseteq X_\alpha$ for the corner action $P_\alpha A P_\alpha$. The union $S = \bigcup_\alpha S_\alpha$ is packet pure. Since every $x \in X$ has the unique decomposition $x = \sum_\alpha x_\alpha$ and every x_α lies in $(P_\alpha A P_\alpha) S_\alpha \subseteq AS$, the union generates X. Its cardinality is at most the displayed sum. □

Definition 9.6 (Packet system surjective along edges)**.** The module resolved into packets is surjective along edges relative to $\Gamma(\mathcal{G}, \mathcal{P})$ when, for every graph edge $\alpha \to \beta$, there exists $B \in \mathcal{A}$ such that the pure block

$$P_\beta B P_\alpha : X_\alpha \twoheadrightarrow X_\beta$$

is surjective.

Theorem 9.7 (Source component formula for packet pure seed rank)**.** *Assume I is finite, every packet space is nonzero, and the module resolved into packets is surjective along edges. Let $\mathfrak{C}_0$ be the set of source strongly connected components of the condensation graph of $\Gamma(\mathcal{G}, \mathcal{P})$. Then*

$$\boxed{\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) = \sum_{C \in \mathfrak{C}_0} r_C.}$$

Proof. Let S be a packet pure generating family for X. Discard zero seeds, which do not change the generated hull, and fix a source component C. Seeds outside C cannot reach C by proposition 9.3. Moreover, for $s \in X_C$ and $A \in \mathcal{A}$,

$$P_C A s = (P_C A P_C) s \in \mathcal{A}_C s.$$

Thus the seeds of S lying in X_C must generate X_C under $\mathcal{A}_C$, and there are at least r_C of them. Summing over disjoint source components gives

$$\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) \geq \sum_{C \in \mathfrak{C}_0} r_C.$$

For the reverse inequality, choose for each source component C a packet pure family S_C of size r_C generating X_C under $\mathcal{A}_C$, and put $S = \bigcup_C S_C$. Then every source component lies in $\mathcal{A}S$. Traverse the finite condensation graph in a topological order. Suppose all components preceding a component D that is not a source have already been shown to lie in $\mathcal{A}S$. Choose an incoming condensation edge from such a component to D, represented by a graph edge $\alpha \to \beta$ with α already generated and $\beta \in D$. Surjectivity along edges gives a pure block

$$B_{\beta\alpha} : X_\alpha \twoheadrightarrow X_\beta.$$

Because $X_\alpha \subseteq \mathcal{A}S$ and $\mathcal{A}S$ is invariant under $\mathcal{A}$, surjectivity implies $X_\beta \subseteq \mathcal{A}S$. For any other vertex $\gamma \in D$, choose a directed path inside the strongly connected component from β to γ. Successive surjective edge blocks propagate the full packet space along the path, so $X_\gamma \subseteq \mathcal{A}S$. Hence $X_D \subseteq \mathcal{A}S$. Induction over the condensation graph gives $X = \mathcal{A}S$, proving the upper bound. □

Why the hypotheses matter

The formula for source components uses local generation inside those components and surjectivity along the edges. Local generation supplies the starting packet spaces. Surjectivity then propagates their full spaces through the condensation graph. Without it, a path may exist while its blocks reach only a proper subspace.

Definition 9.8 (Packet propagating system)**.** A packet system that is surjective along edges is called packet propagating when every packet space X_α is cyclic under its diagonal corner algebra

$$P_\alpha \mathcal{A} P_\alpha.$$

Corollary 9.9 (Unweighted source component count)**.** *Assume the module resolved into packets is packet propagating and $X_\alpha \neq 0$ for every $\alpha \in I$. If c_0 denotes the number of source strongly connected components, then*

$$\boxed{\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) = c_0.}$$

Proof. Fix a source component C and a vertex $\alpha \in C$. Choose a cyclic vector $s \in X_\alpha$ for $P_\alpha \mathcal{A} P_\alpha$. It generates all of X_α. Strong connectivity and surjectivity along edges then propagate the whole packet space to every vertex of C. Thus $r_C = 1$ for every source component. Apply theorem 9.7. □

Boundary 9.10 (Mixed support seeds can merge source requirements). The source component formulas concern packet pure seeds. They do not give the unrestricted seed rank. For example, let

$$\mathcal{A} = \Bbbk \times \Bbbk, \qquad X = \Bbbk \oplus \Bbbk$$

with the coordinate action and the two coordinate packet projectors. The transfer graph has two source components and

$$\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) = 2,$$

but the mixed vector $(1, 1)$ is cyclic, so

$$\operatorname{srank}_{\mathcal{A}}(X) = 1.$$

Why mixed seeds change the answer

Let the acting algebra be diagonal on $X = X_1 \oplus X_2$, with no transfer between the packets. Generation by packet pure seeds requires one seed in each source component, so psrank $= 2$. A single mixed vector $x_1 + x_2$ may generate both packets of dimension one under the diagonal action, so unrestricted seed rank can be 1.

What we have established

Graph reachability restricts which blocks can be nonzero in the algebra generated by the declared operators. Source components give the exact rank for packet pure seeds under the stated local generation and edge propagation hypotheses. Seeds with several nonzero packet coordinates have a different minimum count and may meet several source requirements at once.

10 Coordinate transport, morphisms, invariant exact sequences, and completion

A route through this section

This section follows packet data through changes of coordinates, maps between systems, and passage to a quotient. It then explains the additional assumptions needed when density, topology, or completion enters the argument.

10.1 Coordinate changes and packet compatible morphisms

Theorem 10.1 (Coordinate transport). *Let $U : X \to Y$ be a vector space isomorphism and let $\mathcal{P} = (P_\alpha)$ be a packet system on X. Define*

$$Q_\alpha := UP_\alpha U^{-1}.$$

Then $\mathcal{Q} = (Q_\alpha)$ is a packet system on Y. For $\widetilde{T} = UTU^{-1}$,

$$\boxed{Q_\beta \widetilde{T} Q_\alpha = U(P_\beta T P_\alpha)U^{-1}.}$$

Hence packet dimensions, zero patterns, and support preorders are invariant under coordinate transport. If a declared algebra generating family $\mathcal{G}$ is transported to $U\mathcal{G}U^{-1}$, then its transfer graph and reachability relation are also preserved.

Proof. Conjugation preserves products and sums, so

$$Q_\alpha Q_\beta = UP_\alpha P_\beta U^{-1} = \delta_{\alpha\beta} Q_\alpha, \qquad \sum_\alpha Q_\alpha = I_Y.$$

The block identity is direct multiplication:

$$Q_\beta \widetilde{T} Q_\alpha = UP_\beta T P_\alpha U^{-1}.$$

All listed invariants are determined by these transported blocks. □

How to read the result

An isomorphism changes the coordinates of each packet while preserving the direct sum structure. Conjugating the projectors and the operator together preserves every block identity. This is the linear prototype for the gauge changes used later in the series.

Definition 10.2 (Packet compatible operator morphism). Let $(X, \mathcal{A}, \mathcal{P})$ and $(Y, \mathcal{B}, \mathcal{Q})$ be packet resolved operator modules with packet index sets I and J. A packet compatible operator morphism is a triple

$$(\Phi, \varphi, \sigma)$$

consisting of a unital algebra homomorphism $\varphi : \mathcal{A} \to \mathcal{B}$, a linear map $\Phi : X \to Y$ satisfying

$$\Phi(Ax) = \varphi(A)\Phi(x),$$

and a map $\sigma : I \to J$ satisfying

$$Q_j \Phi = \Phi P_{\sigma^{-1}(j)}, \qquad P_{\sigma^{-1}(j)} := \sum_{\sigma(\alpha)=j} P_\alpha.$$

An empty fiber is interpreted as the zero projector.

The packet index map records which source packets are grouped into each target packet. Its compatibility equation says that projecting after transport gives the same result as first collecting those source

packets. The intertwining equation separately ensures that the declared operator actions agree with the transport. Both conditions matter when comparing transfer blocks.

Definition 10.3 (Morphism of seeded systems)**.** A morphism

$$(X, \mathcal{A}, S, \mathcal{P}) \longrightarrow (Y, \mathcal{B}, S', \mathcal{Q})$$

is a packet compatible operator morphism satisfying the seed condition

$$\Phi(S) \subseteq \mathrm{Hull}_{\mathcal{B}}(S').$$

In the topological category all maps and actions are required to be continuous and the seed condition uses the topological hull when declared.

Theorem 10.4 (Naturality of generated hulls and transfer blocks)**.** *Let (Φ, φ, σ) be a packet compatible operator morphism. For every subset $S \subseteq X$,*

$$\boxed{\Phi(\mathrm{Hull}_{\mathcal{A}}(S)) = \mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi(S)) \subseteq \mathrm{Hull}_{\mathcal{B}}(\Phi(S)).}$$

For $T \in \mathcal{A}$ and $i, j \in J$,

$$\boxed{Q_j \varphi(T) Q_i \Phi = \sum_{\substack{\sigma(\beta)=j \\ \sigma(\alpha)=i}} \Phi P_\beta T P_\alpha.}$$

If Φ is surjective and S generates X, then $\Phi(S)$ generates Y under $\varphi(\mathcal{A})$ and hence under $\mathcal{B}$. If, in addition, the morphism is seeded, then S' generates Y.

Proof. Every element of $\Phi(\mathrm{Hull}_{\mathcal{A}}(S))$ is a finite sum of vectors

$$\Phi(As) = \varphi(A)\Phi(s),$$

so it belongs to $\mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi(S))$. Conversely, every generator $\varphi(A)\Phi(s)$ equals $\Phi(As)$, giving equality.

For the block formula, use intertwining and packet compatibility twice:

$$\begin{aligned} Q_j \varphi(T) Q_i \Phi &= Q_j \varphi(T) \Phi P_{\sigma^{-1}(i)} \\ &= Q_j \Phi T P_{\sigma^{-1}(i)} \\ &= \Phi P_{\sigma^{-1}(j)} T P_{\sigma^{-1}(i)} \\ &= \sum_{\substack{\sigma(\beta)=j \\ \sigma(\alpha)=i}} \Phi P_\beta T P_\alpha. \end{aligned}$$

If Φ is surjective and $\mathrm{Hull}_{\mathcal{A}}(S) = X$, the hull equality gives $Y = \mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi(S))$. If $\Phi(S) \subseteq \mathrm{Hull}_{\mathcal{B}}(S')$, then $\mathrm{Hull}_{\mathcal{B}}(\Phi(S)) \subseteq \mathrm{Hull}_{\mathcal{B}}(S')$, so S' generates Y. □

The central idea

Naturality gives two ways to compute the same transported block. One may apply the target operator between target projectors, or sum the source blocks whose packet indices map to those target indices and then apply the morphism. The theorem also identifies the image of the generated hull. These equalities make the comparison between the two systems precise.

Proposition 10.5 (Category of seeded packet systems)**.** *Packet compatible operator morphisms compose, seeded morphisms compose, and identity morphisms satisfy both definitions. Thus packet resolved operator modules form a category* **PktMod** *and seeded packet systems form a category* **SeedSys***.*

Proof. Let $(\Phi, \varphi, \sigma) : (X, \mathcal{A}, \mathcal{P}) \to (Y, \mathcal{B}, \mathcal{Q})$ and $(\Psi, \psi, \tau) : (Y, \mathcal{B}, \mathcal{Q}) \to (Z, \mathcal{C}, \mathcal{R})$ be morphisms. Intertwining is preserved because

$$\Psi\Phi(Ax) = \Psi(\varphi(A)\Phi x) = (\psi \circ \varphi)(A)\Psi\Phi x.$$

For k in the target packet set,

$$\begin{aligned} R_k \Psi\Phi &= \Psi Q_{\tau^{-1}(k)}\Phi \\ &= \Psi\Phi \sum_{\tau(\sigma(\alpha))=k} P_\alpha. \end{aligned}$$

Thus the composite packet map is $\tau \circ \sigma$. If the morphisms are seeded, then

$$\Phi(S) \subseteq \mathrm{Hull}_{\mathcal{B}}(S'), \qquad \Psi(S') \subseteq \mathrm{Hull}_{\mathcal{C}}(S'').$$

By theorem 10.4,

$$\Psi\Phi(S) \subseteq \Psi(\mathrm{Hull}_{\mathcal{B}}(S')) \subseteq \mathrm{Hull}_{\mathcal{C}}(\Psi(S')) \subseteq \mathrm{Hull}_{\mathcal{C}}(S'').$$

Identity maps satisfy the definitions with identity algebra and packet maps. □

10.2 Invariant subspaces and quotient packets

Passage to a quotient uses two separate invariance assumptions. The packet projectors must preserve the subspace for packet coordinates to descend. An operator must also preserve that subspace for its action, and hence its transfer blocks, to descend. The first condition is enough for the packet exact sequence. The second enters the corollary about transfer blocks.

Theorem 10.6 (Packet exact sequence for an invariant subspace)**.** *Let $K \leq X$ satisfy $P_\alpha K \subseteq K$ for every α. Define*

$$K_\alpha := P_\alpha K = K \cap X_\alpha$$

and

$$\overline{P}_\alpha(x + K) := P_\alpha x + K.$$

Then:

(i) The nonzero restrictions $P_\alpha|_K$ form a packet system on K.

(ii) The nonzero $\overline{P}_\alpha$ form a packet system on X/K.

(iii) For every α there is a short exact sequence

$$0 \longrightarrow K_\alpha \longrightarrow X_\alpha \longrightarrow \overline{P}_\alpha(X/K) \longrightarrow 0,$$

and

$$\overline{P}_\alpha(X/K) \cong X_\alpha/(X_\alpha \cap K) \cong (X_\alpha + K)/K.$$

(iv) The full exact sequence decomposes packetwise as the direct sum of these short exact sequences.

Proof. Restriction preserves idempotency, pairwise annihilation, and the identity sum on K. If $x \in K \cap X_\alpha$, then $x = P_\alpha x \in P_\alpha K$, proving $K_\alpha = K \cap X_\alpha$.

The quotient operator is well defined because replacing x by $x + k$ changes $P_\alpha x$ by $P_\alpha k \in K$. The idempotent and annihilation identities descend, and the sum is the identity on X/K. The map $X_\alpha \to X/K$ has image $(X_\alpha + K)/K$ and kernel $X_\alpha \cap K$, giving the short exact sequence and the quotient isomorphisms. Exact packet coordinates identify the original sequence with the direct sum over α. □

Packet descent to a quotient

Let $X = X_1 \oplus X_2$ and let $K \subseteq X_1$ be a subspace. The quotient has packets X_1/K and X_2. Any operator preserving K descends with the same organization by source and target packets, with blocks entering or leaving the first packet replaced by their induced quotient maps. An induced block can become zero even when its original block is nonzero, so the pattern of nonzero blocks can shrink. Any resulting zero packet is removed from the quotient packet system.

Theorem 10.7 (Packet descent through an invariant quotient)**.** *Under the hypotheses of theorem 10.6, the operators*

$$\overline{P}_\alpha(x + K) = P_\alpha x + K$$

are well defined pairwise annihilating idempotents with sum $I_{X/K}$, and the quotient map satisfies

$$\boxed{\pi P_\alpha = \overline{P}_\alpha \pi.}$$

After zero packets are removed, they form the canonical quotient packet system.

Proof. All assertions are the quotient part of theorem 10.6. The intertwining identity follows directly from the definition:

$$\overline{P}_\alpha \pi(x) = P_\alpha x + K = \pi P_\alpha(x).$$

□

Corollary 10.8 (Restriction and quotient of transfer blocks)**.** *Under the hypotheses of theorem 10.6, let $T \in \mathrm{End}(X)$ preserve K. Then every block $T_{\beta\alpha}$ maps K_α into K_β, and the induced quotient operator $\overline{T}$ satisfies*

$$\boxed{\overline{T}_{\beta\alpha}\,\pi = \pi T_{\beta\alpha},}$$

where $\pi : X \twoheadrightarrow X/K$.

Proof. If $x \in K_\alpha$, then $Tx \in K$, so

$$T_{\beta\alpha}x = P_\beta Tx \in K \cap X_\beta = K_\beta.$$

On the quotient,

$$\overline{T}_{\beta\alpha}\pi = \overline{P}_\beta \overline{TP}_\alpha \pi = \pi P_\beta T P_\alpha.$$

□

Corollary 10.9 (Topological packet exact sequence)**.** *If X is Banach, the P_α are bounded, and K is closed and packet invariant, then every packet sequence in theorem 10.6 is a short exact sequence of Banach spaces with bounded maps, and the quotient projectors are bounded.*

Proof. Closedness of K makes X/K Banach. The restricted projectors are bounded, and the quotient projectors are bounded because

$$\|\overline{P}_\alpha(x+K)\|_{X/K} \le \|P_\alpha\|\,\|x+K\|_{X/K}.$$

The packet spaces are closed ranges of bounded idempotents. □

10.3 Dense images, quotient topology, and completion

Algebraic generation uses finite linear combinations of operator images. Topological generation allows limits of those combinations in the declared topology. A continuous surjection carries this approximation property to the target, but identifying the target with a topological quotient requires a further assumption.

Theorem 10.10 (Dense realization theorem)**.** *Let X and Y be Hausdorff topological vector spaces, let $\Phi : X \to Y$ be continuous, surjective, and intertwining with respect to φ, and let S topologically generate X. Then $\Phi(S)$ topologically generates Y. If finite continuous packet systems satisfy*

$$Q_j \Phi = \Phi P_{\sigma^{-1}(j)},$$

then

$$\boxed{Q_j Y = \Phi(P_{\sigma^{-1}(j)} X)}$$

for every j.

Proof. Given $y = \Phi(x)$, choose a net $x_\lambda \in \mathrm{Hull}_{\mathcal{A}}(S)$ converging to x. Then

$$\Phi(x_\lambda) \to y,$$

and naturality places every $\Phi(x_\lambda)$ in $\mathrm{Hull}_{\mathcal{B}}(\Phi(S))$. Hence the latter hull is dense. For packets, one inclusion follows from compatibility. Conversely, if $y = Q_j y$, choose x with $\Phi(x) = y$. Then

$$y = Q_j \Phi(x) = \Phi P_{\sigma^{-1}(j)} x.$$

□

Theorem 10.11 (Quotient topology and completed realization)**.** *Let $\Phi : X \twoheadrightarrow Y$ be a continuous linear quotient map between Hausdorff topological vector spaces, and put $K = \operatorname{Ker}\Phi$. Then the induced map*

$$\widetilde{\Phi} : X/K \longrightarrow Y$$

is a topological isomorphism. If $D \subseteq X$ is a linear subspace whose image $\Phi(D)$ is dense in a complete space Y, then the completion of

$$D/(D \cap K)$$

in the topology transported from Y is canonically isomorphic to Y.

Proof. The algebraic first isomorphism theorem gives a bijection $\widetilde{\Phi}$. By definition of the quotient topology, a set $U \subseteq X/K$ is open exactly when its preimage in X is open. Because Φ is a quotient map, this is equivalent to $\widetilde{\Phi}(U)$ being open in Y. Thus $\widetilde{\Phi}$ is a homeomorphism. The second statement applies the dense completion argument of theorem 3.6 to the injective map $D/(D \cap K) \to Y$. □

Boundary 10.12 (Continuous surjections and quotient topology). Continuity and surjectivity transport density as in theorem 10.10. They do not by themselves identify the given topology on Y with the quotient topology from X. The stronger conclusion in theorem 10.11 requires the quotient map hypothesis or an equivalent open mapping condition.

Scope of the argument

A continuous surjective linear map need not be a quotient map in arbitrary topological vector spaces. The algebraic first isomorphism theorem gives a bijection on the quotient. A topological isomorphism requires the quotient topology to agree with the target topology. An applicable open mapping theorem can supply this agreement, as it does for continuous linear surjections between Banach spaces.

The completion statement uses the topology transported from the target space. This choice ensures that approximation in the quotient means approximation in the target. A topology inherited from the original subspace need not give the same completion unless the two topologies agree. The theorem therefore names the topology as part of its conclusion.

What we have established

Packet systems transport by conjugation, form a category under packet compatible seeded morphisms, restrict to invariant subspaces, descend to invariant quotients, and survive completion under explicit boundedness and quotient topology hypotheses.

11 Realization functors and semantic theorem transport

A route through this section

A later domain is a genuine realization only when the relevant structures and identities are preserved. The purpose of this section is to replace informal analogy by a precise preservation profile.

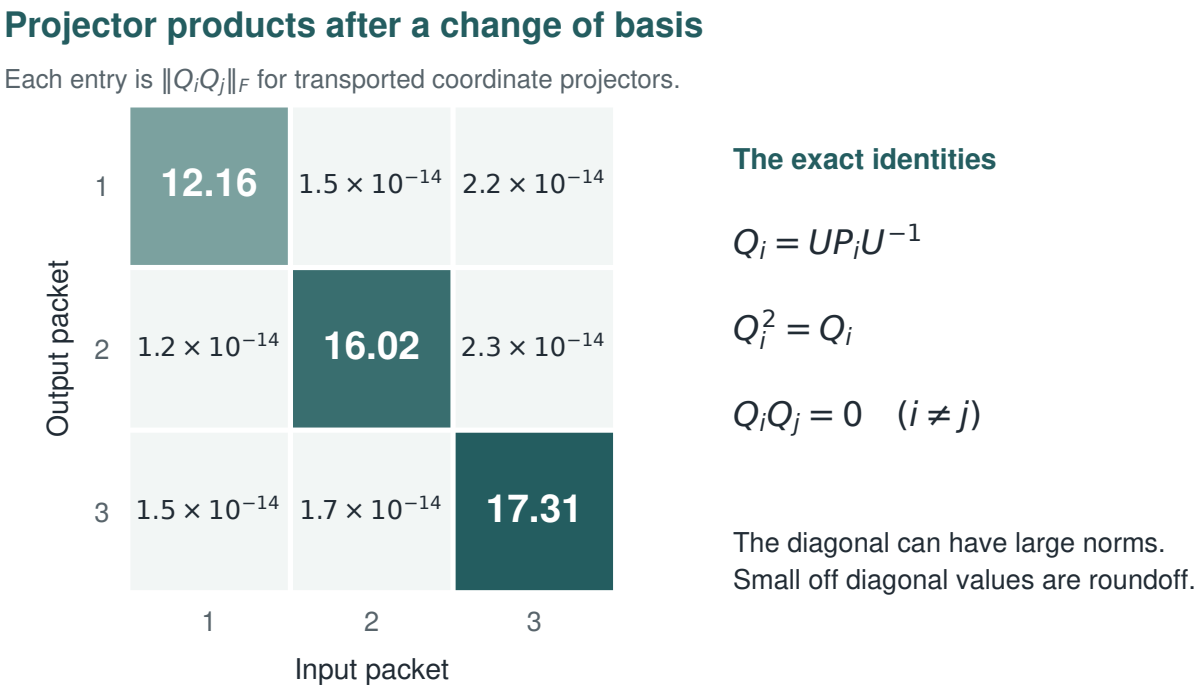

Figure 5. Numerical certificate for a nonorthogonal transported packet system. The diagonal products retain idempotent size while off diagonal products remain at roundoff level.

11.1 Preservation profiles

Definition 11.1 (Realization functor and preservation profile)**.** Let $\mathbf{SeedSys}_{\mathrm{abs}}$ be an abstract category of seed systems and let $\mathbf{C}_D$ be a domain category. A realization functor is a functor

$$\mathrm{Ev}_D : \mathbf{SeedSys}_{\mathrm{abs}} \longrightarrow \mathbf{C}_D$$

with a declared preservation profile specifying which of the following structures are preserved:

$$0,\ I,\ \text{finite sums},\ \text{composition},\ \text{biproducts},$$
$$\text{kernels},\ \text{cokernels},\ \text{quotients},\ \text{tensor products},$$
$$\text{packet idempotents},\ \text{transfer blocks},\ \text{topological completions}.$$

Preservation of a structure means preservation of its defining identity or universal property, not merely a similarity of notation.

Theorem 11.2 (Equational realization principle)**.** *Let $F : \mathbf{C} \to \mathbf{D}$ be an additive functor between preadditive categories. Any equality of morphisms constructed from declared generating morphisms by finite sums, additive inverses, identities, zero maps, and composition is preserved by F. Scalar multiplication by a coefficient ring is also preserved when the categories are enriched over that ring and F is linear for*

the declared enrichment. If a proof additionally uses a chosen biproduct, kernel, cokernel, quotient, tensor product, or completion and F preserves that construction in its declared profile, then the corresponding proof diagram is transported to $\mathbf{D}$.

Proof. Functoriality gives

$$F(I) = I, \qquad F(g \circ f) = F(g) \circ F(f),$$

and additivity gives

$$F(0) = 0, \qquad F(f + g) = F(f) + F(g), \qquad F(-f) = -F(f).$$

If the declared enrichment is present, linearity additionally gives $F(af) = aF(f)$ for every coefficient a. A structural induction on the construction of a morphism expression therefore carries every permitted equational proof to its image under F. If a step invokes a universal construction, preservation means that the image diagram satisfies the same universal property. The uniquely induced morphism in the source proof is therefore carried to the uniquely induced morphism in the target proof. Repeating this argument through the finite proof diagram transports the conclusion. □

How to read the result

The equational principle covers identities built from operations the functor preserves. Additive identities require additivity. Identities with scalar coefficients require linear enrichment. Quotients, tensor products, completions, kernels, or limits require their own preservation assumptions. The preservation profile records the assumptions needed to carry each step of the proof into the target category.

11.2 From equation transport to semantic realization

Proposition 11.3 (Realization export principle)**.** *Every canonical Chapter I identity whose proof uses only the operations listed in a realization functor's verified preservation profile remains valid after applying that functor. If the proof uses a domain specific hypothesis not encoded by the functor, that hypothesis must be verified separately before the transported statement is promoted to a theorem.*

Proof. The first assertion is theorem 11.2. The second is a logical boundary: a functor transports established identities and preserved universal constructions, but it does not create an unverified analytic, topological, positivity, finiteness, or integrality hypothesis. □

Definition 11.4 (Semantic realization criterion)**.** A domain theorem is a semantic realization of a canonical seed calculus theorem only when:

(i) An explicit realization functor or intertwining construction is given.

(ii) The preservation profile covers every construction used in the canonical proof.

(iii) Every additional analytic, finiteness, convergence, positivity, or integrality hypothesis is verified in the domain.

(iv) The resulting conclusion is stated in the domain's native objects.

Reuse of the words “seed”, “packet”, or “transfer” without these data is only syntactic reuse.

Scope of the argument

A change of nouns is not a realization theorem. Calling a frequency band, a ramification sector, and a symmetry sector a “packet” is only terminology until one exhibits the idempotents, proves reconstruction, identifies the transfer blocks, and checks that the relevant morphisms or limits preserve those structures.

What we have established

The preservation profile determines which equations and proof constructions pass to a new domain. Checking it gives later chapters a concrete test for transporting a theorem: identify the realization, check each operation used in the proof, and verify the additional domain hypotheses.

12 Canonical export interface and claim boundary

A route through this section

The export interface lets later chapters use the foundational proofs directly. Each chapter can cite the stable record ID, state its domain hypotheses, and prove the new step specific to its realization.

Definition 12.1 (Worked realization interface)**.** The foundational calculus is illustrated by four canonical algebraic realizations:

(i) A typed quiver reachability model.

(ii) An algebraic coordinate ring presentation.

(iii) A companion and repeated primary single operator model.

(iv) Path and cycle adjacency models.

The worked model sections below instantiate these four interfaces. A bilateral shift example records the analytic completion mechanism also used in Chapter V. Computational specifications connect the proofs with the verification companion and are not premises of the foundational theorems.

Definition 12.2 (Chapter I export object)**.** The canonical Chapter I export is

$$\mathsf{PSC}_I = \left(\begin{array}{c} \text{typed grammars and realized operator algebras,} \\ \text{seed systems, free presentations, and seed rank,} \\ \text{module-top, semisimple, and single-operator formulas,} \\ \text{finite and unconditional packet coordinates,} \\ \text{transfer blocks and support algebras,} \\ \text{reachability and packet-pure source generation,} \\ \text{morphisms, invariant exact sequences, quotients, completions,} \\ \text{realization functors and equational theorem transport} \end{array} \right).$$

12.1 Use across chapters

Chapter I export	Primary users	Later role
Typed grammar and module equivalence	II to XII	Gives each domain a legal operator syntax and a concrete module realization.
Free seed presentation	IV, IX, X	Converts generated families into quotient presentations and relation modules.
Jacobson top seed rank	VII, X, XII	Computes minimal generators from semisimple multiplicity data.
Single operator formula	IV, VI, IX	Resolves recurrence, companion, and spectral chain generator counts.
Exact packet coordinates	II to XII	Supplies analysis, synthesis, and packetwise equality.
Tensor and dual packet systems	V, VII, VIII, XI	Controls product systems, observables, and paired representations.
Transfer block multiplication	II to XII	Converts operator composition into sums over packet paths.
Block intertwining equations	III, VII, XI	Expresses global equivalence or gluing as local packet equations.
Support preorder algebra	II, VIII, X	Produces triangular transfer structure and nilpotent strict transfer ideals.
Source component seed rank	VIII, X	Identifies the packet pure source requirements under propagation hypotheses.
Packet exact sequences and quotient descent	III, VI, X, XII	Carries packets through constraints, reductions, and deformation quotients.
Semantic realization criterion	IV to XII	Specifies when a domain theorem is a true realization of the common calculus.

Boundary 12.3 (Exact limits of Chapter I). The existence of an exact packet decomposition does not imply that the decomposition is computationally discoverable, numerically well conditioned, statistically identifiable, dynamically invariant, or mathematically useful. The condition number in definition 7.11 quantifies only coordinate stability once the packets are supplied. Refinement towers, filtered transfer, nonlinear obstruction objects, automatic packet recovery, continuum limits, arithmetic lifts, and automorphic occupancy require additional theorems in later chapters.

13 A typed quiver model

A small quiver model shows how the path algebra records a direction that the available seeds cannot reach.

Let the quiver have vertices U, V and arrows

$$R : U \to U, \qquad A : U \to V, \qquad B : V \to U,$$

with the relation in the path algebra

$$BA = e_U,$$

whose realization is the operator identity $BA = I_U$. Realize

$$U = \Bbbk^2, \qquad V = \Bbbk^3,$$

by

$$R = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \qquad A(u_1, u_2) = (u_1, u_2, 0), \qquad B(v_1, v_2, v_3) = (v_1, v_2).$$

Starting from the seed $e_1 \in U$, repeated application of R spans U, and A carries that span onto the first two coordinates of V. Any path from U to V ends with A and therefore lands in $\operatorname{im} A$. The third coordinate direction, which spans $\ker B$, is unreachable from a seed supported only at U. Therefore the generated representation is

$$U \oplus \operatorname{span}\{(1, 0, 0), (0, 1, 0)\} \subsetneq U \oplus V.$$

Adding the seed $(0, 0, 1) \in V$ generates the full representation.

Proposition 13.1 (Typed reachability certificate)**.** *In the preceding quiver realization, no seed supported at U can generate the full representation, whereas the two seeds*

$$e_1 \in U, \qquad e_3 \in V$$

do generate it.

Proof. The first claim follows because every path that starts at U and ends in V has final arrow A, so its image lies in $\operatorname{im} A$. For the second, e_1 and Re_1 span U. Their images under A span $\operatorname{im} A$, and e_3 spans $\ker B$, the missing complementary direction in V. □

This example shows why a typed grammar is more than a notational convenience. The obstruction lies in the subspace $\ker B \subset V$, which is unreachable from seeds supported at U, and is visible before any coordinate calculation.

The arrow from one vertex to another records which type can be reached. Its image records which directions can be reached within that type. Here the first seed reaches both vertices, yet misses one direction at the second vertex. The extra seed supplies that direction directly. This is why reachability of a vertex alone does not settle generation of its entire space.

14 Worked algebraic model: an elliptic coordinate ring

Let $\operatorname{char} \Bbbk \neq 2$ and let

$$A = \Bbbk[x, y]/(y^2 - x^3 + x).$$

The affine equation $y^2 = x^3 - x$ has classical discriminant 64, which is nonzero under this hypothesis. Standard algebraic geometry then identifies its smooth projective completion as an elliptic curve [9]. The Lean development checks the algebraic implication $2 \neq 0 \Rightarrow 64 \neq 0$, the quotient normal form, and the operator identities below. It does not formalize projective smoothness, genus, or the geometric identification of the discriminant. The packet computation itself uses only the displayed relation in the quotient ring. Every class has a unique normal form

$$f(x, y) = a(x) + yb(x).$$

Indeed, $y^2 - (x^3 - x)$ is monic of degree two in y, so division in $\Bbbk[x][y]$ gives a unique remainder of degree less than two in y. Concretely, every power y^m with $m \geq 2$ can be reduced using

$$y^2 = x^3 - x.$$

14.1 One module seed and two address operators

Take the seed

$$s = 1$$

and let M_x, M_y be multiplication by x and y. Then

$$M_x^i M_y^j s = x^i y^j,$$

so the algebra, regarded as a module over its multiplication algebra, is generated by one seed.

The two packet spaces are

$$A_0 = \Bbbk[x], \qquad A_1 = y\Bbbk[x].$$

Let

$$P_0(a + yb) = a, \qquad P_1(a + yb) = yb.$$

These idempotents are linear over $\Bbbk$, annihilate one another, and satisfy $P_0 + P_1 = I$. They are not module maps over A, because multiplication by y exchanges the two packets.

Identify the packet coefficients by

$$A_0 \oplus A_1 \longrightarrow \Bbbk[x] \oplus \Bbbk[x], \qquad (a, yb) \longmapsto (a, b).$$

In these ordered coefficient coordinates, with M_x and M_{x^3-x} denoting multiplication on $\Bbbk[x]$,

$$M_x = \begin{pmatrix} M_x & 0 \\ 0 & M_x \end{pmatrix}, \qquad M_y = \begin{pmatrix} 0 & M_{x^3-x} \\ I & 0 \end{pmatrix}.$$

The two rows of the second matrix record the outgoing packet coefficients. An even input enters the odd packet without an additional factor. An odd input returns to the even packet through the factor im-

posed by the curve equation. Applying the matrix twice therefore preserves each packet and multiplies its coefficient by that factor.

The relation is reconstructed as an operator identity:

$$M_y^2 = M_x^3 - M_x.$$

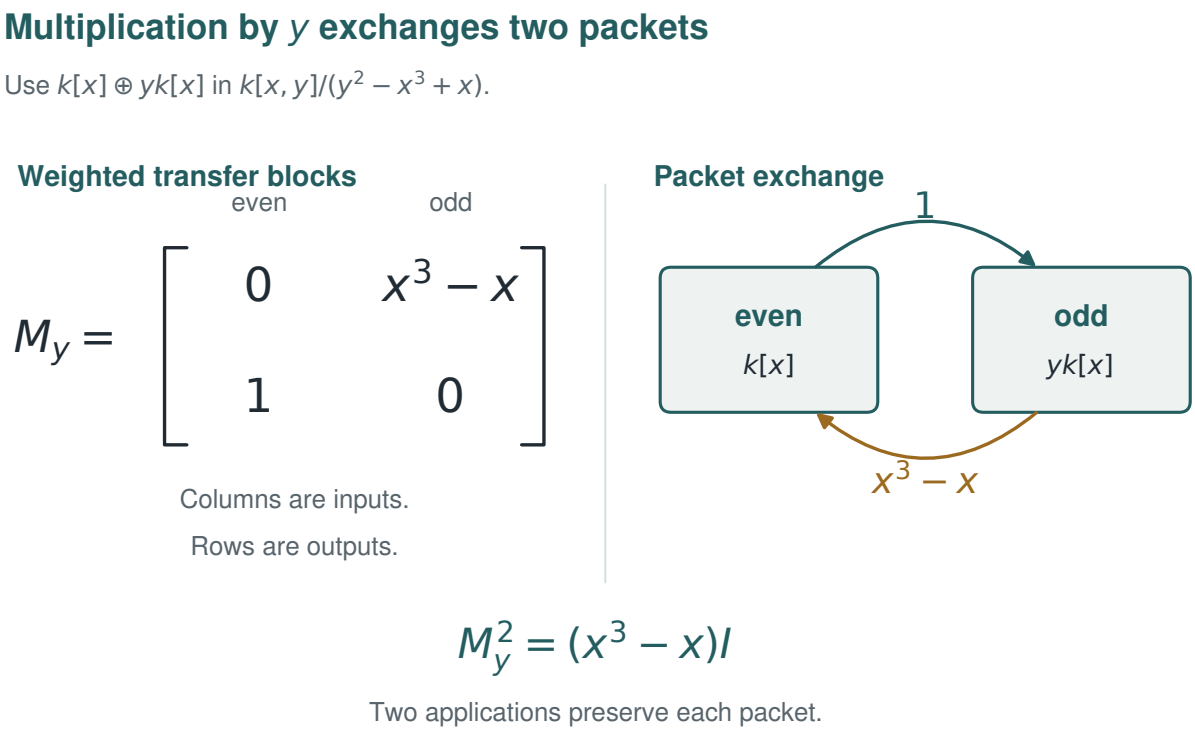

Figure 6. Multiplication by y exchanges the even and odd packets. The transfer from the odd packet to the even packet carries the relation weight $x^3 - x$.

14.2 Exact product law

Write

$$f = a_0 + ya_1, \qquad g = b_0 + yb_1.$$

Then

$$fg = (a_0b_0 + (x^3 - x)a_1b_1) + y(a_0b_1 + a_1b_0).$$

This is a convolution law for the two packets. It is already visible at the linear operator level because multiplication by a fixed element is a transfer operator. The even output collects the product of the two even coefficients and the weighted product of the two odd coefficients. The odd output collects the two products with one even and one odd coefficient. The quotient relation is thus retained in the weight rather than discarded during the decomposition.

Example 14.1 (Worked reduction)**.** Take

$$f = x^2 + y, \qquad g = x - y.$$

Then

$$\begin{aligned} fg &= x^3 - x^2y + xy - y^2 \\ &= x^3 - x^2y + xy - (x^3 - x) \\ &= x + (x - x^2)y. \end{aligned}$$

Thus

$$P_0(fg) = x, \qquad P_1(fg) = (x - x^2)y.$$

The symbolic certificate in the companion code performs the same quotient reduction exactly.

14.3 What this example establishes

The coordinate ring illustrates four distinct parts of the calculus:

(i) the unit is a module seed.

(ii) M_x and M_y are address operators.

(iii) the curve equation is an operator relation.

(iv) parity in y gives exact packet analysis, transfer, and reconstruction.

It does not imply that every algebra can be presented as an algebra generated by one element. It shows instead that unital algebras are cyclic as modules over their full multiplication algebra.

15 Worked signal model: a bilateral shift

Let $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$ and let

$$X = \ell^2(\mathbb{Z}; \mathbb{F})$$

with a family of bounded reindexing operators indexed by the integers

$$(S_m x)[n] = x[n - m] \qquad (m, n \in \mathbb{Z}).$$

Thus $S_0 = I$, $S_{m+r} = S_m S_r$, and S_1 is the usual bilateral shift. We use the standard conventions for Hilbert spaces and bounded operators of [3]. The impulse δ_0 satisfies

$$S_m \delta_0 = \delta_m$$

for every $m \in \mathbb{Z}$. Therefore sequences with finite support lie in its algebraic orbit hull and are dense in $\ell^2(\mathbb{Z})$.

Proposition 15.1 (Shift seed)**.** *For $n \in \mathbb{N}$, let $G(n)$ mean that some finite seed set with n elements has dense hull under the declared family $\{S_m : m \in \mathbb{Z}\}$. Then*

$$1 = \min\{n \in \mathbb{N} : G(n)\}.$$

Equivalently, one seed suffices and no empty seed family generates densely.

Proof. The orbit of δ_0 contains every standard basis vector. Their finite linear span is dense, so $G(1)$ holds. The hull of the empty seed set is zero, while $\ell^2(\mathbb{Z}; \mathbb{F})$ is nonzero, so $G(0)$ fails. Therefore 1 is the least admissible finite cardinality. □

For $N \geq 1$, define residue projectors

$$(P_{N,j}x)[n] = \begin{cases} x[n], & n \equiv j \pmod{N}, \\ 0, & \text{otherwise.} \end{cases}$$

They form an orthogonal packet system and satisfy

$$S_1 P_{N,j} = P_{N,j+1} S_1,$$

with indices modulo N. The shift is therefore a cyclic transfer between residue packets.

The seed claim concerns density, rather than equality with the algebraic hull. Finite linear combinations of shifted impulses give precisely the sequences with finite support. Taking their closure gives the whole Hilbert space. The packet decomposition and the choice of completion answer different questions, and both must be specified for this realization.

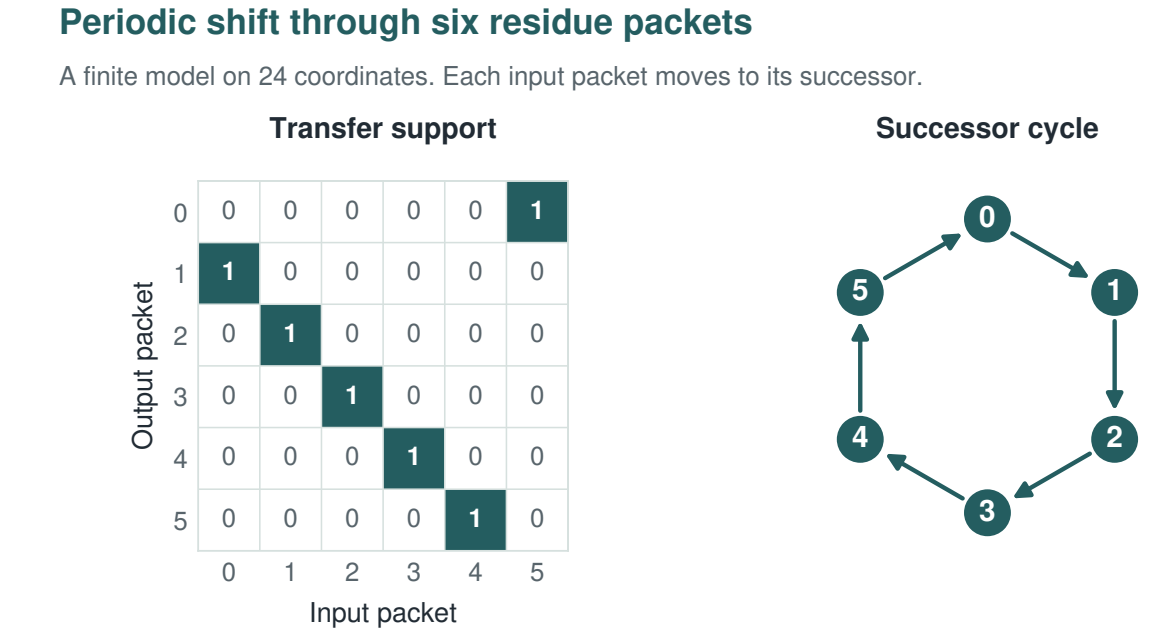

Figure 7. Support among residue packets in the periodic shift model on 24 coordinates with six packets. Each input residue transfers into the next output residue. The theorem for the infinite bilateral shift is established separately in the text.

Boundary 15.2. This section uses residue packets only to demonstrate the foundational transfer algebra. Nested refinement and structures for filter banks require additional definitions and are outside Chapter I.

16 Worked matrix models

16.1 The full matrix algebra

Let $X = \Bbbk^n$ and let $\mathcal{A} = M_n(\Bbbk) = \mathrm{End}_{\Bbbk}(X)$, with the full matrix algebra declared before a seed or target is chosen. By corollary 5.8, every nonzero seed is cyclic. This is the maximal linear grammar on X. It does not give a compression result. Under a smaller declared operator algebra, the same vector need not be cyclic.

16.2 Companion operators and repeated blocks

For one operator T, theorem 6.2 turns verified primary data into an exact certificate for the minimum number of seeds. The numerical companion compares:

(a) a nilpotent companion operator with one Jordan chain, for which the Krylov rank is $1, 2, \dots, n$.

(b) two equal Jordan blocks, for which one diagonal seed produces a chain only as long as one block and then stalls.

The observed stall is not numerical failure. The associated scalar quotient of dimension two certifies the lower bound in theorem 6.2. Identifying that quotient with the space that measures geometric multiplicity is the classical Jordan input stated above.

17 Worked graph model: adjacency algebras

Let G be a nonempty finite graph with adjacency matrix A_G, and regard $\Bbbk^{V(G)}$ as a module over $\Bbbk[A_G]$. The general result applies directly to a spectral certificate. For a symmetric real adjacency matrix, the classical spectral theorem supplies such data.

Within one eigenspace, every polynomial in the adjacency operator acts by a scalar. A seed therefore supplies at most one vector direction in that eigenspace. Distinct eigenvalues can be separated by projector polynomials, so the same seed may supply one direction to each of several eigenspaces. With a complete eigenbasis, the largest eigenspace determines how many seeds are needed, rather than the number of distinct eigenvalues.

Corollary 17.1 (Certified graph seed number)**.** *Let $\Bbbk$ be a field and let Λ be a nonempty finite set. Suppose there are pairwise distinct scalars $a_\lambda \in \Bbbk$, multiplicities $m_\lambda \in \mathbb{N}$, and an eigenbasis*

$$\{b_{\lambda,j} : \lambda \in \Lambda,\ 1 \le j \le m_\lambda\}$$

of $\Bbbk^{V(G)}$ satisfying

$$A_G b_{\lambda,j} = a_\lambda b_{\lambda,j}.$$

If $m_\lambda \le R$ for all λ and $m_{\lambda_*} = R$ for some λ_*, then R is the least natural number of adjacency seeds:

$$R = \min\left\{ r \in \mathbb{N} : \begin{array}{l} \text{there exist } s_1, \dots, s_r \text{ with} \\ \Bbbk^{V(G)} = \mathrm{span}_{\Bbbk}\{p(A_G)s_j : p \in \Bbbk[t],\ 1 \le j \le r\} \end{array} \right\}.$$

Proof. The distinct eigenvalue labels give Lagrange polynomials that project onto the individual eigenspace packets. Padding one basis vector from every packet into each of R seeds gives the upper

bound. Projection to the m_λ eigenspace coordinates is a surjective scalar quotient, so any generating family has at least m_λ members for every λ. The label λ_* gives the matching lower bound R. □

Boundary 17.2 (Input from spectral classification). For a finite undirected graph over $\mathbb{C}$, the spectral theorem for real symmetric matrices classically supplies a certificate of the displayed kind, and the numbers m_λ are the usual eigenvalue multiplicities. See [2]. The formal declaration verifies the formula for the number of seeds from the supplied eigenbasis and distinct eigenvalue labels. It does not derive diagonalizability from symmetry or implement an eigensolver.

17.1 Path graphs

For every field $\Bbbk$ and every $n \geq 1$, an endpoint of P_n is a cyclic vector for the adjacency operator. Consequently one is the least finite number of adjacency seeds:

$$1 = \min\left\{r \in \mathbb{N} : \exists s_1, \dots, s_r, \quad \Bbbk^n = \operatorname{span}_{\Bbbk}\{p(A_{P_n})s_j : p \in \Bbbk[t],\ 1 \leq j \leq r\}\right\}.$$

Over $\mathbb{C}$, the familiar spectral description has the distinct eigenvalues

$$\lambda_k = 2\cos\frac{k\pi}{n+1}, \qquad 1 \leq k \leq n,$$

and the normalized eigenvectors have endpoint coordinate proportional to

$$\sin\frac{k\pi}{n+1} \neq 0.$$

There is also a combinatorial proof valid over every field. Let

$$K_n = [e_1, Ae_1, \dots, A^{n-1}e_1].$$

Its (i, j) entry counts walks of length $j-1$ from the first vertex to vertex i. This entry is zero when $i > j$, while the diagonal entry is one because there is a unique shortest walk of length $i-1$ from vertex 1 to vertex i. Hence K_n is upper triangular with unit diagonal, so

$$\det K_n = 1 \qquad (n \geq 1).$$

Thus the endpoint is cyclic for every path size, not merely for the tested range.

17.2 Cycle graphs

Two adjacent vertex vectors generate the adjacency module of every simple cycle. Over $\mathbb{C}$, a Fourier quotient built from a primitive root of unity supplies a matching scalar obstruction of dimension two. Hence, for every $n \geq 3$, two is the least finite number of adjacency seeds:

$$2 = \min\left\{r \in \mathbb{N} : \exists s_1, \dots, s_r, \quad \mathbb{C}^n = \operatorname{span}_{\mathbb{C}}\{p(A_{C_n})s_j : p \in \mathbb{C}[t],\ 1 \leq j \leq r\}\right\}.$$

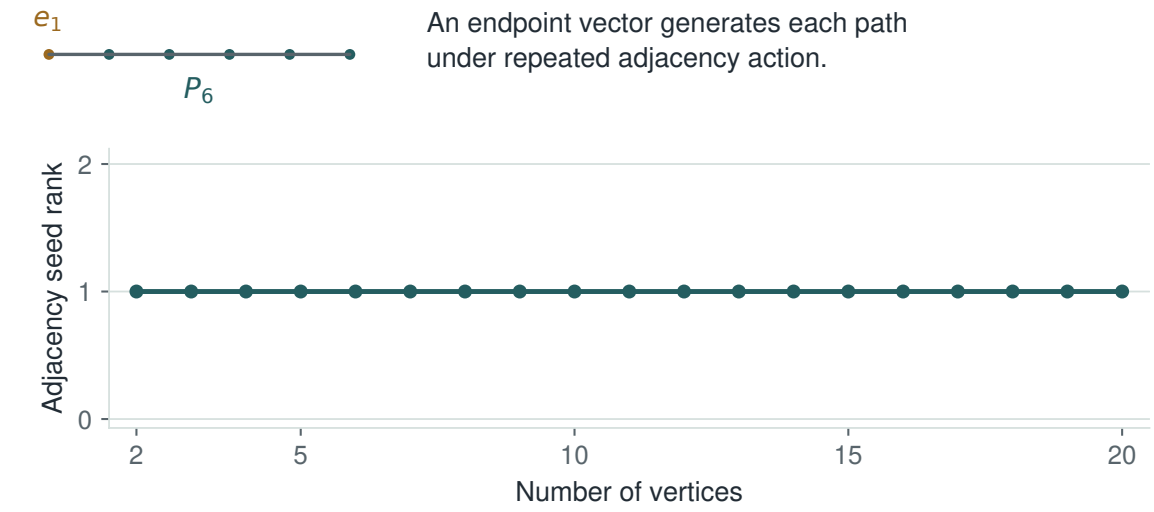

Figure 8. The endpoint Krylov certificate gives every nonempty path one adjacency seed.

To see the upper bound directly, index the vertices modulo n. The identity $Ae_j = e_{j-1} + e_{j+1}$ recovers successive vertex vectors from e_0 and e_1, over any field. For the lower bound over $\mathbb{C}$, let ζ be a primitive nth root of unity and define

$$q(x) = \left(\sum_{j=0}^{n-1} \zeta^j x_j, \sum_{j=0}^{n-1} \zeta^{-j} x_j \right).$$

Then $q(Ax) = (\zeta + \zeta^{-1}) q(x)$. The images of e_0 and e_1 are $(1, 1)$ and (ζ, ζ^{-1}), which are independent because $\zeta \neq \zeta^{-1}$ for $n \geq 3$. Thus q is a scalar quotient of dimension two, and proposition 4.13 gives the matching lower bound.

The usual spectral description writes the eigenvalues as

$$\lambda_k = 2 \cos \frac{2\pi k}{n}, \qquad 0 \leq k < n.$$

The values for k and $n - k$ coincide. Apart from the simple characters at $k = 0$ and, for even n, $k = n/2$, the remaining Fourier characters occur in pairs. Therefore the maximum eigenspace multiplicity is two, although some eigenspaces have multiplicity one, and the certified minimum above is two.

The path and cycle examples use nearly identical local operators. Their minimum finite seed numbers differ because the path has an endpoint Krylov basis, whereas the cycle has a Fourier quotient obstruction of dimension two.

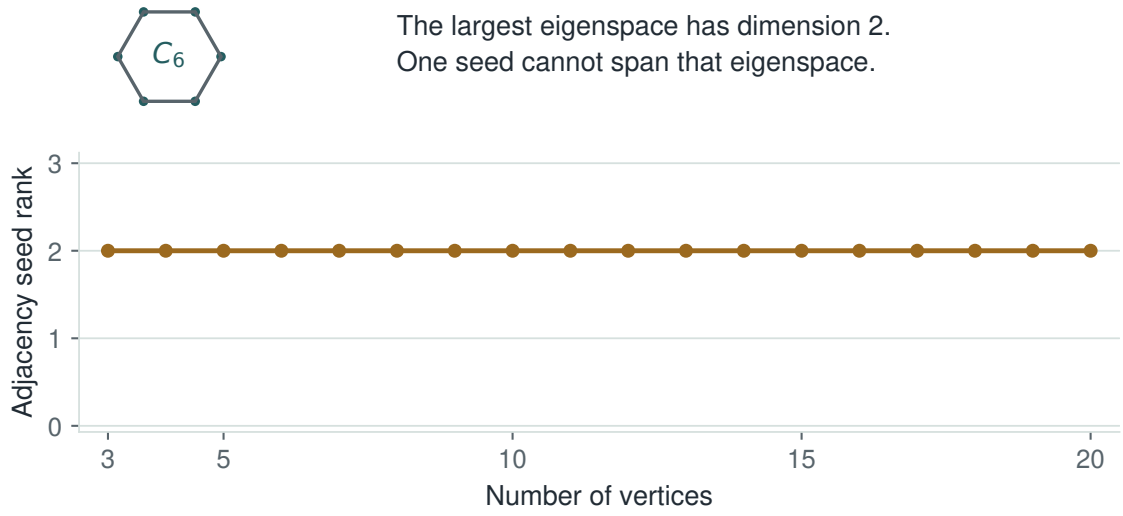

Figure 9. Cycle graphs have maximum eigenspace multiplicity two for the adjacency operator and therefore require two adjacency seeds, although one or two exceptional eigenspaces are simple.

18 The common operator language

The preceding examples can be written without changing the foundational notation.

Table 3. Foundational realizations of the common operator language.

Realization	Seed	Operator grammar	Packets	Completion or quotient
Coordinate ring	1	M_x, M_y	even/odd y degree	quotient by $y^2 - x^3 + x$
Shift system	δ_0	$(S_m)_{m\in\mathbb{Z}}$	residue classes of n	ℓ^2 closure
Full matrix module	$s \neq 0$	$M_n(\Bbbk)$	chosen idempotents	finite dimensional
Single operator	$s_1, \dots, s_r$	$\Bbbk[T]$	primary or spectral	finite dimensional
Graph adjacency	vertex seeds	$\Bbbk[A_G]$	eigenspaces	finite dimensional
Typed grammar	vertex seeds	path algebra $\Bbbk Q/I$	vertex idempotents	relation quotient

For a finite ordered seed family $S = (s_1, \dots, s_r)$, let $\varepsilon_S : \mathcal{A}^{\oplus r} \to X$ be the seed evaluation map of definition 3.1. Its kernel is the relation module. The free module modulo that kernel presents the generated hull by theorem 3.2. The invariant content is:

$$
\begin{aligned}
&\text{generated hull: } \operatorname{Hull}_{\mathcal{A}}(S),\\
&\text{seed complexity: } \operatorname{srank}_{\mathcal{A}}(X),\\
&\text{packet coordinates: } x \leftrightarrow (P_\alpha x)_\alpha,\\
&\text{operator coordinates: } T \leftrightarrow (P_\beta T P_\alpha)_{\beta,\alpha},\\
&\text{relation module: } N_S := \operatorname{Ker} \varepsilon_S \le \mathcal{A}^{\oplus r},\\
&\text{free presentation: } \mathcal{A}^{\oplus r}/N_S \cong \operatorname{Hull}_{\mathcal{A}}(S),\\
&\text{coordinate invariance: } P_\alpha \mapsto U P_\alpha U^{-1},\\
&\text{realization: } \Phi A = \varphi(A)\Phi.
\end{aligned}
$$

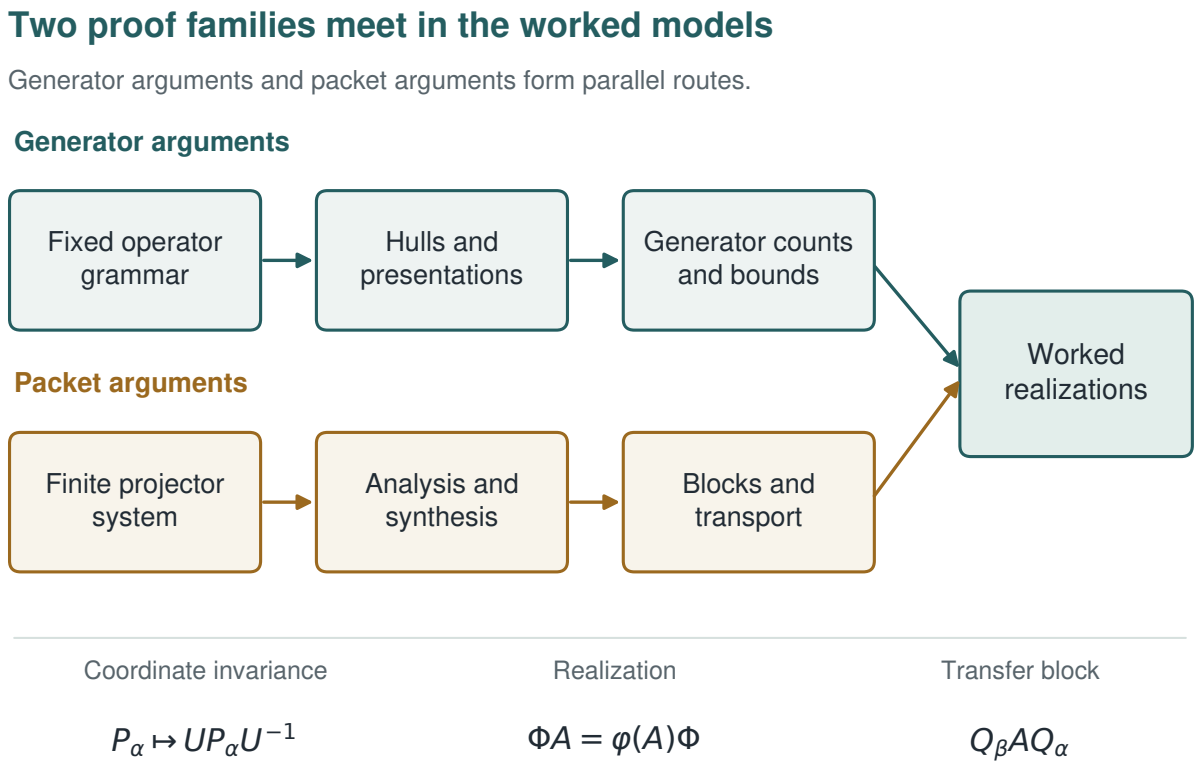

Figure 10. Structural overview of the two proof families. The generator and packet arguments meet in the worked realizations. This diagram is not an exhaustive graph of Lean declaration dependencies.

19 Computational certificates

The accompanying Python package is not used as a substitute for proof. It provides exact symbolic checks and finite numerical regression tests for formulas already proved. The computed ranges and random seeds are recorded explicitly. These checks do not extend a theorem beyond its hypotheses or certify an unrestricted numerical implementation. The journal companion also tests integer counts beyond the precision of floating point arithmetic and rejects the unsupported spectral shortcut for complex symmetric matrices.

19.1 Test suite

The test suite checks:

(i) projector idempotence, annihilation, and completeness.

(ii) exact vector analysis and synthesis.

(iii) exact operator reconstruction from all transfer blocks.

(iv) coordinate transport under a dense random similarity transform.

(v) cyclicity of a companion operator.

(vi) the obstruction that requires two seeds for repeated Jordan blocks.

(vii) the semisimple multiplicity formula in representative cases.

(viii) full orbit dimension for two representative nonzero seeds under the full matrix algebra.

(ix) exact reduction and packet multiplication in the elliptic coordinate ring.

(x) seed ranks of path and cycle adjacency modules over the reported finite ranges.

(xi) the cyclic residue transfer pattern of a finite shift.

19.2 Recorded results

The finite shift pattern recovered by the experiment is

$$\begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix},$$

which is the exact packet adjacency of a cyclic transfer among four phases.

19.3 Algorithms

The following finite constructions state mathematical specifications for the companion. Their Lean counterparts and exact scope are listed in the separate guide. They do not assert code extraction or a particular backend's performance.

Table 4. Representative finite checks recorded for the worked models. The computational companion distinguishes these records from its separately verified runs.

Quantity	Result
Projector idempotence residual	0
Projector annihilation residual	0
Projector completeness residual	0
Operator reconstruction residual	0
Residual for transported projectors, maximum	1.85×10^{-15}
Companion seed rank	1
Two equal Jordan blocks, seed rank	2
$M_3(\mathbb{C})$ acting on seven copies, seed rank	3
Sampled path graph seed ranks, $2 \le n \le 12$	1
Sampled cycle graph seed ranks, $3 \le n \le 12$	2
Full $M_4(\mathbb{R})$ orbit dimensions for two sampled nonzero seeds	$4, 4$
Automated tests	$33/33$ passed

Construction 19.1 (Closure specification for the orbit hull)**.** Let V have finite dimension, let $(O_i)_{i\in I}$ be a finite operator family, and let $S \subseteq V$. Define

$$W_0 = \operatorname{span}_{\Bbbk} S, \qquad W_{n+1} = W_n + \sum_{i\in I} O_i(W_n).$$

Then there is an $n \in \mathbb{N}$ such that

$$W_{n+1} = W_n \qquad \text{and} \qquad W_n = \operatorname{Hull}_{(O_i)}(S),$$

where the right side is the least subspace containing S and invariant under every O_i. Thus the ascending subspace iteration terminates and its stable value is exactly the finite operator hull.

Each strict enlargement increases dimension, so finite dimension prevents the iteration from continuing indefinitely. Equality at one step means that applying any declared operator keeps every vector in the current subspace. The stable subspace is therefore invariant, while every earlier step belongs to any invariant subspace that contains the seeds.

Construction 19.2 (Table specification for transfer blocks)**.** Given finite projector systems $(P_i)_{i\in I}$ and $(Q_j)_{j\in J}$ and a linear map T, form the table

$$B_{ji} = Q_j T P_i.$$

Its assembly reconstructs the input map exactly,

$$\sum_{j\in J}\sum_{i\in I} B_{ji} = T,$$

and its reported support relation is exactly $\{(i,j) : B_{ji} \neq 0\}$. The latter equality is the specification of the transfer graph output. It does not claim that Lean extracts a routine that decides the edge list for every coefficient field.

Construction 19.3 (Exact graph seed rank from a certificate)**.** For a finite square matrix A over a field K, define the noncomputable exact spectral quantity

$$r_{\mathrm{spec}}(A) = \max_{\mu \in \mathrm{Spec}_K(A)} \dim_K \ker(A - \mu I),$$

with value zero for an empty spectrum. Suppose an exact certificate supplies a finite eigenbasis indexed by labels and multiplicities, the eigenvalue equations, a multiplicity bound attained by one label, projector polynomials that extract the padded eigenbasis generators, coverage of every spectral value by a label, equality of the declared and actual eigenspace dimensions, and membership of the maximizing eigenvalue in the spectrum. Then $r_{\mathrm{spec}}(A)$ is the least natural number of seeds under polynomial orbits for A.

This is a verified certificate checker/specification. It does not construct the eigenbasis, prove that a symmetric matrix is diagonalizable, or implement an exact eigensolver. The companion Python code performs symbolic computations in the reported finite graph range. The path and cycle results for every size are proved separately above.

20 Reading guide: common confusions and diagnostic questions

20.1 Common confusions

Do not conflate	Correct distinction
Grammar with realized algebra	The grammar may contain relations or words that act as zero. Seed rank depends only on the image action.
Seed with basis vector	A seed is a generator under an algebra action. One seed may generate a module with large dimension.
Cyclic vector with eigenvector	A cyclic vector must generate the whole module under operator words. It is usually not an eigenvector.
Packet with orthogonal subspace	A packet is the range of an idempotent in a complete annihilating family. Orthogonality is optional.
Exact reconstruction with good conditioning	Algebraic inverse identities may coexist with large analysis and synthesis norms.
Nonzero transfer edge with surjective transfer	A nonzero block can have small rank. Graph reachability alone does not prove generation.
Seed rank for single packet seeds with unrestricted seed rank	Seeds supported in several packets may meet several source components simultaneously.
Continuous surjection with quotient isomorphism	The target topology must agree with the quotient topology.
Repeated notation with semantic realization	A true realization must preserve a declared collection of operations and identities.

20.2 Diagnostic questions for a new application

Before claiming that a new subject is a realization of Chapter I, answer the following.

1. What is the fixed operator grammar or acting algebra?
2. What is the concrete realization space or module?
3. Which seeds are declared before the target is chosen?
4. Is generation algebraic, topological, probabilistic, or approximate?
5. What are the idempotent packets, and in what sense do they sum to the identity?
6. Are the packets finite, countable unconditional, or merely formal?
7. What are the transfer blocks, and which blocks are known to vanish?
8. Which morphisms preserve the packet system?
9. Which quotient, completion, tensor, or limit operations must be preserved?
10. What exact theorem from Chapter I is being specialized, and what new domain theorem remains to be proved?

20.3 Theorem spine at a glance

free seed presentation	packet idempotents
$\Downarrow$	$\Downarrow$
minimal generator number	exact analysis/synthesis
$\Downarrow$	$\Downarrow$
reduction modulo the Jacobson radical	transfer block algebra
$\Downarrow$	$\Downarrow$
semisimple or primary computation	graphs, quotients, and realization

21 Notation and convention ledger

Address.
An operator word applied to a seed.

Analysis.
The map sending an object to all packet coordinates.

Block support.
The set of packet pairs (β, α) for which $P_\beta T P_\alpha \neq 0$.

Collapsed realization.
The direct sum of all typed vertex spaces.

Condensation graph.
The acyclic graph obtained by collapsing strongly connected components.

Generated hull.
The submodule generated by a seed family, or its declared closure.

Grammar.
A typed quiver and relation ideal describing legal operator words.

Packet.
The range of one idempotent in a complete annihilating family.

Packet pure.
Supported in at most one packet.

Preservation profile.
The operations a realization functor is required to preserve.

Realized algebra.
The image of the grammar algebra in the endomorphism algebra of a realization.

Seed rank.
The smallest cardinality of a generating family. For a finite value, this is the minimum number of seeds.

Source component.
A strongly connected component with no incoming edge in the condensation graph.

Synthesis.
The map adding packet coordinates into the original object.

Transfer block.
The map from one packet space to another obtained by sandwiching an operator between packet projectors.

Transfer graph.
The directed graph formed from nonzero blocks of a declared algebra generating family.

> **How to use the chapter after the first reading**
>
> For a concrete calculation, first reduce the action to the realized algebra. Next compute or bound seed rank using quotients, the module top, or primary decomposition. Then declare the packet system and use exact analysis and synthesis. Finally move all operator equations into transfer blocks, where support, graph, quotient, and functorial constraints become explicit.

23 Conclusions and further use

The results establish the following tools for working with a declared operator action and packet system:

I.1. The two sided annihilator criterion is proved in proposition 3.5.

I.2. Generator detection modulo the Jacobson radical is proved in theorem 5.2.

I.3. The semisimple seed rank formula applies over arbitrary division rings, with the conventions for left and right modules kept explicit in theorem 5.6.

I.4. The single operator formula and its cyclic criteria apply over arbitrary fields in theorem 6.2 and corollary 6.5.

I.5. The countable unconditional packet theorem is proved in theorem 7.16.

I.6. The classification of support compatible with $*$ is proved in corollary 8.14.

I.7. The weighted source component formula gives the packet pure generation requirement under the propagation hypotheses in theorem 9.7.

I.8. Seed system composition, packet exact sequences, quotient block descent, dense realization, quotient completion, and semantic theorem transport are proved in proposition 10.5, theorems 10.6, 10.10, 10.11 and 11.2, and corollary 10.8.

I.9. Exact sequence bounds, monotonicity under enlargement of the acting algebra, coordinate stability, projection onto diagonal blocks, and preorder decomposition are established in theorems 4.6 and 8.15 and propositions 4.3, 7.12 and 8.11.

A Stable statement concordance

These identifiers preserve the expanded foundation's namespace of 108 records. The display numbers refer to Chapter I. The identifiers track mathematical statements, and their count does not measure how many theorems have been verified in Lean. Statements in the worked models retain their source labels and are mapped separately by the Lean guide.

B Visual atlas

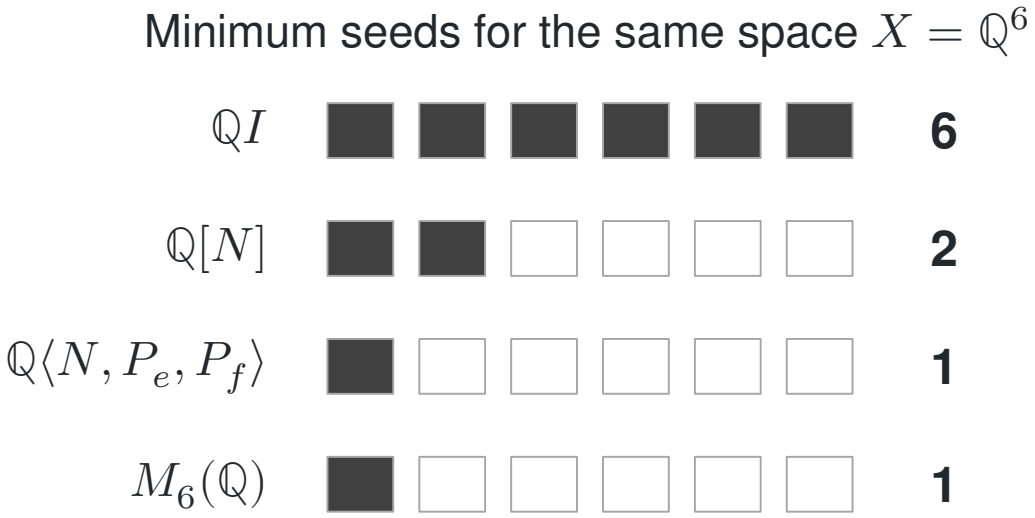
The following twenty-two plates present exact finite models, explanatory diagrams, and one analytic density example. Each plate follows a calculation, identity, or obstruction from the main text. All graphics are generated from mathematical source, and the cross-references refer to the mathematical text.

Plate	Route through the examples
1, 2	Fixed grammars, seed power, and the objects of the calculus.
3, 4	Two linked chains and a quotient proving the minimum seed count.
5, 6	Left ideal relations and typed reachability with a missing direction.
7, 8	Oblique exact coordinates and complete transfer block multiplication.
9, 10	Cancellation along paths and the algebra of admissible zero patterns.
11, 12	Coordinate transport, shared action, and independent control.
13, 14	Semisimple multiplicity budgets and primary extraction polynomials.
15, 16	Path endpoints and the cycle's two dimensional quotient obstruction.
17	A coordinate ring relation as a two packet product rule.
18, 19	Dense shift generation, residue coordinates, and address carry.
20, 21	Exact orbit hull stabilization and all tensor cross terms.
22	The scope of mathematical, formal, and computational evidence.

The seed examples can be read consecutively. The packet and graph plates also provide entry points for readers interested in coordinates or propagation. The displayed matrices are exact. Numerical illustrations in the earlier figures retain their explicitly stated finite ranges. Each diagram is accompanied by the equation or obstruction it represents, so it can be read alongside the relevant proof.

Plate I.1 / CHAPTER I / A VISUAL APPENDIX OF WORKED EXAMPLES

What can one seed actually do?



Main text: definition 4.1, proposition 4.3, and theorem 7.5

A seed does not carry a fixed amount of generative power by itself. The answer depends on the operators that are allowed to act on it. Chapter I makes that dependence part of the mathematical object rather than leaving it implicit.

Use the same space of dimension six throughout the first comparison:

$$X = \mathbb{Q}^6, \qquad N = J_3(0) \oplus J_3(0), \qquad s = e_0 + f_0.$$

Here each $J_3(0)$ moves a basis vector forward along a chain of three basis vectors. The projectors P_e, P_f select the two chains. Their formulas and the proofs of the minimum seed counts appear on Plate I.3 and Plate I.4.

A count of minimum generators, not a timing comparison. The ambient space is unchanged. Enlarging the acting algebra changes what one seed can separate.

Three questions to keep apart

Generation	Can the fixed grammar reach every vector by finite linear combinations of operator words?
Coordinates	Can every vector be split into packets and then reconstructed exactly?
Completion	When finite words do not suffice, does their span become dense in the specified topology?

A packet projector can be available as a way to *inspect* a vector without belonging to the *generation* grammar. Admitting it as a new primitive can lower seed rank. That distinction explains the second and third rows of the figure.

> **Read this as:** The useful question is not "How powerful is this seed?" It is "What does this seed generate under this particular, previously fixed algebra of operators?"

Plate I.2 / ORIENTATION / SYMBOLS WITH JOBS

An atlas of the objects

Main text: definitions 2.1, 2.6, 4.1, 7.1 and 8.1

Most of the chapter can be read by tracking a small collection of objects. The table distinguishes their mathematical roles and names a concrete instance used in this appendix.

Object	What it means	Instance here
X	The ambient vector space or module. It specifies the objects that might be generated.	$\mathbb{Q}^6$ with two chains of length three.
$S \subseteq X$	The selected seed family. A family can contain vectors with components in several packets.	$\{e_0 + f_0\}$ or $\{e_0, f_0\}$.
$\mathcal{A}$	The fixed unital algebra of admissible operators. It is not chosen anew for each target.	$\mathbb{Q}[N]$ versus $\mathbb{Q}\langle N, P_e, P_f\rangle$.
$\mathrm{Hull}_{\mathcal{A}}(S)$	The smallest invariant linear subspace containing the seeds.	$\mathrm{span}\{e_j + f_j : 0 \le j \le 2\}$.
P_α	A finite family of pairwise annihilating idempotents whose sum is I.	Chain projections, oblique projections, or residue masks.
X_α	The packet subspace $P_\alpha X$. It can have dimension greater than one.	One chain of dimension three.
$T_{\beta\alpha}$	The block $P_\beta T P_\alpha$: input α, output β.	A numerical entry when each coordinate packet has dimension one.
F/I_s	A module of operator words modulo relations that kill the seed.	A quotient of left modules. It need not be a quotient algebra.
U	An invertible change of realization coordinates.	A shear that makes orthogonal packets oblique.
Φ	An intertwiner that need not be invertible.	Projection from two chains to the first chain.
τ	The topology used when taking the closure of an algebraic hull.	The ℓ^2 norm for a bilateral shift.

Read products from right to left

In $P_\beta T P_\alpha x$, first select the input packet, then apply T, then select the output packet. In a matrix, this is why the output label belongs to the row and the input label to the column.

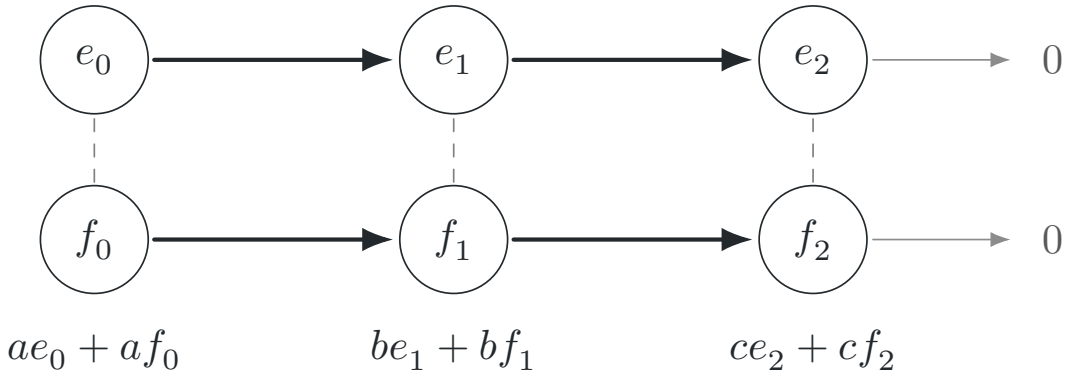
Where to begin

For seed rank, start with Plate I.3. For exact reconstruction, start with Plate I.7. For graphs, use Plate I.15 and Plate I.16. For completion in infinite dimensions, use Plate I.18 and Plate I.19. The scope of the formal proofs is collected on Plate I.22.

Plate I.3 / MODEL A / AN OPERATOR IN SIX DIMENSIONS

Two chains can stay linked

Main text: theorem 6.2. Matrices over $\mathbb{Q}$



Use the ordered basis $(e_0, e_1, e_2, f_0, f_1, f_2)$. Define

$$Ne_0 = e_1, \quad Ne_1 = e_2, \quad Ne_2 = 0, \qquad Nf_0 = f_1, \quad Nf_1 = f_2, \quad Nf_2 = 0.$$

Starting with $s = e_0 + f_0$, the two chains advance together:

$$s = e_0 + f_0, \qquad Ns = e_1 + f_1, \qquad N^2 s = e_2 + f_2, \qquad N^3 s = 0.$$

$$Ne_j = e_{j+1}, \qquad Nf_j = f_{j+1} \quad (j = 0, 1)$$

The vertical dotted pairings record equal coefficients, not an additional allowed operator. Every polynomial in N uses the same coefficients on both chains.

Since $N^3 = 0$, every polynomial orbit vector has the form

$$p(N)s = a(e_0 + f_0) + b(e_1 + f_1) + c(e_2 + f_2).$$

The generated hull therefore has dimension three, even though the seed has a nonzero component in each packet of dimension three. The Krylov ranks are $1, 2, 3, 3, 3, 3$.

What changes when a projector becomes admissible?

Let P_e keep the coordinates along the e chain and P_f those along the f chain. If these are merely measurement maps, the preceding hull is unchanged. If they become allowed generators, then

$$P_e s = e_0, \qquad P_f s = f_0,$$

and powers of N now recover all six basis vectors. The same seed becomes cyclic for the larger algebra $\mathbb{Q}\langle N, P_e, P_f\rangle$.

> **Read this as:** Nonzero components in every packet are not enough. One must also be able to separate the independent directions inside and across those packets using the allowed operations.

Plate I.4 / MODEL A / A CERTIFICATE FOR THE LOWER BOUND

A quotient proves two seeds are necessary

Main text: proposition 4.13 and theorem 6.2

The failure of the particular seed on Plate I.3 does not prove that *every* single seed fails. A certificate for the lower bound does.

Define a surjective linear map

$$q : X \longrightarrow \mathbb{Q}^2, \qquad q\Big(\sum a_j e_j + \sum b_j f_j\Big) = (a_0, b_0).$$

The quotient keeps only the two chain heads

e_0	e_1	e_2	f_0	f_1	f_2
1	0	0	0	0	0
0	0	0	1	0	0

$$q(a_0, a_1, a_2, b_0, b_1, b_2) = (a_0, b_0)$$

An actual 2×6 quotient matrix. It forgets the advanced positions in both chains and retains two independent head coordinates.

Because $qN = 0$, one has, for every polynomial p,

$$q(p(N)x) = p(0)q(x).$$

Thus every operator acts as a *scalar* on the quotient. The image of the orbit of one seed stays on one line in $\mathbb{Q}^2$. It cannot span this quotient of dimension two.

Lower and upper bounds meet

If r seeds generated X, their images would generate the quotient. Since scalar multiplication cannot create a new independent direction, $r \geq 2$. Conversely, the two seeds e_0, f_0 generate their respective chains, so

$$\boxed{\operatorname{srank}_{\mathbb{Q}[N]}(X) = 2.}$$

This proof uses the displayed operator and quotient. It does not ask a computer to search every possible seed, and it does not need an existence theorem for Jordan form.

A general pattern worth recognizing

A surjective intertwiner $q : X \twoheadrightarrow Y$ turns any generating family of X into a generating family of Y. Therefore a quotient on which the grammar loses mixing power can certify a lower bound in the original, much larger space.

> **Read this as:** To rule out one seed, find a quotient in which its entire orbit is forced onto one line while the quotient still has at least two independent directions.

Plate I.5 / PRESENTATIONS / WHY A LEFT IDEAL APPEARS

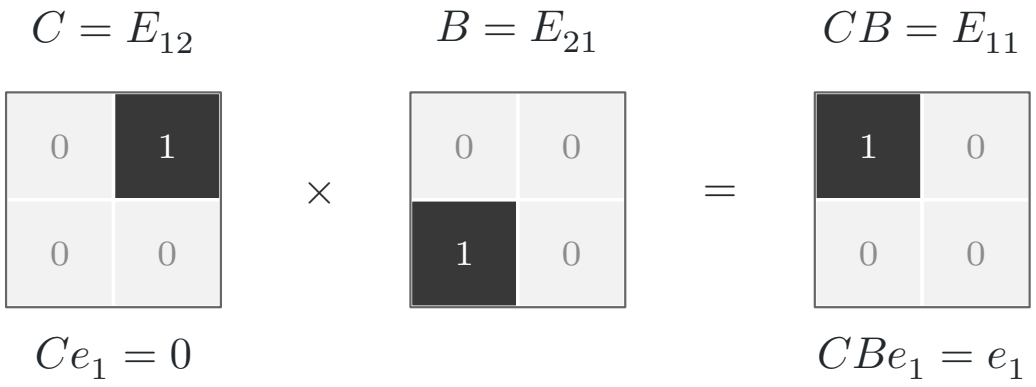
Relations identify words, not just outputs

Main text: theorem 3.2, corollary 3.4, and proposition 3.5

Let $F = \Bbbk\langle z_1, \dots, z_r\rangle$ be the algebra of noncommuting operator words. Evaluation at a fixed seed is

$$\Phi_s : F \to X, \qquad f \mapsto f(T_1, \dots, T_r)s.$$

Two words represent the same generated vector exactly when their difference lies in $I_s = \operatorname{Ker} \Phi_s$. Consequently



$$F/I_s \cong \operatorname{Hull}_F(s)$$

as *left modules*. The relation $f(T)s = 0$ implies $g(T)f(T)s = 0$ for every word g, which explains closure under multiplication on the left.

The distinction is visible in two dimensions

Use $X = \mathbb{Q}^2$, seed $e_1 = (1, 0)^{\mathsf{T}}$, and the full matrix algebra. Its seed annihilator is the set of matrices with zero first column:

$$I_{e_1} = \left\{ \begin{pmatrix} 0 & a \\ 0 & b \end{pmatrix} : a, b \in \mathbb{Q} \right\}.$$

The relation $Ce_1 = 0$ is destroyed by multiplying C on the right by B. The product CB sends the seed to itself.

For arbitrary D, $(DC)e_1 = D(Ce_1) = 0$. But $(CB)e_1 = e_1 \neq 0$. Thus I_{e_1} is a left ideal, but it is not stable under multiplication on the right. The quotient retains the action on generated vectors. Calling it a ring would lose the distinction that makes the presentation correct.

Several seeds give a module of relations

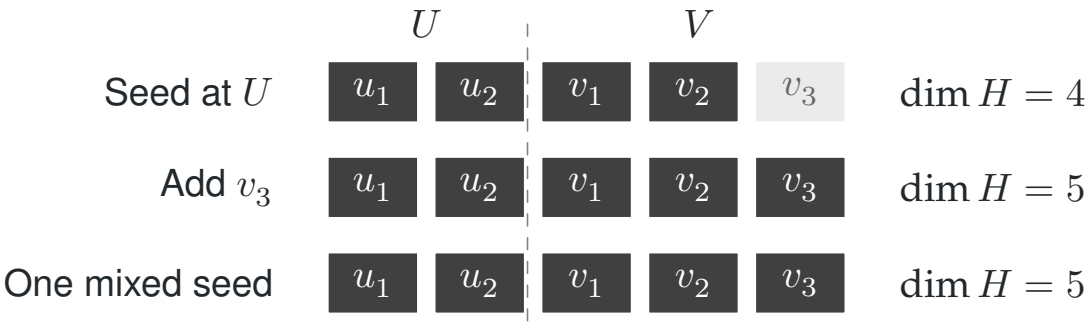
For $(s_1, \dots, s_m)$, evaluation is $(f_1, \dots, f_m) \mapsto \sum_j f_j(T)s_j$. Its kernel is a submodule of F^m and can include relations *between* seeds, not only relations annihilating each seed separately.

> **Read this as:** A presentation says which operator expressions are identified in a particular realization. A seed annihilator is not automatically an algebra relation ideal.

Plate I.6 / TYPED MODEL / $U = \mathbb{Q}^2$ AND $V = \mathbb{Q}^3$

A reached type can still hide a direction

Main text: proposition 13.1 and definition 9.4



The chapter's typed model has a rotation $R : U \to U$, an inclusion $A : U \to V$, and a retraction $B : V \to U$:

$$R = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \qquad A = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad B = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

The typed relation is $BA = I_U$. In the opposite order,

$$AB = \operatorname{diag}(1, 1, 0) \neq I_V.$$

The missing direction is $\operatorname{Ker} B = \mathbb{Q}v_3$, not an entirely missing vertex.

Dark slots indicate independent directions in the generated hull. The same two vertex types are present in every row, but their generated subspaces differ.

One seed supported at U

The vectors u_1, Ru_1 span U. Their images under A span $\mathbb{Q}v_1 + \mathbb{Q}v_2$. Every path from U to V ends with A, so it cannot supply v_3. The hull has dimension four. Adding the pure seed v_3 gives all five dimensions.

Why this does not prove an unrestricted minimum of two

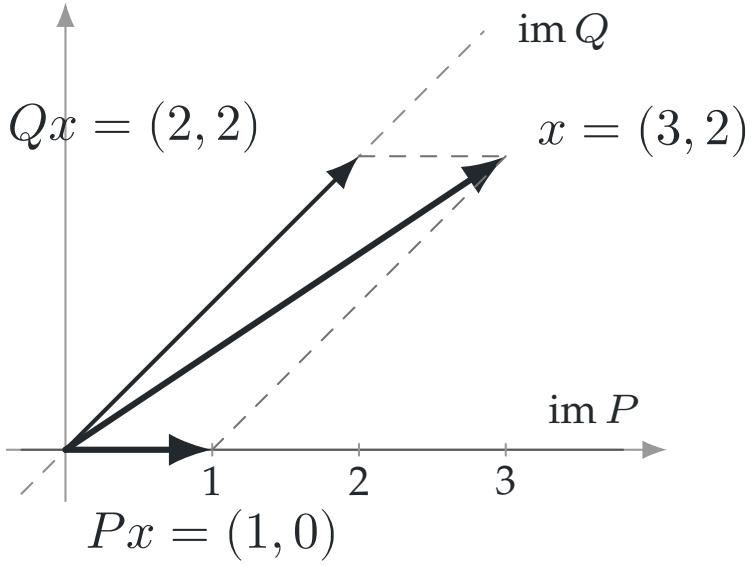
The bound path algebra includes the vertex idempotents P_U, P_V. A mixed seed

$$s = u_1 + v_3 \in U \oplus V$$

satisfies $P_U s = u_1$ and $P_V s = v_3$. It therefore generates the entire representation by itself. The chapter proves that no seed *supported at* U is enough and that two displayed pure seeds suffice. It does not claim that two arbitrary mixed seeds are necessary.

> **Read this as:** Keep three notions separate: reaching a vertex, filling its entire vector space, and minimizing seeds when each seed must lie in a single packet. They answer different questions.

Plate I.7 / PACKET COORDINATES / AN OBLIQUE SPLITTING



Exact does not mean orthogonal

Main text: theorem 7.5 and corollary 8.5

In $\mathbb{R}^2$, take

$$P = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}, \qquad Q = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}.$$

These maps satisfy $P^2 = P$, $Q^2 = Q$, $PQ = QP = 0$ and $P + Q = I$. Their images are the horizontal line and the diagonal line, respectively. They are not self-adjoint in the usual Euclidean inner product.

Actual Euclidean vector geometry for $x = (3, 2)$. The parallelogram reconstructs x from $Px = (1, 0)$ and $Qx = (2, 2)$. Neither component is an orthogonal projection of x.

Analysis records (Px, Qx) and synthesis adds the two vectors. For a packet tuple $(u, v) \in \operatorname{im} P \times \operatorname{im} Q$,

$$P(u + v) = u, \qquad Q(u + v) = v.$$

Both inverse identities follow from annihilation and completeness, without any angle condition.

What the algebra does not preserve

For the displayed x,

$$\|x\|^2 = 13, \qquad \|Px\|^2 + \|Qx\|^2 = 1 + 8 = 9.$$

There is no Parseval identity here. The cross term is nonzero because the packet directions are not perpendicular. Likewise, the simple formula for reversing adjoints of packet blocks requires self-adjoint projectors. It is not justified for this oblique pair.

> **Read this as:** Exact reconstruction is an algebraic inverse statement. Energy preservation and adjoint identities require additional geometric hypotheses.

Plate I.8 / OPERATOR COORDINATES / MULTIPLICATION AS A SUM

A transfer block has an input and an output

Main text: theorems 8.2 and 8.3 and corollary 8.4

Use the three coordinate packets of dimension one in $\mathbb{Q}^3$. The block $T_{ij} = P_i T P_j$ sends input packet j into output packet i. For this example, its nonzero scalar is the (i, j) matrix entry.

T

1	2	0
0	1	3
4	0	1

input column; output row

$T \cdot T$

T^2

1	4	6
12	1	6
8	8	1

sum over intermediate packets

All displayed entries are exact integers. The square is computed from the operator, not from a thresholded graph or a matrix of block norms.

Reconstruction retains every block

The identity $P_1 + P_2 + P_3 = I$ gives

$$T = \sum_{i,j=1}^{3} P_i T P_j.$$

Selecting only the diagonal would change the operator. The entries $2, 3, 4$ carry transfers between different packets.

Composition sums over intermediate packets

The $(1, 2)$ entry of the square has two contributing routes:

$$(T^2)_{12} = T_{11}T_{12} + T_{12}T_{22} + T_{13}T_{32} = 1 \cdot 2 + 2 \cdot 1 + 0 = 4.$$

For input 3 and output 1, only the route through packet 2 survives:

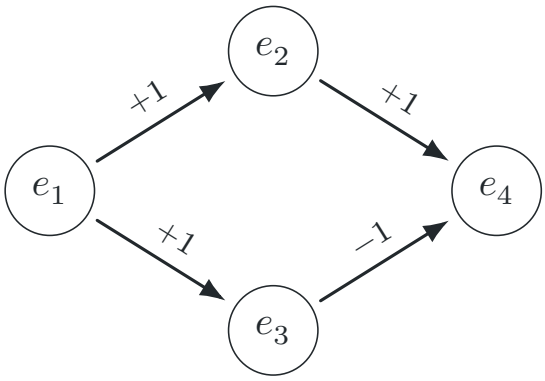
$$(T^2)_{13} = T_{12}T_{23} = 2 \cdot 3 = 6.$$

For packets of higher dimension, the same law uses actual linear maps as entries. The order of their composition still matters.

> **Read this as:** An edge says a block is nonzero. The block itself carries the coefficient, sign, rank and action. A transfer graph alone does not retain those data.

Plate I.9 / REACHABILITY / NECESSARY IS NOT SUFFICIENT

Two visible routes can cancel exactly



Main text: corollary 8.4 and proposition 9.3

Let a single operator D on $\mathbb{Q}^4$ act by

$$De_1 = e_2 + e_3, \qquad De_2 = e_4, \qquad De_3 = -e_4, \qquad De_4 = 0.$$

Every vertex of its transfer graph for the coordinate packets is reachable from vertex 1. Nevertheless,

$$D^2 e_1 = e_4 - e_4 = 0, \qquad D^2 = 0.$$

$$(D^2)_{41} = 1 - 1 = 0$$

$$[e_1, De_1, D^2 e_1]$$

1	0	0
0	1	0
0	1	0
0	0	0

$$\text{rank} = 2$$

The diamond is the actual weighted action of D. The two paths of length two exist, but their contributions to the same transfer block sum to zero.

What the seed generates

With the fixed algebra $\mathbb{Q}[D]$ and seed e_1,

$$\text{Hull}_{\mathbb{Q}[D]}(e_1) = \text{span}\{e_1, e_2 + e_3\}.$$

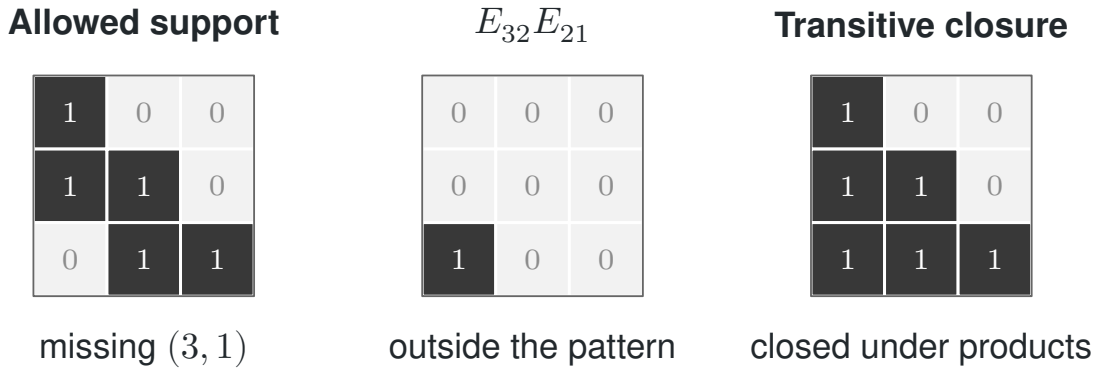
It has dimension two, not four. Both the independent difference $e_2 - e_3$ and the last coordinate e_4 are missing.

Why projecting in the middle changes the experiment

If P_2 becomes an admissible primitive, the word DP_2D satisfies

$$DP_2De_1 = DP_2(e_2 + e_3) = De_2 = e_4.$$

But P_2 was not an allowed generator of the original $\mathbb{Q}[D]$ grammar. Using it to argue that the original seed already reached e_4 would silently enlarge the algebra.



> **Read this as:** Unreachable nonzero packets obstruct generation. Reachability by itself does not prove generation: coefficients can cancel, blocks can have small images, and intermediate projectors may not be admissible.

Plate I.10 / SUPPORT ALGEBRAS / A UNIVERSAL TEST

Which zero patterns survive multiplication?

Main text: theorem 8.13. All packet spaces are nonzero

Suppose every matrix supported in a specified pattern is allowed. Then multiplication can create a new entry whenever two allowed edges compose. Let E_{ij} denote the matrix that sends e_j to e_i and kills the other basis vectors.

Here 1 means "allowed," not that every admissible operator has that numerical value. The middle matrix is an actual product that violates the original pattern.

The first pattern contains the diagonal and permits $1 \to 2$ and $2 \to 3$, but forbids $1 \to 3$. Yet

$$E_{32}E_{21} = E_{31} \neq 0.$$

Both factors obey the pattern and their product does not. Thus the whole supported matrix space is not an algebra.

Reflexivity and transitivity have different jobs

The identity has a nonzero diagonal block on every nonzero packet, so including the identity requires every packet to be related to itself. Multiplicative closure requires every composite pair. Consequently, for arbitrary algebraic block maps on nonzero packet spaces,

unital universal support algebra $\iff$ reflexive, transitive support relation.

The transitive closure in the figure is the lower triangular pattern. It does define a unital algebra.

Why this does not contradict cancellation

On Plate I.9, one particular operator has canceling paths. The support theorem asks whether multiplication works for *every* assignment of allowed block maps. Choosing two suitable maps of rank one removes the possibility of hiding a failed composite behind special cancellation.

> **Read this as:** A zero pattern is a structural rule only when it survives all permitted block assignments. A coincidence in one matrix is not a closure theorem.

Plate I.11 / CONJUGACY / STRUCTURE VERSUS RAW SPARSITY

Move the packets with the coordinates

Main text: theorems 10.1 and 10.4 and corollary 4.5

Start with $T = \mathrm{diag}(1, 2)$ and the two coordinate projections. Apply the invertible shear U. The transformed operator is $T^U = UTU^{-1}$, and the transformed projectors are $Q_i = UP_iU^{-1}$.

T

1	0
0	2

U

1	1
0	1

UTU^{-1}

1	1
0	2

$Q_1 = UP_1U^{-1}$

1	−1
0	0

$Q_2 = UP_2U^{-1}$

0	1
0	1

The transformed operator has a nonzero entry away from the diagonal in the standard basis. Relative to its transported, oblique packets, however, both blocks between distinct packets remain zero.

Indeed,

$$Q_1T^UQ_2 = Q_2T^UQ_1 = 0, \qquad Q_iT^UQ_j = U(P_iTP_j)U^{-1}.$$

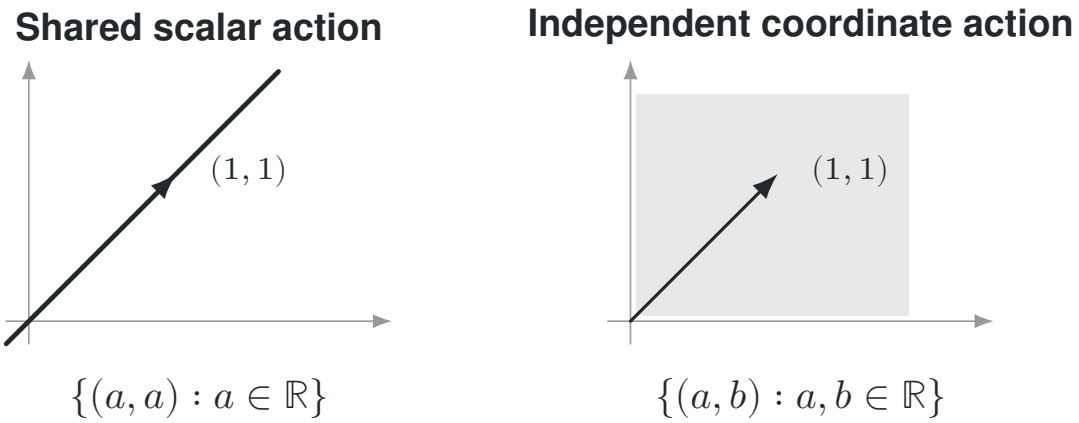
A change in raw matrix sparsity is therefore not necessarily a change in the packet transfer graph. Conjugacy preserves the exact block identities and their zero pattern. A nonunitary shear need not preserve their Euclidean norms.

When the map is not invertible

For an intertwiner $\Phi A = \varphi(A)\Phi$, the hull identity uses the *image algebra*:

$$\Phi(\mathrm{Hull}_{\mathcal{A}}(S)) = \mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi S).$$

Replacing $\varphi(\mathcal{A})$ with a larger target algebra can enlarge the target hull. Seed rank need not be equal relative to that larger algebra. A surjective intertwiner gives the appropriate monotonicity inequality, not automatic equality.



> **Read this as:** Transport the space, operators and packet maps together. The invariant is the collection of commuting algebraic relationships, rather than the appearance of the matrix.

Plate I.12 / DIRECT SUMS / ONE SEED CAN CARRY TWO COMPONENTS

Shared control and independent control differ

Main text: proposition 4.7 and theorem 4.8

Take $X = \Bbbk \oplus \Bbbk$ and $s = (1, 1)$. With one shared scalar acting on both coordinates, every orbit vector is (a, a). With independent scalars, the orbit contains every (a, b).

The geometric picture uses $\Bbbk = \mathbb{R}$. On the right, shading shows a finite window of the whole plane. On the left, only the diagonal line is generated. The algebraic distinction holds over any field.

The corresponding minimum seed numbers are

$$\operatorname{srank}_{\Bbbk I}(\Bbbk^2) = 2, \qquad \operatorname{srank}_{\Bbbk\times\Bbbk}(\Bbbk \oplus \Bbbk) = 1.$$

In the independent case, the algebra contains $(1, 0)$ and $(0, 1)$, which recover the two coordinates of s separately.

This is why the independent formula uses a maximum

For independent actions of $\mathcal{A}$ on X and $\mathcal{B}$ on Y, a common list of seed positions can carry the seeds for both spaces. Pad the shorter list with zeros. Independent operators then select the two components, giving

$$\operatorname{srank}_{\mathcal{A}\times\mathcal{B}}(X \oplus Y) = \max\{\operatorname{srank}_{\mathcal{A}}(X), \operatorname{srank}_{\mathcal{B}}(Y)\}.$$

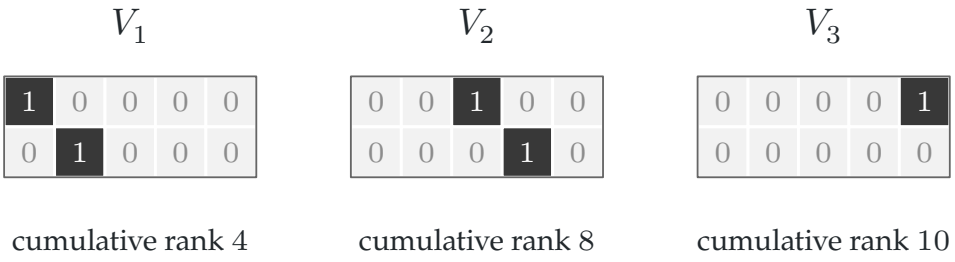
With a shared action, this selection need not be available. The general bound is the sum.

One operator can supply independent control

Over $\mathbb{Q}$, $T = \operatorname{diag}(1, 2)$ has polynomial projectors $2I - T$ and $T - I$. Thus $\mathbb{Q}[T]$ already separates the two eigenspaces. If the eigenvalues coincide, these formulas no longer separate them. Distinct primary labels play the same role on Plate I.14.

> **Read this as:** Counting occupied components is not the same as counting seeds. One mixed seed may generate several components when the algebra can act on them independently.

Plate I.13 / SPLIT SEMISIMPLE MODEL / A CONSTRUCTIVE FORMULA



How much row space can one seed supply?

Main text: theorem 5.6 and corollary 5.7

Let $M_2(\mathbb{Q})$ act on $X = M_{2\times 5}(\mathbb{Q})$ by left multiplication. Think of the five columns as five copies of the same natural module of dimension two. One seed is a 2×5 matrix V.

Every row of AV is a linear combination of the two rows of V. Hence one seed exposes at most two independent directions in the multiplicity space of dimension five. Two seeds expose at most four. At least three are necessary.

Each row is one direction in the five-dimensional multiplicity space.

The three fixed seeds cover multiplicity directions $1, 2$, then $3, 4$, then 5. The exact dimensions of their cumulative matrix orbits are $4, 8, 10$.

An explicit synthesis, not just dimension counting

For

$$W = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 6 & 7 & 8 & 9 & 10 \end{pmatrix},$$

choose A_1 from columns $1, 2$ of W, A_2 from columns $3, 4$, and A_3 with first column equal to column 5 of W and second column zero. Then

$$A_1V_1 + A_2V_2 + A_3V_3 = W.$$

The same construction works for arbitrary entries of W, so the lower bound is attained:

$$\boxed{\operatorname{srank}_{M_2(\mathbb{Q})} M_{2\times 5}(\mathbb{Q}) = \lceil 5/2 \rceil = 3.}$$

Several split simple blocks

If the acting algebra and module are supplied in compatible product coordinates, the row budget is computed separately in each block and the formula for independent actions takes the maximum. For block data $(d, m) = (2, 5)$ and $(3, 4)$, the result is $\max(3, 2) = 3$, not $3 + 2$.

> **Read this as:** The formula measures multiplicity directions per seed. The formal development constructs compatible semisimple decompositions. The split formula uses the displayed algebra and module equivalences.

Plate I.14 / PRIMARY DATA / AN ACTUAL EXTRACTION CERTIFICATE

Distinct labels let one polynomial separate chains

Main text: theorem 6.2 and corollary 6.3

Keep the model in six dimensions, but compare two different operators:

$$N = J \oplus J, \qquad T = J \oplus (2I + J), \qquad J = J_3(0).$$

For the same mixed seed $s = e_0 + f_0$, the Krylov matrices are different:

Equal primary labels

1	0	0	0	0	0
0	1	0	0	0	0
0	0	1	0	0	0
1	0	0	0	0	0
0	1	0	0	0	0
0	0	1	0	0	0

Krylov rank 3

Distinct primary labels

1	0	0	0	0	0
0	1	0	0	0	0
0	0	1	0	0	0
1	2	4	8	16	32
0	1	4	12	32	80
0	0	1	6	24	80

Krylov determinant 512

Exact rational calculations. Changing the primary label from 0 to 2 changes the operator, not merely its coordinates. The determinant on the right is $512 \neq 0$.

The missing separating operation is now a polynomial

Define

$$p_2(t) = \frac{3t^5 - 15t^4 + 20t^3}{16}, \qquad p_0(t) = 1 - p_2(t).$$

These polynomials satisfy

$$p_2 \equiv 0 \pmod{t^3}, \qquad p_2 \equiv 1 \pmod{(t-2)^3}.$$

Consequently $p_0(T) = P_e$ and $p_2(T) = P_f$. Applying them to s extracts both chain heads, after which polynomial powers generate all six directions. Unlike the model on Plate I.3, the separating maps already belong to the polynomial grammar.

> **Read this as:** Repeated labels can lock chains together. Distinct primary labels can admit polynomial extraction. Here the block data and extractor are explicit. No theorem asserting the existence of Jordan form is inferred from this example.

Plate I.15 / GRAPH MODEL / THE PATH CERTIFICATE

Walk counts make an endpoint cyclic

Main text: Worked graph model. Endpoint Krylov proof for every path size

Let A be the adjacency matrix of the path with five vertices. The (i, j) entry of

$$K = [e_1, Ae_1, A^2e_1, A^3e_1, A^4e_1]$$

counts walks of length $j - 1$ from vertex 1 to vertex i.

k	0	1	2	3	4
	1	0	1	0	2
	0	1	0	2	0
	0	0	1	0	3
	0	0	0	1	0
	0	0	0	0	1

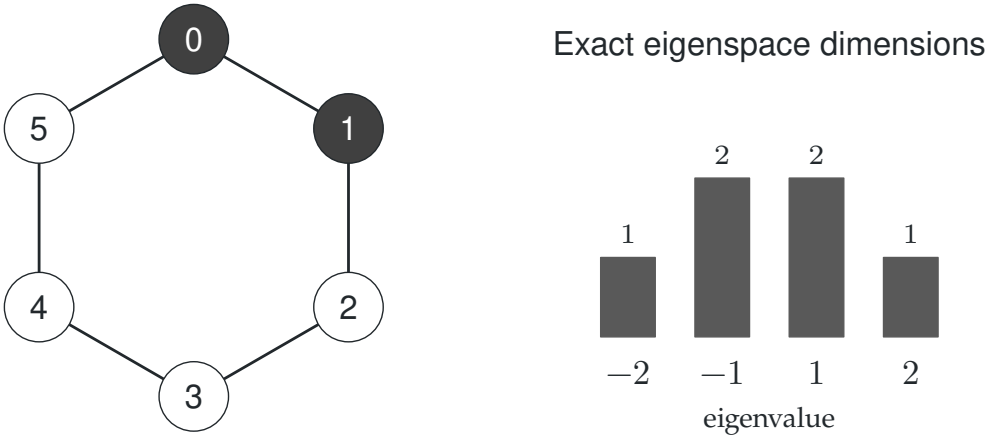
unit diagonal; no entries below it

The entries are walk counts. At each new power, a new furthest vertex appears with coefficient one. The dark graph vertex is the seed.

A walk cannot reach vertex i in fewer than $i - 1$ steps. Therefore entries below the diagonal vanish. There is exactly one walk of length $i-1$ from the first vertex to vertex i: the shortest path. The diagonal entries are all one, so $\det K = 1$.

The same reason works at every size

For a path with any $n \geq 1$, the endpoint Krylov matrix is upper triangular with unit diagonal. This is a combinatorial proof of cyclicity over *every field*. It does not rely on numerical eigenvalues. The appendix checks the finite cases $1 \leq n \leq 12$ as implementation examples, separately from the chapter's proof for every path size.



> **Read this as:** The endpoint distinguishes distances. Each extra operator power reveals one new coordinate before the finite space is exhausted.

Plate I.16 / GRAPH MODEL / A CYCLE WITH SIX VERTICES

Closing a path changes the seed obstruction

Main text: Worked graph model. Proof of the minimum seed count for complex cycles

For the adjacency matrix A of C_6, the distinct eigenvalues are $2, 1, -1, -2$, with multiplicities $1, 2, 2, 1$. A single vertex seed spans only four directions. Two adjacent vertex seeds span all six.

The two dark vertices are the displayed generating pair. The bars show exact eigenspace dimensions, not estimated spectral peaks.

A lower bound without a numerical eigensolver

The two rows of the following matrix are independent and obey $qA = q$:

$$q = \begin{pmatrix} 2 & 1 & -1 & -2 & -1 & 1 \\ 0 & 1 & 1 & 0 & -1 & -1 \end{pmatrix}.$$

Thus $q : \mathbb{Q}^6 \twoheadrightarrow \mathbb{Q}^2$ is a scalar quotient for the eigenvalue 1. Its extension over $\mathbb{C}$ gives the same obstruction of dimension two. The orbit of any single seed projects to a line, so no single seed can generate the full module.

The matching construction

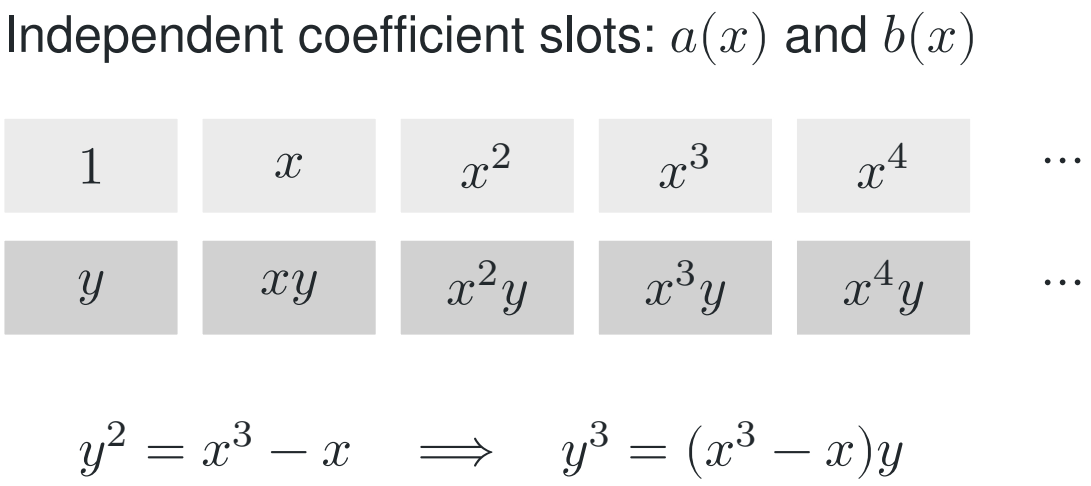
From adjacent vertex vectors e_0, e_1, the identity

$$e_{j+1} = Ae_j - e_{j-1}$$

recovers successive vertices around the cycle. The lower and upper bounds therefore give two seeds for this example. The chapter proves the corresponding minimum for every complex simple cycle of size at least three.

> **Read this as:** Connectedness is not cyclicity for the adjacency grammar. If a directed cyclic shift were allowed instead, one vertex would generate the whole cycle. That would be a different operator algebra.

Plate I.17 / COORDINATE ALGEBRA / NORMAL FORM RATHER THAN A CURVE SKETCH



A relation becomes a packet product rule

Main text: Worked coordinate ring model. Normal form and exact multiplication

Work over $\mathbb{Q}$ in

$$A = \mathbb{Q}[x, y]/(y^2 - x^3 + x).$$

Because the relation is monic of degree two in y, each element has one unique form $a(x) + yb(x)$. The two packet coefficients are polynomials, not scalars.

A finite window of the two infinite coefficient lanes. Higher powers of y are rewritten using the relation rather than discarded. No geometric genus or smoothness claim is encoded by this picture.

Multiplication by y transfers between the lanes

In the ordered coefficient coordinates (a, b),

$$M_y = \begin{pmatrix} 0 & x^3 - x \\ 1 & 0 \end{pmatrix}, \qquad M_y^2 = (x^3 - x)I.$$

The entries denote multiplication maps on $\mathbb{Q}[x]$. For $f = a_0 + ya_1$ and $g = b_0 + yb_1$,

$$fg = (a_0b_0 + (x^3 - x)a_1b_1) + y(a_0b_1 + a_1b_0).$$

In particular,

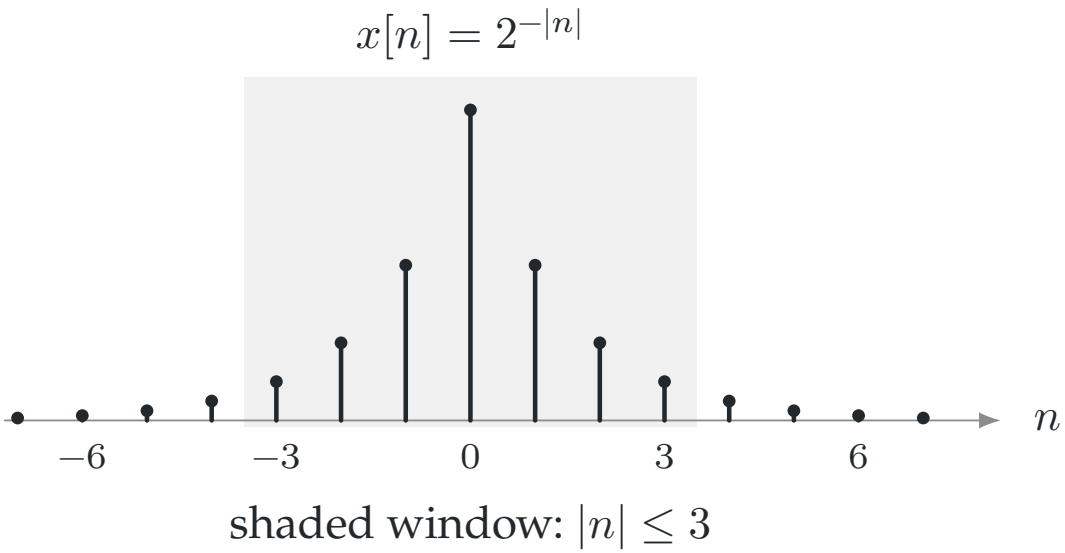
$$(x^2 + y)(x - y) = x + (x - x^2)y.$$

One module seed does not mean one algebra generator

Starting from 1, the fixed multiplication operators M_x, M_y generate every monomial in normal form. Thus the algebra is cyclic as a module over its multiplication algebra. This does not remove either address operator, and does not say that the algebra is generated by one algebra element.

> **Read this as:** The relation controls an exact weighted transfer between coefficient lanes. Packet reconstruction is $a + yb$, while packet multiplication retains the weight $x^3 - x$.

Plate I.18 / INFINITE MODEL / THE BILATERAL SHIFT



Density is not finite generation of each vector

Main text: proposition 15.1 and theorem 3.6

On $\ell^2(\mathbb{Z})$, declare every integer shift

$$(S_m x)[n] = x[n-m].$$

The seed δ_0 generates $\delta_m = S_m \delta_0$. Finite linear combinations give precisely the sequences with finite support. Their norm closure is all of $\ell^2(\mathbb{Z})$.

A finite window of the actual sequence $x[n] = 2^{-|n|}$. Outside every finite window, coefficients remain nonzero. The shaded window illustrates the truncation $x^{(3)}$, not a periodic wraparound.

This x cannot be a finite linear combination of shifted impulses: it has infinite support. But if $x^{(N)}$ agrees with x on $|n| \le N$ and is zero elsewhere, then

$$\left\|x - x^{(N)}\right\|_2^2 = 2 \sum_{n>N} 4^{-n} = \frac{2}{3}\, 4^{-N} \longrightarrow 0.$$

The exact squared errors for $N = 1, 3, 5$ are $1/6$, $1/96$, and $1/1536$. These are identities from a geometric series, not floating residuals.

What the topology contributes

The statement is that *one seed has dense hull*. It is not that every vector is a finite word expression. The completion theorem additionally specifies a normed presentation, a dense linear isometry into a Banach target, and the bounded intertwining needed to extend operators.

> **Read this as:** Completion adds limits in a declared topology. A finite numerical window can illustrate the approximants, but cannot be substituted for the infinite object or its convergence proof.

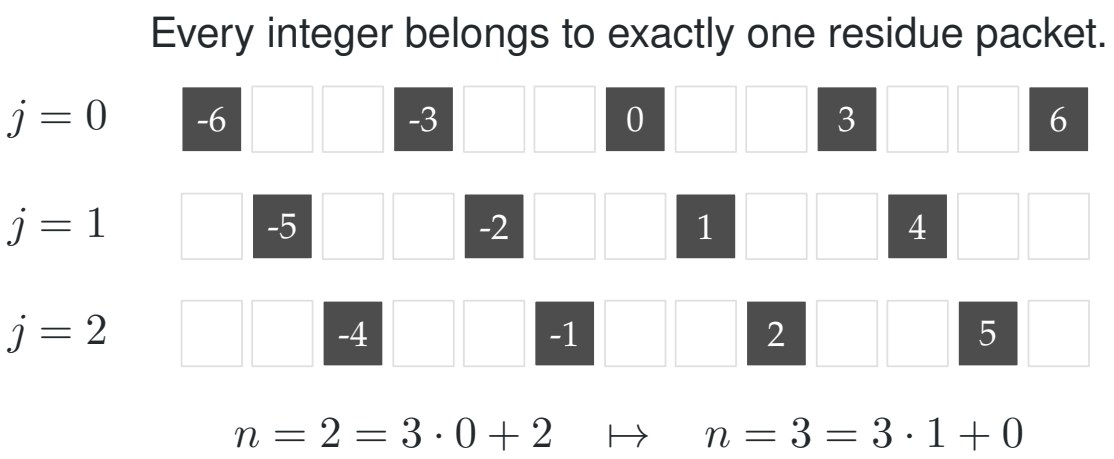


Plate I.19 / INFINITE MODEL / THREE EXACT SUBSEQUENCES

Residue packets retain an address carry

Main text: theorem 7.10. Residue packets

For $j = 0, 1, 2$, let P_j keep the entries with $n \equiv j \pmod 3$. These are bounded orthogonal projectors whose sum is the identity. The packet coordinates can be written as

$$x_j[k] = x[3k + j], \qquad k \in \mathbb{Z}.$$

Each occupied tile represents one integer address in a displayed window. The three rows partition the addresses exactly. Negative indices use the same residue convention.

What one shift does in these coordinates

Let $S = S_1$ and $z = Sx$. Substituting $3k + j$ into the shift definition gives

$$z_1[k] = x_0[k], \qquad z_2[k] = x_1[k], \qquad z_0[k] = x_2[k - 1].$$

The passage from phase 2 to phase 0 carries a shift of the coarse address. If $Lh[k] = h[k - 1]$, the exact packet matrix is

$$S_{\text{packets}} = \begin{pmatrix} 0 & 0 & L \\ I & 0 & 0 \\ 0 & I & 0 \end{pmatrix}.$$

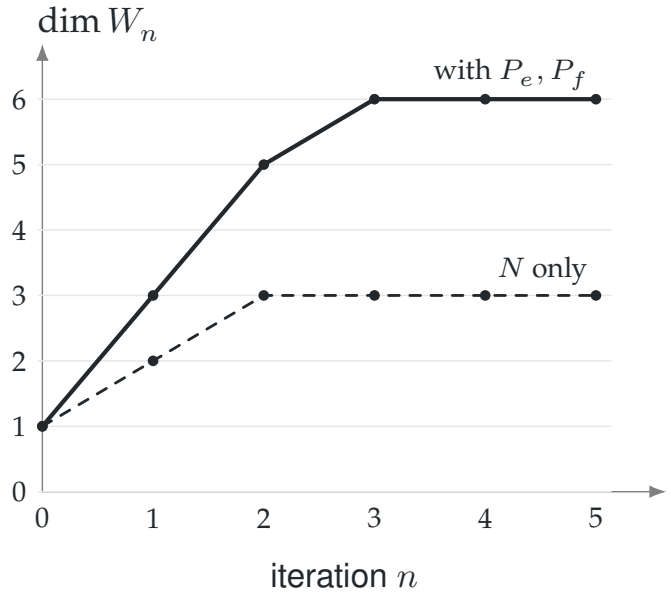
Replacing L by a scalar 1 would preserve the phase graph but would lose the operator's action on the infinite sequences.

Synthesis keeps the positions

To reconstruct x, place $x_j[k]$ at its original address $3k + j$. In the ambient space formulation, this is the finite sum $x = P_0x + P_1x + P_2x$. Boundedness makes the same formulas valid after taking the ℓ^2 completion.

> **Read this as:** A cyclic packet graph is only the routing pattern. The block at the phase boundary still carries an actual shift operator.

Plate I.20 / EXACT COMPUTATION / AN INVARIANCE CERTIFICATE



Stop when the subspace stops growing

Main text: construction 19.1

For a fixed finite operator family (O_i), start from $W_0 = \operatorname{span} S$ and iterate

$$W_{n+1} = W_n + \sum_i O_i W_n.$$

This is an ascending chain. When two consecutive subspaces agree, every generator maps the stable subspace into itself. The stable value is therefore the entire hull of operator words, not just the span of the words tested so far.

Exact dimensions for the same mixed seed in Model A. The dashed curve allows only N. The solid curve also admits the two chain projectors. Plateau values are repeated to show the certified stop.

Why the process stops in finite dimensions

If an inclusion is strict, the dimension rises by at least one. It cannot rise beyond $\dim X$. At equality, invariance and containment of the seeds prove both inclusions between the stable space and the least invariant hull.

What the companion code actually does

The new checker retains exact column bases using rational row reduction. It then verifies that adjoining the images of those bases under every generator does not increase rank. These examples use neither a cutoff on singular values nor a numerical tolerance.

The Lean statement is a mathematical termination and correctness specification. It is not a claim that this Python implementation for maintaining a basis was extracted from Lean or that a particular runtime bound was proved. The original numerical companion and its tolerances remain separate.

> **Read this as:** "No new directions" is a stopping certificate only after checking the full declared operator family. Stopping after a convenient selection of words is not the same test.

Plate I.21 / OPERATIONS ON SEED RANK / A RECTANGLE, NOT A DIAGONAL

Tensor products require every cross term

Main text: proposition 4.9. Algebraic tensor products

If (x_i) generates X under $\mathcal{A}$ and (y_j) generates Y under $\mathcal{B}$, then the candidate tensor seeds are *all* $x_i \otimes y_j$. For finite expansions,

$$x = \sum_i A_i x_i, \qquad y = \sum_j B_j y_j,$$

bilinearity gives the required double sum:

$$x \otimes y = \sum_i \sum_j (A_i \otimes B_j)(x_i \otimes y_j).$$

The coefficient rectangle

	$5f_1$	$7f_2$
$2e_1$	10	14
$3e_2$	15	21

$$10(e_1 \otimes f_1) + 14(e_1 \otimes f_2)$$

$$+15(e_2 \otimes f_1) + 21(e_2 \otimes f_2)$$

The exact expansion of $(2e_1 + 3e_2) \otimes (5f_1 + 7f_2)$. The terms away from the diagonal 14 and 15 cannot be omitted.

Keeping only the tensors with matching indices $e_1 \otimes f_1$ and $e_2 \otimes f_2$ spans a subspace of dimension two in a tensor product of dimension four. It misses both cross directions. Under scalar actions on $\mathbb{Q}^2$ and $\mathbb{Q}^2$, all four basis tensors are necessary and sufficient.

The resulting upper bound

Since simple tensors span the algebraic tensor product, the complete rectangular family proves

$$\boxed{\operatorname{srank}_{\mathcal{A}\otimes\mathcal{B}}(X \otimes Y) \le \operatorname{srank}_{\mathcal{A}}(X)\ \operatorname{srank}_{\mathcal{B}}(Y).}$$

This is not a universal equality claim. Changing the algebra changes the answer: the full independent matrix action can make a single nonzero pure tensor cyclic. Nor does the algebraic argument itself establish a theorem for completed topological tensor products.

> **Read this as:** The generator construction is indexed by a Cartesian product. Its proof must retain the finite double sum and the hypotheses on scalar actions that make the tensor action well defined.

Plate I.22 / PROOF BOUNDARY / RETURN TO THE MANUSCRIPT

What the pictures certify

Main text: Reading the theorem hypotheses and companion evidence

The mathematical statements in the main text have explicit hypotheses and written proofs. The Lean guide separately identifies the checked declarations, hypotheses, and coverage. The computational companion identifies the 108 stable foundation records and the checks executed on their structured representations. These are distinct forms of evidence.

Topic	Mathematical content	What must be retained
Presentations and hulls	Evaluation, module quotients, and generation under a fixed algebra.	The grammar must be fixed independently of the target.
Finite packets	Idempotence, annihilation, completeness and exact finite synthesis.	Orthogonality requires an additional hypothesis.
Semisimple formula	Multiplicities over division rings determine the minimal free cover.	The stated classical inputs and decomposition data.
Primary and graph formulas	Primary components and scalar quotients give sharp generator counts.	The coefficient field and multiplicity conventions.
Paths and cycles	Formulas for paths of every size and for complex cycles have separate proofs.	Finite tests illustrate rather than prove claims for every size.
Coordinate algebra	Normal form, multiplication, packet identities and a unit seed.	Smooth projective geometry needs additional classical input.
Completion	Density and bounded extraction in the stated topology.	Infinite sequences are distinct from periodic finite arrays.

Evidence travels with the examples

The supporting material includes mathematical source, exact model definitions, deterministic graphics, Python checks, Lean source and theorem mapping, and the computational record archive. The visual models use integer, rational, symbolic, or explicitly analytic calculations. The verification record distinguishes the execution evidence for each component.

> **Read this as:** The pictures make the hypotheses visible. Read the traditional proof, the formal contract, and the executable record at their respective stated scopes.

CHAPTER II

Projector Resolved Seed Calculus II

Refinement towers, weighted transfer, and integral separation of operator packets

The linear framework now becomes a language for comparing resolutions.

Refinement towers compare packet descriptions across levels. Weighted transfers and integral separation show which structures survive a change of resolution.

IN THIS CHAPTER

Mathematical text 99

Visual studies 152

Formal companion 1721

Sources and references 2668

Scope

Canonical values are defined for admissible data. A general existence theorem for admissible contours remains a separate question.

The next chapter moves from linear packet coordinates to typed nonlinear operations and analytic jets.

How to use this volume

Reading route. Exact packet coordinates and residue selectors lead to weighted inversion and rational walk series. Lattice gluing then gives separation weights and precision delays. Smith congruences and operator defects connect these formulas to finite computation.

Companions. The worked plates illustrate the constructions of this chapter. The formal companion in the back matter distinguishes the chapter-wide correspondence from the foundational 25-row walkthrough, with explicit evidence and scope.

Overview

A complete family of idempotents gives exact coordinates, but a single family does not record scale or integral visibility. We study towers in which every coarse idempotent is the sum of its fine descendants. The coordinate changes are invertible and coherent, and every operator block is the sum of its refined blocks. Residue selectors give a model over arbitrary rings. When roots of unity are available they agree with character averages, and coprime moduli factor through the Chinese remainder theorem. In a complete filtered algebra, a diagonal operator plus positive weight transfers has an inverse obtained by summing admissible weighted paths. The formula truncates exactly at finite precision, while finite transfer graphs have rational path series. For a rational spectral decomposition over a discrete valuation ring, resultants give denominator bounds. The exact denominator is the largest Smith exponent of the lattice gluing module. This yields a necessary and sufficient precision delay, monotonicity under refinement, and a full congruence solving formula. We close with exact formulas for the propagation of a coarsening defect through powers, resolvents, holomorphic functions, exponentials, and multilevel towers.

The exposition distinguishes general written proofs, formal specifications, and finite computational examples. The worked plates supply concrete models. The formal companion identifies the exact declarations and hypotheses that support each mapped statement.

1 Introduction

A complete family of pairwise annihilating idempotents decomposes a module into exact coordinate pieces. Many problems require more than one such decomposition. A signal may be split first into two residue classes and then into four. A filtered operator may be resolved into transfers that appear at different valuation depths. A rational spectral splitting may exist over the fraction field while remaining invisible on the original lattice. These are all refinement problems, but they involve different notions of scale.

The first part of the chapter concerns exact refinement. If a fine packet family refines a coarse family, then each coarse idempotent is the sum of its fine descendants. The coordinate spaces at the two levels are canonically isomorphic because both represent the whole module. The refinement relation adds more information. It tells us which fine coordinates belong to each coarse coordinate, and it gives a compatible decomposition of every operator block. This is the algebra behind polyphase coordinates and nested filter banks. Standard treatments of those subjects may be found in [10, 2].

The second part studies inversion in a complete filtered algebra. Suppose an operator has the form

$$T = D + N,$$

where D is invertible and every packet transfer in N raises the filtration by a positive amount. The ordinary Neumann series can then be expanded into weighted paths. The weight is not the number of edges. It is the total filtration gain along the path. At precision L, every path of weight at least L vanishes. A finite transfer graph also gives a rational generating function for the number of paths of each total weight. The relevant generating function facts are classical and are discussed in [9].

The third part concerns integral separation. Let V be a vector space over the fraction field of a discrete valuation ring $\mathcal{O}$, and let Λ be an $\mathcal{O}$ lattice in V. A rational projector E need not preserve Λ. Its separation weight is the least s such that

$$\pi^{s} E\Lambda \subseteq \Lambda.$$

A Bézout construction gives an upper bound through a polynomial resultant. That bound need not be exact because it does not see the position of the lattice. The exact answer is controlled by the finite length module

$$G_{\Lambda,\mathcal{P}} = \Lambda \Big/ \bigoplus_{\alpha} (\Lambda \cap V_{\alpha}),$$

where $V = \bigoplus_{\alpha} V_{\alpha}$ is the rational packet decomposition. The largest Smith exponent of this gluing module is exactly the common denominator needed to make every packet projector integral. This interpretation also proves that separation weight cannot decrease under refinement. Background on local fields, Smith normal form, and matrix polynomials may be found in [8, 6, 3].

The last part records how a defect between fine and coarse operators propagates. If

$$\Delta = CT_{f} - T_{c}C,$$

then exact formulas describe the corresponding defect for powers, resolvents, holomorphic functions, exponentials, and a chain of several refinement levels. These formulas are elementary, but collecting them in one place makes the later analytic uses transparent. The spectral and resolvent background follows the usual operator theory in [4].

Every theorem in this chapter concerns linear operators. An exact refinement retains the full object and changes its coordinates. Questions about nonlinear operation trees, nonlinear correction, and obstruction complexes require a separate theory.

2 Depth and compatibility

Packet, filtration, and separation depths describe three different kinds of scale. Compatibility is initially recorded by an operator defect. Keeping these notions separate makes the later formulas easier to read.

The first is packet depth. A finer packet family has more idempotents and a more detailed address set. The passage from residues modulo two to residues modulo four is an example. Packet depth is combinatorial. It says how many distinctions have been made in the coordinate system.

The second is filtration depth. A transfer in $F^r\mathcal{B}$ vanishes modulo $F^r\mathcal{B}$. This membership gives a lower bound on its depth. A nonzero transfer may first become visible only at a higher precision. Two paths with the same number of edges can have different filtration depths. A longer path can appear earlier when its edges have smaller weights.

The third is separation depth. A rational packet projector may require multiplication by π^s before it preserves the chosen lattice. This number depends on both the rational decomposition and the lattice. It can be zero even when the corresponding eigenvalues are close, and it can be positive even when the rational projector is simple.

The fourth notion is the compatibility defect. A fine operator and a separately chosen coarse operator need not commute with coarsening. Their discrepancy is

$$\Delta = CT_f - T_cC.$$

This operator records the failure of one model to represent another exactly. A chosen norm measures its size, while a chosen filtration can assign a depth. No integer compatibility depth is assigned without that additional structure.

The four notions meet in applications, but no one of them determines the others. An exact refinement tower may have zero coordinate error while its fine spectral packets have positive lattice weight. A filtered inverse may truncate exactly at a given depth while the coarse operator still has a nonzero compatibility defect. The chapter treats each quantity with its own theorem before combining them.

The central idea

Packet depth changes the address of a component. Filtration depth controls when a transfer survives a precision cutoff. Separation depth clears a rational denominator on a chosen lattice. The compatibility defect records a discrepancy between two operator models. These quantities can interact, but each needs its own hypothesis and its own calculation.

A simple two packet model already contains all four notions. Let

$$X = X_0 \oplus X_1, \qquad D = \begin{pmatrix} D_0 & 0 \\ 0 & D_1 \end{pmatrix}, \qquad N = \begin{pmatrix} 0 & N_{01} \\ N_{10} & 0 \end{pmatrix}.$$

A finer family may split X_0 and X_1 into smaller summands. The blocks N_{01} and N_{10} may enter at different filtration weights. Over a fraction field, the rational packet spaces may fail to split the chosen

lattice. A coarse operator on one selected summand may also fail to intertwine with the full matrix. The later sections isolate these four effects one at a time.

3 Packet systems and refinement towers

Packet coordinates split a module into pieces that can be recovered separately and then added back together. The construction uses idempotents and does not need an inner product.

Definition 3.1 (Packet system)**.** Let X be a module over a unital ring. A finite packet system on X is a family

$$\mathcal{P} = (P_\alpha)_{\alpha \in I} \subseteq \mathrm{End}(X)$$

of nonzero idempotents such that

$$P_\alpha P_\beta = 0 \quad \text{when } \alpha \neq \beta, \qquad \sum_{\alpha \in I} P_\alpha = I_X.$$

Write

$$X_\alpha = P_\alpha X, \qquad X^{\mathcal{P}} = \bigoplus_{\alpha \in I} X_\alpha.$$

The analysis and synthesis maps are

$$\mathcal{A}_{\mathcal{P}} x = (P_\alpha x)_\alpha, \qquad \mathcal{S}_{\mathcal{P}}(x_\alpha)_\alpha = \sum_\alpha x_\alpha.$$

They are inverse isomorphisms.

Definition 3.2 (Refinement)**.** Let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ and $\mathcal{Q} = (Q_\beta)_{\beta \in J}$ be packet systems on the same module. We say that $\mathcal{Q}$ refines $\mathcal{P}$ when there is a surjection

$$\rho : J \longrightarrow I$$

such that

$$P_\alpha = \sum_{\rho(\beta) = \alpha} Q_\beta$$

for every $\alpha \in I$. The index β is then called a child of $\rho(\beta)$.

Theorem 3.3 (Children, parents, and transitivity)**.** *Suppose that $\mathcal{Q}$ refines $\mathcal{P}$ through ρ. Then*

$$P_\alpha Q_\beta = Q_\beta P_\alpha = \begin{cases} Q_\beta & \rho(\beta) = \alpha, \\ 0 & \rho(\beta) \neq \alpha. \end{cases}$$

Hence $Q_\beta X \subseteq P_{\rho(\beta)} X$. If a third packet system $\mathcal{R}$ refines $\mathcal{Q}$, then $\mathcal{R}$ refines $\mathcal{P}$ through the composite parent map.

Proof. Multiply the identity

$$P_\alpha = \sum_{\rho(\gamma)=\alpha} Q_\gamma$$

by Q_β on either side. Pairwise annihilation in the fine family leaves Q_β when $\rho(\beta) = \alpha$ and leaves zero otherwise. For transitivity, substitute the child expansion of each Q_β into the expansion of P_α and group the resulting terms by the composite parent. □

A refinement tower is a sequence $(\mathcal{P}_\ell)_{\ell\geq 0}$ with parent maps

$$\rho_{m,\ell} : I_m \longrightarrow I_\ell \qquad (m \geq \ell)$$

such that $\mathcal{P}_m$ refines $\mathcal{P}_\ell$ through $\rho_{m,\ell}$ for every $m \geq \ell$, and

$$\rho_{\ell,\ell} = \mathrm{id}_{I_\ell}, \qquad \rho_{n,\ell} = \rho_{m,\ell} \circ \rho_{n,m} \qquad (n \geq m \geq \ell).$$

Thus every parent map witnesses the stated refinement and the maps compose coherently. The next result shows that the coordinate changes form a coherent system.

Definition 3.4 (Coordinate change across levels)**.** For two packet systems $\mathcal{P}$ and $\mathcal{Q}$ on X, define

$$J_{\mathcal{Q}\leftarrow\mathcal{P}} = \mathcal{A}_{\mathcal{Q}}\mathcal{S}_{\mathcal{P}} : X^{\mathcal{P}} \longrightarrow X^{\mathcal{Q}}$$

and

$$C_{\mathcal{P}\leftarrow\mathcal{Q}} = \mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{Q}} : X^{\mathcal{Q}} \longrightarrow X^{\mathcal{P}}.$$

When $\mathcal{Q}$ refines $\mathcal{P}$, the first map resolves each coarse coordinate into its children and the second adds the children back to their parent.

The central idea

A coarse coordinate retains a whole vector in its coarse packet. Adding its children keeps the whole vector inside that packet. Fine analysis recovers each child by applying its projector. This explains why the two coordinate maps can be inverse even when the fine system has more packet labels.

Theorem 3.5 (Exact coordinate change and coherence)**.** *For any two packet systems on X,*

$$C_{\mathcal{P}\leftarrow\mathcal{Q}}J_{\mathcal{Q}\leftarrow\mathcal{P}} = I_{X^{\mathcal{P}}}, \qquad J_{\mathcal{Q}\leftarrow\mathcal{P}}C_{\mathcal{P}\leftarrow\mathcal{Q}} = I_{X^{\mathcal{Q}}}.$$

For three packet systems $\mathcal{P}$, $\mathcal{Q}$, and $\mathcal{R}$ on X,

$$J_{\mathcal{R}\leftarrow\mathcal{Q}}J_{\mathcal{Q}\leftarrow\mathcal{P}} = J_{\mathcal{R}\leftarrow\mathcal{P}},$$

$$C_{\mathcal{P}\leftarrow\mathcal{Q}}C_{\mathcal{Q}\leftarrow\mathcal{R}} = C_{\mathcal{P}\leftarrow\mathcal{R}}.$$

If $\mathcal{Q}$ refines $\mathcal{P}$ through ρ, then

$$\left(J_{\mathcal{Q}\leftarrow\mathcal{P}}x\right)_\beta = Q_\beta x_{\rho(\beta)}, \qquad \left(C_{\mathcal{P}\leftarrow\mathcal{Q}}y\right)_\alpha = \sum_{\rho(\beta)=\alpha} y_\beta.$$

Proof. The packet analysis and synthesis maps are inverse. Therefore

$$C_{\mathcal{P}\leftarrow\mathcal{Q}}J_{\mathcal{Q}\leftarrow\mathcal{P}} = \mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}}\mathcal{S}_{\mathcal{P}} = \mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{P}} = I.$$

The other inverse identity is the same calculation with the two systems exchanged. The coherence identities follow by inserting

$$\mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}} = I_X.$$

Now assume that $\mathcal{Q}$ refines $\mathcal{P}$. If $x = (x_\alpha)_\alpha$ with $x_\alpha \in P_\alpha X$, then

$$Q_\beta \sum_\alpha x_\alpha = Q_\beta x_{\rho(\beta)}$$

by theorem 3.3. The formula for C follows by synthesis followed by projection onto the parent packet. □

Remark 3.6 (Refinement and reduction). The maps in theorem 3.5 are isomorphisms because both coordinate spaces represent all of X. They do not reduce dimension and they do not discard packets. Approximation begins only after one chooses a truncation or compression rule.

Corollary 3.7 (Orthogonal Hilbert packets)**.** *If X is a real or complex Hilbert space and every packet system in the tower consists of orthogonal projections, equip each finite packet direct sum with the Hilbert inner product $\langle (x_\alpha), (y_\alpha)\rangle = \sum_\alpha \langle x_\alpha, y_\alpha\rangle$. Then analysis and synthesis are unitary. Every coordinate change in theorem 3.5 is unitary.*

Proof. For an orthogonal packet system,

$$\|x\|^2 = \sum_\alpha \|P_\alpha x\|^2.$$

Thus analysis is an isometry onto the full packet direct sum. Synthesis is its inverse. A coordinate change is a composition of two unitary maps. □

Every coarse packet is also uniquely reconstructed from its fine children. If vectors $x_\beta \in Q_\beta X$ sum to a coarse packet x, applying Q_γ recovers $x_\gamma = Q_\gamma x$. This is the uniqueness clause of the canonical nested-refinement statement.

3.1 Typed coordinate naturality

These coordinate changes are coherent through every finite tower. If three complete packet systems are denoted by a, b, c, then

$$J_{c,b}J_{b,a} = J_{c,a}, \qquad J_{a,a} = I, \qquad J_{b,a}^{-1} = J_{a,b}.$$

These laws hold for arbitrary exact packet systems representing the same ambient module. The parent maps supply the component formulas linking children to their parents. Coordinate coherence itself does not require them.

The same coherence applies to operators. Let P_a, P_b be packet systems on X, let Q_a, Q_b be packet systems on Y, where X and Y are modules over the same scalar ring, and let $T : X \to Y$ be a linear map over that ring. Its exact coordinate representation

$$\widehat{T}_{Q,P} = \mathcal{A}_Q T \mathcal{S}_P$$

preserves identities and typed composition, and the naturality square is

$$\boxed{J^{Y}_{Q_b,Q_a}\,\widehat{T}_{Q_a,P_a} = \widehat{T}_{Q_b,P_b}\,J^{X}_{P_b,P_a}.}$$

The identity, cocycle, composition, inverse, and naturality laws are all proved in Lean. The separate refinement hypotheses supply the local component formulas linking each child to its parent.

How to read the result

These identities concern complete coordinates of the same module. A quotient is a different operation: it identifies vectors that differ by an element of a chosen submodule. Later, finite precision will be expressed by a quotient that removes terms beyond the chosen filtration depth. This distinction explains why refinement is exactly reversible while precision truncation has a prescribed residual.

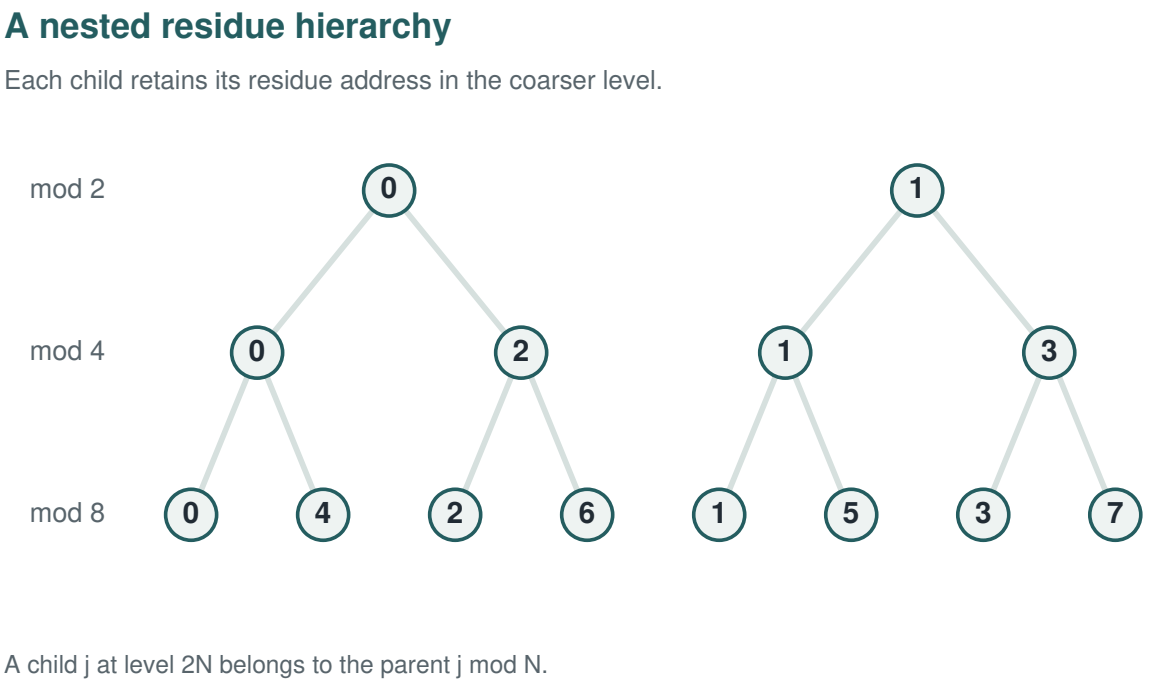


Figure 1. A nested residue hierarchy. Each residue modulo 2 is the union of two residues modulo 4, and each residue modulo 4 is the union of two residues modulo 8.

3.2 Operator blocks across refinement

For $T \in \mathrm{End}(X)$ and a packet system $\mathcal{P}$, write

$$T^{\mathcal{P}}_{\beta\alpha} = P_\beta T P_\alpha.$$

Theorem 3.8 (Refinement of operator blocks). *Suppose that $\mathcal{Q}$ refines $\mathcal{P}$ through ρ. Then*

$$T^{\mathcal{P}}_{ba} = \sum_{\substack{\rho(\beta)=b \\ \rho(\alpha)=a}} T^{\mathcal{Q}}_{\beta\alpha}.$$

The matrix of T in fine coordinates is related to the matrix in coarse coordinates by

$$[T]_{\mathcal{P}} = C_{\mathcal{P}\leftarrow\mathcal{Q}}[T]_{\mathcal{Q}}J_{\mathcal{Q}\leftarrow\mathcal{P}}.$$

Proof. Expand the two coarse projectors into their children:

$$P_b T P_a = \left(\sum_{\rho(\beta)=b} Q_\beta\right) T \left(\sum_{\rho(\alpha)=a} Q_\alpha\right).$$

Distributing the finite sums gives the first identity. For the coordinate identity, use

$$[T]_{\mathcal{P}} = \mathcal{A}_{\mathcal{P}} T \mathcal{S}_{\mathcal{P}}$$

and insert

$$I_X = \mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}}.$$

□

Corollary 3.9 (Support under refinement). *Under the hypotheses of theorem 3.8, a coarse block $T^{\mathcal{P}}_{ba}$ is zero if and only if every fine descendant block*

$$T^{\mathcal{Q}}_{\beta\alpha} \qquad (\rho(\beta) = b,\ \rho(\alpha) = a)$$

is zero.

Proof. If every fine block is zero, the coarse block is zero by theorem 3.8. Conversely, suppose $P_b T P_a = 0$. Multiply on the left by Q_β and on the right by Q_α. The child identities in theorem 3.3 give

$$Q_\beta T Q_\alpha = 0.$$

□

Thus refinement cannot hide an active transfer inside a zero coarse block. It can only reveal where the active transfer sits among the descendants.

3.3 Common refinements

Two packet systems need not be comparable. When their idempotents commute, their products give a common refinement.

Theorem 3.10 (Common refinement of commuting packet systems). *Let $\mathcal{P} = (P_\alpha)_{\alpha\in I}$ and $\mathcal{Q} = (Q_\beta)_{\beta\in J}$ be packet systems on X. Assume*

$$P_\alpha Q_\beta = Q_\beta P_\alpha$$

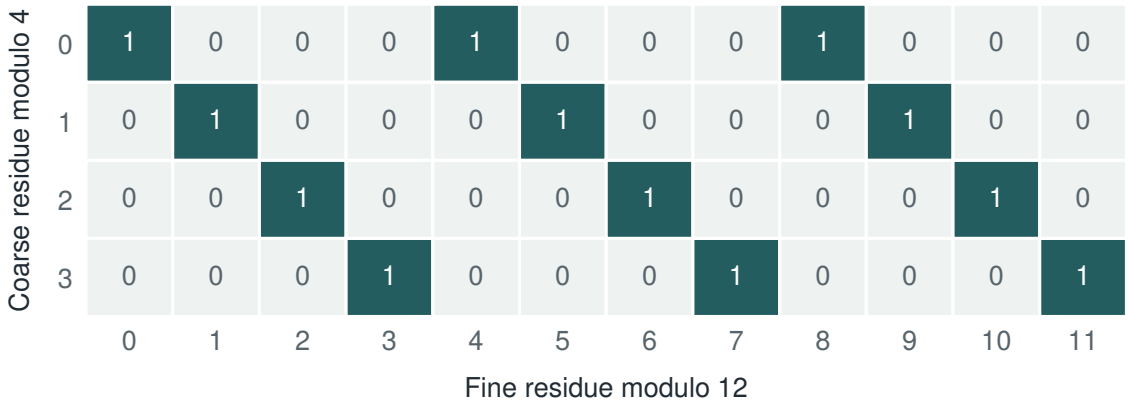

Figure 2. The incidence matrix $M_{r,s} = 1$ when the fine residue s belongs to the coarse residue r. Its rows implement exact aggregation from fine packets to coarse packets.

for all α and β. Remove the zero operators from the family

$$R_{\alpha\beta} = P_\alpha Q_\beta.$$

The remaining operators form a packet system that refines both $\mathcal{P}$ and $\mathcal{Q}$. The same statement holds for any finite collection of pairwise commuting packet systems.

Proof. Commutativity gives

$$R_{\alpha\beta}^2 = P_\alpha^2 Q_\beta^2 = R_{\alpha\beta}.$$

If $(\alpha, \beta) \neq (\alpha', \beta')$, then either $P_\alpha P_{\alpha'} = 0$ or $Q_\beta Q_{\beta'} = 0$, so the corresponding products annihilate one another. Finally,

$$\sum_{\alpha,\beta} R_{\alpha\beta} = \left(\sum_\alpha P_\alpha\right)\left(\sum_\beta Q_\beta\right) = I_X.$$

For a fixed α,

$$P_\alpha = P_\alpha \sum_\beta Q_\beta = \sum_\beta R_{\alpha\beta},$$

and the same argument works for a fixed β. Since each P_α and Q_β is nonzero, these identities ensure that every parent has a nonzero product child. The two parent maps on the supported product family are therefore surjective. Iteration proves the finite family statement. For the empty collection, use the supported identity family: (I_X) when $X \neq 0$ and the empty family when $X = 0$. □

Proposition 3.11 (Coarsest common refinement)**.** *Under the hypotheses of theorem 3.10, let $\mathcal{R}$ be a packet system that refines both $\mathcal{P}$ and $\mathcal{Q}$. Then $\mathcal{R}$ refines the nonzero product family $(P_\alpha Q_\beta)$. Hence that product family is the coarsest packet system that refines both $\mathcal{P}$ and $\mathcal{Q}$.*

Proof. Let R_γ be a packet in $\mathcal{R}$. Because $\mathcal{R}$ refines $\mathcal{P}$, there is a unique α with

$$P_\alpha R_\gamma = R_\gamma.$$

Likewise there is a unique β with

$$Q_\beta R_\gamma = R_\gamma.$$

Therefore

$$P_\alpha Q_\beta R_\gamma = R_\gamma.$$

Every packet of $\mathcal{R}$ lies in one product packet. Multiplying $\sum_\gamma R_\gamma = I_X$ by $P_\alpha Q_\beta$ and using the parent identities gives

$$P_\alpha Q_\beta = \sum_{\substack{\gamma:\ P_\alpha R_\gamma = R_\gamma \\ Q_\beta R_\gamma = R_\gamma}} R_\gamma.$$

Thus the packets with the same pair of parents reconstruct the product packet. If that product packet is nonzero, the sum has a child, so the parent map onto the supported product family is surjective. □

Example 3.12 (A two level split)**.** Let

$$X = X_{00} \oplus X_{01} \oplus X_{10} \oplus X_{11}.$$

Assume that all four summands are nonzero. The four coordinate projections form a fine packet system. The two sums

$$P_0 = Q_{00} + Q_{01}, \qquad P_1 = Q_{10} + Q_{11}$$

form a coarse packet system. If $x = (x_{00}, x_{01}, x_{10}, x_{11})$, the coarse coordinates are

$$(x_{00} + x_{01}, x_{10} + x_{11})$$

when the sums are interpreted inside the two coarse direct summands. Fine analysis recovers the four entries exactly. Nothing has been approximated.

4 Residue coordinates and coprime factorization

Residue packets sort a formal series by the congruence classes of its exponents. This construction works over every coefficient ring. The character formula describes the same selectors through an operator average and needs stronger hypotheses.

Definition 4.1 (Residue selector)**.** Let R be a commutative ring and let

$$F(z) = \sum_{n \geq 0} a_n z^n \in R[[z]].$$

For $N \geq 1$ and $0 \leq j < N$, define

$$(P_{N,j} F)(z) = \sum_{n \equiv j \pmod N} a_n z^n.$$

Proposition 4.2 (Residue packet algebra)**.** *For every commutative ring R, the operators $(P_{N,j})_{0\le j<N}$ satisfy the identities below. If R is nonzero, they form a packet system on $R[[z]]$:*

$$P_{N,i}P_{N,j} = \delta_{ij}P_{N,j}, \qquad \sum_{j=0}^{N-1} P_{N,j} = I.$$

Proof. Every nonnegative integer belongs to one residue class modulo N. A coefficient survives both $P_{N,i}$ and $P_{N,j}$ exactly when the two labels are equal to its residue. Summing all selectors preserves every coefficient once. □

4.1 Finite orthogonality certificates

The coefficient-mask definition of $P_{N,j}$ also makes sense over a commutative semiring: it only retains or sets coefficients to zero. We use that same definition in the following semiring statement.

Let U act on coefficient sequences by

$$(UF)(z) = F(\omega z).$$

If $\omega^N = 1$, then $U^N = I$.

Theorem 4.3 (Root-of-unity realization)**.** *Let R be a commutative semiring, let $N > 0$, and suppose $\omega, \omega^\vee, \eta \in R$ satisfy $\omega^N = 1$ and the finite $N \times N$ Fourier orthogonality table*

$$\eta \sum_{k=0}^{N-1} (\omega^\vee)^{jk}\omega^{rk} = \begin{cases} 1, & r = j, \\ 0, & r \neq j, \end{cases} \qquad 0 \le j, r < N.$$

Then

$$\boxed{P_{N,j} = \eta \sum_{k=0}^{N-1} (\omega^\vee)^{jk} U^k.}$$

In particular, if R is a field, $N > 0$, and ω is a primitive Nth root of unity, the certificate holds with $\omega^\vee = \omega^{-1}$ and $\eta = N^{-1}$.

Proof. On the monomial z^n, the right-hand side acts by

$$\eta \sum_{k=0}^{N-1} (\omega^\vee)^{jk}\omega^{nk}.$$

The identity $\omega^N = 1$ reduces this expression to the table entry indexed by $r = n \bmod N$. The finite certificate therefore gives exactly the coefficient mask defining $P_{N,j}$. Over a field, the primitive-root geometric sum supplies the certificate. □

The field or orthogonality condition is essential. A primitive element of order N in a ring with zero divisors does not by itself force the geometric sums away from the diagonal to vanish. For example, in $\mathbb{F}_3 \times \mathbb{F}_3$ the element $(-1, 1)$ has order two, but the second component of its nontrivial character sum is nonzero. The coefficient selector uses no division and remains valid without any Fourier certificate. This distinction becomes decisive at the dyadic prime.

4.2 The field specialization

Theorem 4.4 (Character realization)**.** *Let $\Bbbk$ be a field, assume that N is nonzero in $\Bbbk$, and suppose that $\Bbbk$ contains a primitive Nth root of unity ω. Define*

$$(UF)(z) = F(\omega z).$$

Then

$$P_{N,j} = \frac{1}{N} \sum_{k=0}^{N-1} \omega^{-jk} U^k.$$

Proof. On z^n, the right side acts by the scalar

$$\frac{1}{N} \sum_{k=0}^{N-1} \omega^{k(n-j)}.$$

This is one when $n \equiv j \pmod N$ and zero otherwise by the geometric sum identity in the field $\Bbbk$. □

Remark 4.5 (Two distinct constructions). The coefficient selector of definition 4.1 uses no division. The character formula in theorem 4.4 divides by N. At a prime that divides N, the coefficient selector may remain integral even when the character average does not.

Theorem 4.6 (Nested residue refinement)**.** *Let N, M be positive integers with N dividing M, and let $0 \le j < N$. Then*

$$P_{N,j} = \sum_{\substack{0 \le s < M \\ s \equiv j \pmod N}} P_{M,s}.$$

When R is nonzero, the packet system modulo M refines the packet system modulo N.

Proof. An exponent n satisfies $n \equiv j \pmod N$ exactly when its unique residue s modulo M satisfies $s \equiv j \pmod N$. □

Example 4.7 (The shift graph of residue packets)**.** Assume that R is nonzero and $N > 0$. Multiplication by z sends the residue packet $P_{N,j}R[[z]]$ into $P_{N,j+1}R[[z]]$, where the index is read modulo N. Its packet graph is the directed cycle

$$0 \longrightarrow 1 \longrightarrow \cdots \longrightarrow N-1 \longrightarrow 0.$$

Multiplication by a polynomial supported on a set of residues gives the corresponding finite set of phase shifts. This is the simplest transfer graph behind a polyphase representation.

Theorem 4.8 (Coprime factorization)**.** *Let A and B be coprime positive integers. For each j modulo AB, write*

$$j_A = j \pmod A, \qquad j_B = j \pmod B.$$

Then

$$P_{AB,j} = P_{A,j_A} P_{B,j_B}.$$

Every pair (j_A, j_B) occurs for one residue j modulo AB.

Proof. A coefficient survives the product on the right exactly when its exponent satisfies both congruences. The Chinese remainder theorem gives one residue class modulo AB with those two coordinates. The needed form of the theorem is standard and may be found in [5]. □

Corollary 4.9 (Dyadic and odd coordinates)**.** *Write $N = 2^a M$ with M odd. Every residue packet modulo N is the product of one packet modulo 2^a and one packet modulo M.*

Proof. Apply theorem 4.8 to the coprime moduli 2^a and M. □

Example 4.10 (Residues modulo twelve)**.** The pair

$$(j \pmod 4, j \pmod 3) = (3, 1)$$

corresponds to $j = 7$ modulo 12. Hence

$$P_{12,7} = P_{4,3} P_{3,1}.$$

This factorization concerns addresses. It does not say that the two factors have the same integral spectral behavior.

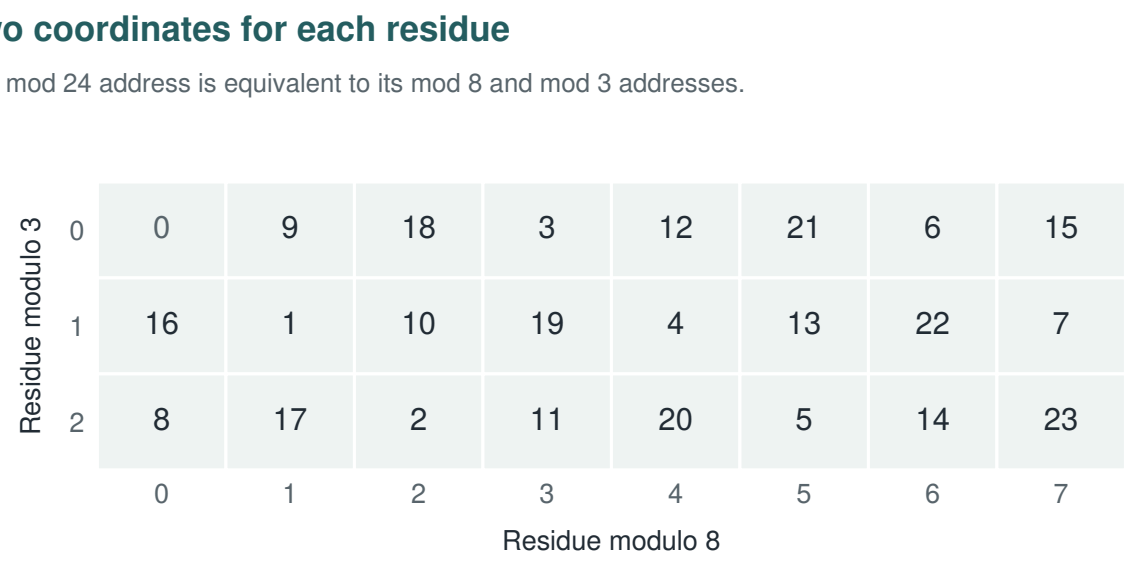

Figure 3. A composite residue packet is addressed by its dyadic and odd coordinates. The displayed mod-24 system is the product of mod 8 and mod 3.

5 Complete filtered transfer algebras

A filtration records how deeply a term lies in the chosen notion of precision. The weights record guaranteed filtration gains that add under multiplication. A discrete valuation ring provides the main example.

Definition 5.1 (Complete multiplicative filtration)**.** A complete filtered algebra is a unital algebra $\mathcal{B}$ with a decreasing sequence of two-sided ideals

$$\mathcal{B} = F^0\mathcal{B} \supseteq F^1\mathcal{B} \supseteq F^2\mathcal{B} \supseteq \cdots$$

such that

$$F^r\mathcal{B}\,F^s\mathcal{B} \subseteq F^{r+s}\mathcal{B}, \qquad \bigcap_{L\geq 0} F^L\mathcal{B} = 0,$$

and the natural map

$$\mathcal{B} \longrightarrow \varprojlim_L \mathcal{B}/F^L\mathcal{B}$$

is an isomorphism. A transfer term N_e has a declared positive integer weight $w(e) \in \mathbb{Z}_{>0}$ when

$$N_e \in F^{w(e)}\mathcal{B}.$$

In the filtration topology, reduction to $\mathcal{B}/F^L\mathcal{B}$ is continuous when the quotient has the discrete topology. Its kernel $F^L\mathcal{B}$ is therefore closed. In particular, a convergent sum of terms in $F^L\mathcal{B}$ remains in that ideal.

If $\mathcal{O}$ is a complete discrete valuation ring with uniformizer π and $\mathcal{B}$ is a separated and complete $\mathcal{O}$ algebra for the filtration

$$F^L\mathcal{B} = \pi^L\mathcal{B},$$

then this is a standard example. Finite matrix algebras over $\mathcal{O}$ satisfy these conditions. Completeness of $\mathcal{O}$ alone does not imply completeness of every $\mathcal{O}$ algebra. Basic facts about completeness in this setting are reviewed in [8].

Theorem 5.2 (Weighted inverse)**.** *Let $\mathcal{B}$ be a complete filtered algebra. Let $D \in \mathcal{B}$ be invertible with*

$$D, D^{-1} \in F^0\mathcal{B}.$$

Let E be a finite set and suppose

$$T = D + \sum_{e\in E} N_e, \qquad N_e \in F^{w(e)}\mathcal{B}, \qquad w(e) \geq 1.$$

Set

$$A_e = D^{-1}N_e.$$

For a word $\gamma = (e_1, \ldots, e_r)$, write

$$A_\gamma = A_{e_r}\cdots A_{e_1}, \qquad W(\gamma) = \sum_{j=1}^{r} w(e_j).$$

The empty word has weight zero and contributes the identity. Then T is invertible and

$$T^{-1} = \sum_{\gamma} (-1)^{|\gamma|} A_\gamma D^{-1}.$$

The series converges in the filtration, and the term indexed by γ belongs to $F^{W(\gamma)}\mathcal{B}$.

Proof. Put

$$A = \sum_{e \in E} A_e.$$

Since left multiplication by D^{-1} preserves the filtration, $A \in F^1\mathcal{B}$. Completeness gives the convergent Neumann series

$$(I + A)^{-1} = \sum_{r \geq 0} (-A)^r.$$

Because $T = D(I + A)$,

$$T^{-1} = (I + A)^{-1} D^{-1}.$$

Expanding each power of A gives the sum over words, with the rightmost edge acting first. Multiplicativity of the filtration gives

$$A_\gamma \in F^{W(\gamma)}\mathcal{B}.$$

For each L, only finitely many words have weight below L because E is finite and every edge has positive weight. Thus the word expansion converges to the same inverse. □

The preceding formula does not yet use packet blocks. When D is packet diagonal and the terms N_e are individual transfers, only words with compatible packet endpoints can contribute. These words become directed paths.

Theorem 5.3 (Block path formula). *Let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ be a finite packet system in a complete filtered algebra of operators. Suppose*

$$D = \sum_\alpha P_\alpha D P_\alpha$$

belongs to $\mathcal{B}$ and is invertible on every packet. Assume that the assembled inverse

$$D^{-1} = \sum_\alpha D_\alpha^{-1} P_\alpha \in \mathcal{B} = F^0\mathcal{B}, \qquad D_\alpha = P_\alpha D P_\alpha,$$

where each packet inverse is extended by zero to the other packets. Let the edge set be finite, assume $w(e) \geq 1$ for every edge, and write

$$N = \sum_{e : \alpha \to \beta} N_e, \qquad N_e = P_\beta N_e P_\alpha, \qquad N_e \in F^{w(e)}\mathcal{B}.$$

For an edge $e : \alpha \to \beta$, put

$$A_e = (P_\beta D P_\beta)^{-1} N_e.$$

Then the block from $P_\alpha X$ to $P_\beta X$ of $(D + N)^{-1}$ is

$$P_\beta (D + N)^{-1} P_\alpha = \sum_{\gamma : \alpha \rightsquigarrow \beta} (-1)^{|\gamma|} A_\gamma D_\alpha^{-1},$$

where $D_\alpha = P_\alpha D P_\alpha$ and the sum runs over directed paths from α to β, including the empty path when $\alpha = \beta$.

Proof. The diagonal inverse is

$$D^{-1} = \sum_{\alpha} D_{\alpha}^{-1} P_{\alpha}.$$

The block $P_{\beta} D^{-1} N P_{\alpha}$ is nonzero only when there is a declared edge from α to β. Repeated block multiplication shows that the rth power of $D^{-1}N$ is the sum over all directed paths of length r, with the operator factors ordered along the path. Apply theorem 5.2 and multiply on the right by the packet diagonal inverse. □

Corollary 5.4 (Minimum path weight)**.** *For packets α and β, let $d(\alpha, \beta)$ be the least total weight of a directed path from α to β, with $d = \infty$ when no path exists. Use the convention $F^{\infty}\mathcal{B} = \bigcap_{L \geq 0} F^{L}\mathcal{B} = 0$. If $\alpha \neq \beta$, then*

$$P_{\beta}(D + N)^{-1} P_{\alpha} \in F^{d(\alpha,\beta)}\mathcal{B}.$$

If there is no path from α to β, the block is zero.

Proof. Every term in the block path formula is indexed by a path from α to β and lies in the filtration level given by its total weight. If no such path exists, the sum is empty. □

Example 5.5 (A longer path that appears earlier)**.** Consider three packets α, β, and γ. Suppose there is a direct edge from α to γ of weight three, together with edges

$$\alpha \longrightarrow \beta, \qquad \beta \longrightarrow \gamma$$

of weight one each. The two edge route has total weight two, so it contributes to the inverse before the direct edge does. This is why the truncation rule uses total weight rather than path length. The lower bound in corollary 5.4 need not be an equality because several paths of the same weight may cancel.

> **The central idea**
>
> Word length counts how many transfers are composed. Weight counts how much filtration gain those transfers guarantee. The sign in the inverse expansion depends on length, while the precision cutoff depends on weight. A short word can therefore disappear at a chosen precision while a longer word still contributes.

Corollary 5.6 (Acyclic transfer graph)**.** *If the packet transfer graph is acyclic, then $D^{-1}N$ is nilpotent. The inverse in theorem 5.3 is a finite sum and does not require completeness of the filtration.*

Proof. A finite acyclic directed graph has a bound on path length. Every sufficiently long product of transfer blocks is therefore zero. The Neumann series terminates. □

Corollary 5.7 (Stability of inversion at finite precision)**.** *Let T and $\widetilde{T}$ be invertible elements of $F^{0}\mathcal{B}$. If*

$$T - \widetilde{T} \in F^{L}\mathcal{B},$$

then

$$T^{-1} - \widetilde{T}^{-1} \in F^{L}\mathcal{B}.$$

Proof. Use the resolvent identity at zero in the form

$$T^{-1} - \widetilde{T}^{-1} = T^{-1}(\widetilde{T} - T)\widetilde{T}^{-1}.$$

Both inverse factors belong to $F^0\mathcal{B}$, so the product lies in $F^L\mathcal{B}$. □

Corollary 5.8 (Exact finite precision truncation)**.** *Under the hypotheses of theorem 5.2, define*

$$R_L = \sum_{W(\gamma)<L} (-1)^{|\gamma|} A_\gamma D^{-1}.$$

Then

$$T^{-1} - R_L \in F^L\mathcal{B},$$

$$TR_L - I \in F^L\mathcal{B}, \qquad R_L T - I \in F^L\mathcal{B}.$$

Thus R_L is the exact inverse in $\mathcal{B}/F^L\mathcal{B}$.

Proof. Every omitted word has weight at least L, so the difference from the full inverse lies in $F^L\mathcal{B}$. Multiplication by T or by its inverse preserves membership in $F^L\mathcal{B}$ under the stated filtration assumptions. The two residual statements follow. □

Example 5.9 (A triangular transfer)**.** Let $\mathcal{O}$ be complete with uniformizer π, and consider

$$T = \begin{pmatrix} 1 & \pi^a \\ 0 & 1 \end{pmatrix}$$

with $a \geq 1$. The only nontrivial transfer has weight a, and its square is zero. Hence

$$T^{-1} = \begin{pmatrix} 1 & -\pi^a \\ 0 & 1 \end{pmatrix}.$$

At precision $L \leq a$, the transfer vanishes and the inverse is the identity modulo π^L. At depth $a+1$, the transfer between the two packets first becomes visible.

Two compatible word conventions. The path expansion above labels a word in chronological order and writes its operator product in reverse order, so the first edge acts first. The following finite-word contract uses written multiplication order. Reversing all word labels identifies the sums over all words. Individual path labels must retain their stated convention. The two conventions do not change a weight or an inverse.

5.1 Finite quotient and normed-ring realizations

5.1.1 Normalized edges and written-word convention

Let $\mathcal{O}$ be a complete discrete valuation ring with uniformizer π, fraction field K, and filtration

$$F^m\mathcal{B} = \pi^m\mathcal{B}$$

on an $\mathcal{O}$-algebra $\mathcal{B}$. The finite quotient statements below do not require $\mathcal{B}$ itself to be complete. Suppose

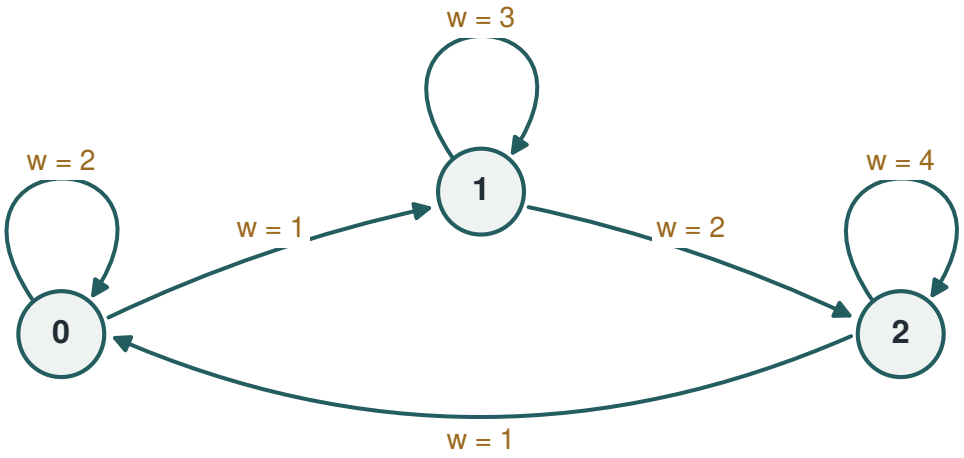
$$T = D + H,$$

where D is invertible and the perturbation H raises filtration. The symbol K is reserved for the fraction field.

A packet decomposition resolves $H = \sum_{e \in E} H_e$ and assigns a certified filtration gain

$$D^{-1}H_e \in F^{w(e)}\mathcal{B}, \qquad w(e) \in \mathbb{Z}_{>0}.$$

Each e is a directed transfer edge. For an ordered transfer word



$$\gamma = (e_1, \dots, e_r),$$

define

$$W(\gamma) = \sum_{j=1}^{r} w(e_j), \qquad A_\gamma = A_{e_1} \cdots A_{e_r}, \qquad A_e = D^{-1}H_e.$$

Weighted transfer graph

Edge weights measure filtration gain. Every edge has multiplicity one.

The weighted walk series below starts at packet 0 and ends at packet 2.

Figure 4. A finite packet-transfer graph. Edge weights record filtration gain rather than merely the number of operator compositions.

Theorem 5.10 (Certified weighted inverse). *Let R be a possibly noncommutative ring, let D^{-1} be a supplied two-sided inverse of D, and put $A = D^{-1}H$.*

(a) If $A^r = 0$, then $D + H$ has the two-sided inverse

$$\boxed{(D+H)^{-1} = \left(\sum_{k=0}^{r-1} (-A)^k\right) D^{-1}.}$$

(b) If R is a complete normed ring and $\|A\| < 1$, then $\sum_{k\geq 0}(-A)^k$ converges and

$$\boxed{(D+H)^{-1} = \left(\sum_{k\geq 0}(-A)^k\right) D^{-1}.}$$

Proof. Factor

$$T = D(I+A), \qquad A = D^{-1}H.$$

For a finite cutoff r, multiplication on either side gives the noncommutative telescoping identity

$$(I+A)\sum_{k=0}^{r-1}(-A)^k = \left(\sum_{k=0}^{r-1}(-A)^k\right)(I+A) = 1-(-A)^r.$$

This proves (a). In (b), the strict norm bound makes the geometric series summable. Continuity of multiplication passes the same identities to the limit. Multiplication by D^{-1} gives the displayed inverse in both orders. □

Corollary 5.11 (Finite precision). *Let $F^\bullet R$ be a multiplicative decreasing filtration and let $q_L : R \to R_L$ be a ring homomorphism that kills $F^L R$. Suppose*

$$H = \sum_{e\in E} H_e, \qquad D^{-1}H_e \in F^{w(e)}R, \qquad w(e) \geq 1,$$

with E finite. Then $q_L(D^{-1}H)^L = 0$, the finite sum in theorem 5.10(a) is a two-sided inverse after applying q_L, and its word expansion may discard every word of weight at least L. More explicitly, for a length cutoff N, define

$$S^{\mathrm{pr}}_{L,N} = \sum_{n=0}^{N-1}(-1)^n \sum_{\substack{\gamma\in E^n \\ W(\gamma)<L}} A_\gamma.$$

Lean proves directly that $q_L(S^{\mathrm{pr}}_{L,N})$ equals the mapped geometric inverse whenever $q_L(A^N) = 0$, and hence is a two-sided inverse of $q_L(I+A)$, where $A = \sum_e A_e = D^{-1}H$. With the supplied two-sided inverse D^{-1} of D, this gives the explicit two-sided inverse

$$\boxed{q_L\left(S^{\mathrm{pr}}_{L,N}D^{-1}\right)} \quad \textit{of} \quad q_L(D+H).$$

If every edge weight is at least m and $L \leq mN$, then the nilpotence condition follows from the filtration data because $m|\gamma| \leq W(\gamma)$. For $m > 0$, the executable choice $N = \lceil L/m\rceil$ satisfies $L \leq mN$. This elementary ceiling inequality is also proved in Lean. The choice $m = 1, N = L$ gives the standard cutoff. In the DVR example $q_L : R \to R/\pi^L R$, this reads

$$q_L(T)^{-1} = q_L\left(\sum_{W(\gamma)<L}(-1)^{|\gamma|}A_\gamma D^{-1}\right).$$

Here $A_\gamma = (D^{-1}H_{e_1})\cdots(D^{-1}H_{e_r})$ in the written order. Multiplicativity places it in $F^{W(\gamma)}R$, so the quotient kills it when $W(\gamma) \geq L$. Positive weights also imply $|\gamma| \leq W(\gamma)$, making the retained search finite.

How to read the result

Using the standard length cutoff, every discarded word has weight at least the chosen depth and vanishes in the quotient. The retained sum therefore satisfies both inverse identities exactly at that precision. The earlier truncation theorem states the corresponding residual bounds in the complete filtered algebra itself.

The inherited finite-word contract proves the result in the finite quotients above and in the contraction specialization for complete normed rings. The complete filtered statement has its own separation and inverse-limit completeness hypotheses. Its Lean coverage is recorded separately in the correspondence.

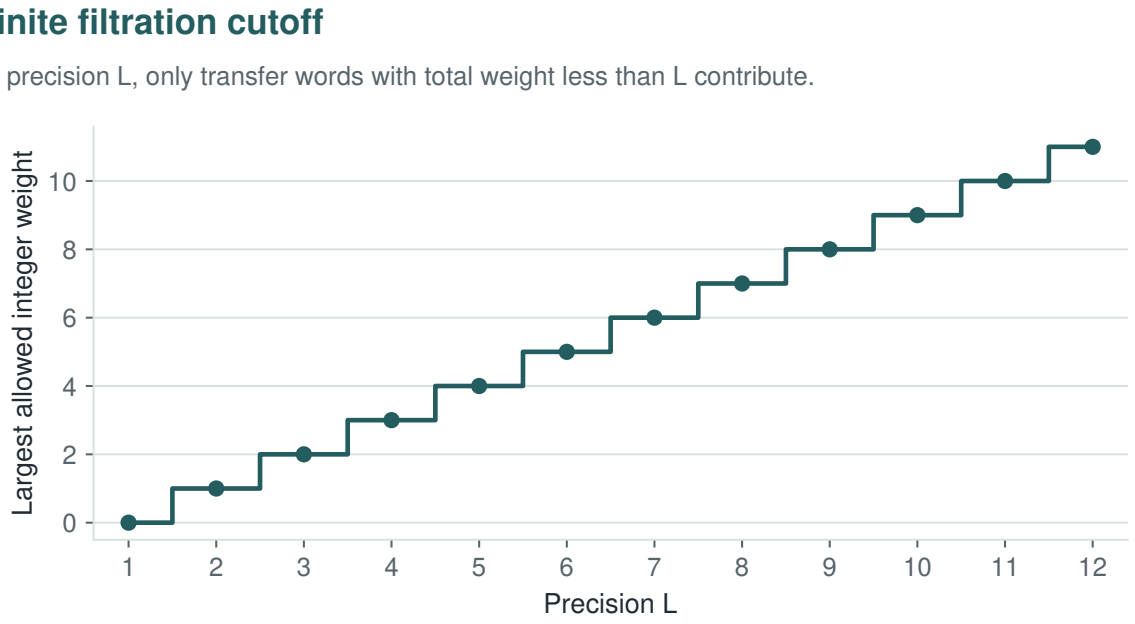


Figure 5. At precision L, weighted inversion requires only transfer words whose cumulative weight is below L.

6 Rational weighted transfer series

A finite weighted graph records which path terms can occur in the inverse. Collecting paths by total weight turns this support information into a generating function. The finite adjacency matrix makes that function rational.

Definition 6.1 (Weighted transfer series)**.** Let G be a finite directed multigraph. Give every edge e a positive integer weight $w(e)$ and a scalar multiplicity $m(e)$ in a field $\Bbbk$. Define the polynomial adjacency matrix

$$A(t)_{ij} = \sum_{e:i\to j} m(e)t^{w(e)}.$$

For column vectors u and v, define

$$Z_{u,v}(t) = \sum_{n\geq 0} a_n t^n,$$

where

$$a_n = \sum_{i,j} \sum_{\substack{\gamma: i\rightsquigarrow j \\ W(\gamma)=n}} u_i v_j \prod_{\nu=1}^{|\gamma|} m(e_\nu).$$

Here $\gamma = (e_1, \dots, e_{|\gamma|})$ is a directed walk. Vertices and edges may repeat, and the empty walk has weight zero and multiplicity one. Thus the endpoint vectors weight the start and end of each walk, rather than only selecting subsets of vertices.

Theorem 6.2 (Rationality of the transfer series)**.** *The weighted transfer series satisfies*

$$Z_{u,v}(t) = u^{\mathsf{T}}(I - A(t))^{-1}v.$$

It is a rational function whose denominator divides

$$\det(I - A(t)).$$

Proof. Since every entry of $A(t)$ has zero constant term, the inverse exists in the formal power series ring and

$$(I - A(t))^{-1} = \sum_{r\geq 0} A(t)^r.$$

The (i, j) entry of $A(t)^r$ is the sum of the monomials attached to all paths of length r from i to j. Summing over r records paths of every length. Multiplication by the endpoint vectors gives the stated series. The adjugate formula gives

$$(I - A(t))^{-1} = \frac{\operatorname{adj}(I - A(t))}{\det(I - A(t))},$$

so every entry is rational. □

Corollary 6.3 (Recurrence for path counts)**.** *Write*

$$Z_{u,v}(t) = \frac{P(t)}{Q(t)}, \qquad Q(t) = 1 + q_1 t + \cdots + q_d t^d.$$

Use the convention $\deg 0 = -\infty$*. Then, for every nonnegative integer* $n > \deg P$*,*

$$a_n + q_1 a_{n-1} + \cdots + q_d a_{n-d} = 0.$$

Proof. Compare coefficients in the identity

$$Q(t)Z_{u,v}(t) = P(t).$$

Beyond the degree of P, the coefficient on the right is zero. □

In the recurrence, set $a_k = 0$ when $k < 0$. This is the coefficient convention for the formal power series $Z_{u,v}(t)$ and makes the first recurrence equations meaningful even when $n < d$.

Corollary 6.4 (Several independent weights)**.** *Suppose every edge has a weight vector*

$$w(e) = (w_1(e), \dots, w_r(e)) \in \mathbb{N}^r \setminus \{0\}.$$

Replace $t^{w(e)}$ by

$$t_1^{w_1(e)} \cdots t_r^{w_r(e)}.$$

The resulting multigraded transfer series is rational in $t_1, \dots, t_r$.

Proof. The same matrix inverse proof works over the formal power series ring in several variables. The adjugate formula gives rationality. □

The multigraded form is useful when dyadic depth, odd depth, and another filtration are tracked separately rather than collapsed into one number.

Example 6.5 (A transfer series with one loop)**.** Take vertices 0, 1, and 2. Give the edge $0 \to 1$ weight one, the loop $1 \to 1$ weight two, and the edge $1 \to 2$ weight one. Every path from 0 to 2 uses the first and last edges and may traverse the loop any number of times. Hence

$$Z_{0,2}(t) = t^2(1 + t^2 + t^4 + \cdots) = \frac{t^2}{1 - t^2}.$$

There is one path at every positive even weight and no path at an odd weight. The denominator records the increase of two units produced by the loop.

6.1 Automatic finite-graph construction

Let G be a finite directed graph with positive integer edge weights. Define the polynomial adjacency matrix

$$A(t)_{ij} = \sum_{e : i \to j} t^{w(e)},$$

where parallel edges are distinct elements of the finite edge type and are therefore counted with their full multiplicity.

For fixed start and target vertices s, t, define

$$Z_{s,t}(t) = \sum_{n \geq 0} a_n(s,t) t^n,$$

where $a_n(s,t)$ counts directed walks from s to t with total weight n. Vertices and edges may repeat. Thus "path zeta" is retained as the name of the series and Lean API, but the walks are not required to visit each vertex only once.

Theorem 6.6 (Automatic finite-graph transfer-zeta rationality). *Assume the vertex and edge sets are finite and every edge has positive integer weight. For every n, exact enumeration of edge tuples of lengths at most n, followed by endpoint and total-weight filtering, returns $a_n(s,t)$. These coefficients obey the recurrence obtained by removing the first edge*

$$a_n(s,t) = \mathbf{1}_{s=t,\, n=0} + \sum_{\substack{e:\, \mathrm{source}(e)=s \\ w(e)\le n}} a_{n-w(e)}(\mathrm{target}(e), t).$$

Let

$$T(t) = I - A(t), \qquad Q(t) = \det T(t), \qquad P_{s,t}(t) = \mathrm{adj}(T(t))_{s,t}.$$

Then $Q(0) = 1$, hence $Q \neq 0$ and Q is a unit in $\mathbb{Z}[[t]]$, and the independently enumerated walk series satisfies

$$\boxed{Z_{s,t}(t) = Q(t)^{-1} P_{s,t}(t), \qquad Q(t) Z_{s,t}(t) = P_{s,t}(t)} \quad \text{in } \mathbb{Z}[[t]].$$

Proof. Every edge has weight at least one, so a word of weight n has length at most n. The enumerator therefore searches a finite set containing every contributing walk, and its filters are exactly the defining predicates for a_n. Removing the first edge gives the displayed disjoint decomposition into the empty diagonal walk and the first-edge tails. In matrix form this is

$$Z = I + AZ, \qquad (I - A)Z = I.$$

Positive weights give $A(0) = 0$, so $T(0) = I$ and $Q(0) = \det(I) = 1$. The two adjugate identities

$$T\,\mathrm{adj}(T) = QI, \qquad \mathrm{adj}(T)T = QI$$

remain valid after inclusion into $\mathbb{Z}[[t]]$. Multiplying the adjugate by the formal-series inverse of Q constructs a two-sided inverse of T. Uniqueness of the inverse identifies that construction with the independently enumerated matrix Z, yielding the entrywise formulas. □

This is the finite transfer-matrix method of [9], but here its determinant, adjugate, normalization, recurrence from the first edge, and identification with the enumerated series are all formalized. The older API accepting an independently supplied normalized coefficient identity $QZ = P$ is retained for external certificates. It is no longer needed to obtain rationality for the finite graph defined above. The Python companion performs an exact symbolic construction as an independent executable check.

Corollary 6.7 (Linear recurrence). *With the canonical polynomials from theorem 6.6, write*

$$Q(t) = \sum_k q_k t^k, \qquad Z_{s,t}(t) = \sum_{n\ge 0} a_n(s,t) t^n.$$

Then the walk counts satisfy the recurrence with constant coefficients determined by Q after the finite initial range contributed by $P_{s,t}$, with $\deg 0 = -\infty$:

$$\boxed{\sum_{k=0}^{n} q_k a_{n-k}(s,t) = 0 \qquad (n > \deg P_{s,t}).}$$

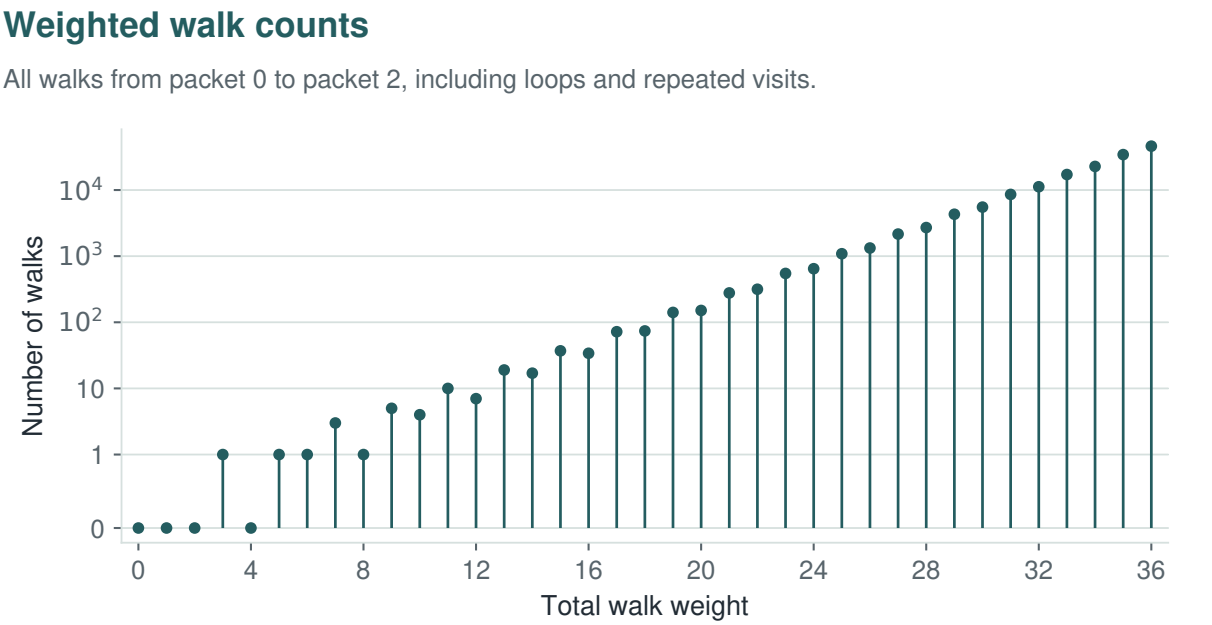

Figure 6. The walk counts for one weighted graph. The exact generating function is rational, so these counts satisfy a finite linear recurrence.

Example 6.8 (A computed transfer zeta)**.** For the graph used in the numerical companion, the walk series from packet 0 to packet 2 is

$$Z_{0,2}(t) = \frac{t^3}{1 - t^2 - t^3 - 2t^4 + t^5 + t^6 + t^7 - t^9}.$$

The first nonzero coefficients are

$$1, 1, 1, 3, 1, 5, 4, 10, 7, 19, 17, 37, \ldots$$

at their corresponding weights. Direct enumeration through weight 30 agrees coefficient by coefficient with the rational expansion.

7 Rational spectral projectors and resultant bounds

Let $\mathcal{O}$ be a discrete valuation ring with fraction field K and uniformizer π. Let Λ be a finite free $\mathcal{O}$ module and put

$$V = K \otimes_{\mathcal{O}} \Lambda.$$

Suppose $A \in \mathrm{End}_{\mathcal{O}}(\Lambda)$.

Theorem 7.1 (Bézout spectral projector)**.** *Assume that*

$$\chi_A(x) = f(x)g(x)$$

with monic polynomials $f, g \in \mathcal{O}[x]$ that are coprime in $K[x]$. Choose $u, v \in \mathcal{O}[x]$ and a nonzero $r \in \mathcal{O}$ such that

$$u(x)f(x) + v(x)g(x) = r.$$

Then

$$E_f = r^{-1}v(A)g(A)$$

is the projector of V onto Ker $f(A)$ *along* Ker $g(A)$. *In particular,*

$$E_f^2 = E_f, \qquad rE_f \in \mathrm{End}_{\mathcal{O}}(\Lambda).$$

Proof. Cayley Hamilton gives

$$f(A)g(A) = 0.$$

If $x \in \mathrm{Ker}\, f(A)$, then the Bézout identity gives

$$v(A)g(A)x = rx,$$

so $E_f x = x$. If $x \in \mathrm{Ker}\, g(A)$, then $E_f x = 0$. The same identity gives the direct sum decomposition

$$V = \mathrm{Ker}\, f(A) \oplus \mathrm{Ker}\, g(A).$$

Indeed, every $x \in V$ is the sum of

$$r^{-1}v(A)g(A)x \in \mathrm{Ker}\, f(A)$$

and

$$r^{-1}u(A)f(A)x \in \mathrm{Ker}\, g(A).$$

Thus E_f is the stated projector and is idempotent. The formula for rE_f has coefficients in $\mathcal{O}$, so it preserves Λ. □

Theorem 7.2 (Several coprime spectral packets)**.** *Assume*

$$\chi_A(x) = \prod_{i=1}^{r} f_i(x),$$

where the monic factors $f_i \in \mathcal{O}[x]$ are pairwise coprime in $K[x]$. Put

$$g_i = \prod_{j \neq i} f_j.$$

There are complementary projectors E_i with

$$\mathrm{im}\, E_i = \mathrm{Ker}\, f_i(A), \qquad \sum_i E_i = I, \qquad E_i E_j = 0 \quad (i \neq j).$$

One may choose E_i so that

$$\mathrm{Res}(f_i, g_i)E_i \in \mathrm{End}_{\mathcal{O}}(\Lambda)$$

up to multiplication of the resultant by a unit.

Proof. Apply theorem 7.1 to the factorization $\chi_A = f_i g_i$. The resulting projector is one on $\operatorname{Ker} f_i(A)$ and zero on every $\operatorname{Ker} f_j(A)$ with $j \neq i$. The direct sum decomposition follows from the polynomial Chinese remainder theorem. The orthogonality and sum identities follow by evaluating the corresponding idempotents in $K[x]/(\chi_A)$. The Sylvester Bézout relation for (f_i, g_i) gives the stated denominator bound. □

Corollary 7.3 (Resultant denominator bound)**.** *Under the hypotheses of theorem 7.1, one may take*

$$r = \operatorname{Res}(f, g)$$

up to multiplication by a unit. Therefore

$$\pi^{\operatorname{val}_\pi(\operatorname{Res}(f,g))} E_f \Lambda \subseteq \Lambda.$$

Proof. The Sylvester matrix construction gives a Bézout relation with right side equal to the resultant. Apply theorem 7.1. Standard facts about resultants may be found in [5, 3]. □

Example 7.4 (A resultant bound that is not exact)**.** Let

$$A = \operatorname{diag}(0, \pi^s)$$

on the standard lattice $\Lambda = \mathcal{O}^2$. The factors x and $x - \pi^s$ have resultant $-\pi^s$, up to the harmless choice of resultant order, but the two spectral projectors are the integral coordinate projectors. Their exact separation weight is zero. The resultant sees the closeness of the two eigenvalues. It does not see that the chosen lattice already splits along their eigenspaces.

> **How to read the result**
>
> A resultant bounds the denominator through the characteristic factors. The exact separation weight also depends on how the lattice sits inside the rational packet spaces. These are two stages of the calculation. First construct a rational projector with a known clearing denominator. Then measure the gluing of the chosen lattice to find the least denominator that actually works.

7.1 Evaluated certificates and explicit lattice action

7.1.1 Minimal evaluated Bézout identities

Let $\mathcal{O}$ be a DVR, $K = \operatorname{Frac}(\mathcal{O})$, and $A \in \operatorname{End}_{\mathcal{O}}(\Lambda)$ for a finite free lattice Λ. Suppose the characteristic polynomial factors over $\mathcal{O}$ as

$$\chi_A(x) = f(x)g(x),$$

where f and g are coprime over $K[x]$.

Theorem 7.5 (Evaluated Bézout spectral projector)**.** *Let $F, G, U, V \in \operatorname{End}_K(\Lambda \otimes_{\mathcal{O}} K)$ and let $r \in K^\times$. Suppose*

$$UF + VG = rI, \qquad FG = 0, \qquad FG = GF, \qquad GU = UG.$$

Put $N = VG$. Then

$$\boxed{N^2 = rN.}$$

Consequently the operator

$$\boxed{E = r^{-1}VG}$$

is idempotent, acts as the identity on $\ker F$*, and acts as zero on* $\ker G$*. If* V *and* G *preserve* Λ*, then*

$$rE = VG \in \mathrm{End}_{\mathcal{O}}(\Lambda).$$

Proof. The Bézout identity gives $N = rI - UF$. The two stated commutation relations and $FG = 0$ give

$$N(UF) = VGUF = VUGF = VUFG = 0.$$

Therefore

$$N^2 = N(rI - UF) = rN.$$

Since $r \neq 0$, $E^2 = r^{-2}N^2 = E$. If $Fx = 0$, the evaluated Bézout identity gives $VGx = rx$, hence $Ex = x$. If $Gx = 0$, then $Ex = 0$. The lattice assertion follows directly from $rE = VG$. □

The equality $N^2 = rN$ before division uses neither $r \neq 0$ nor the other pairwise commutation relations that hold in the polynomial application. Normalizing to E uses $r \neq 0$. Its action on $\ker F$ uses only the Bézout identity and $r \neq 0$, while vanishing on $\ker G$ follows immediately from $N = VG$. The bundled Lean certificate records all pairwise commutations as convenient evaluated polynomial data, but the minimal theorems expose only the hypotheses they consume.

For the polynomial application, one supplies $F = f(A)$, $G = g(A)$, $U = u(A)$, and $V = v(A)$. A Bézout or resultant identity $uf + vg = r$ evaluates to the first certificate, while $(fg)(A) = 0$ supplies the second. When $fg = \chi_A$, this last equality is Cayley Hamilton. Standard Bézout, resultant, and DVR facts are recalled from [5, 8]. The inherited certificate theorem begins with the evaluated certificate. It does not infer exact action merely from nilpotence of $f(A)$ or $g(A)$, which would be insufficient.

Definition 7.6 (Separation weight)**.** For a rational projector E and a specified $\mathcal{O}$ lattice Λ, provided at least one clearing exponent exists, define

$$s_{\pi,\Lambda}(E) = \min\{s \geq 0 : \pi^s E(\Lambda) \subseteq \Lambda\}.$$

If the evaluated certificate arises from integral v, g and $r = u\pi^s$ with u^{-1} preserving the lattice, then theorem 7.5 gives the upper bound

$$s_{\pi,\Lambda}(E) \leq s = \mathrm{val}_\pi(r).$$

Indeed,

$$\boxed{\pi^s E = u^{-1}VG}$$

preserves Λ. The minimal Lean theorem needs only the lattice action of u^{-1}. The bundled wrapper for lattice units records both u and u^{-1}. A nonzero scalar in the fraction field need not be an integral unit. Existence of a clearing exponent is an explicit hypothesis. Once one exists, the least one is obtained from the least element property of the natural numbers. Clearing exponents are upward closed provided multiplication by π preserves the lattice.

7.1.2 Certificate-level precision delay

Theorem 7.7 (Projector precision delay)**.** *Let E be a rational projector with $\pi^s E(\Lambda) \subseteq \Lambda$. If*

$$x \equiv y \pmod{\pi^{m+s}\Lambda},$$

then

$$Ex \equiv Ey \pmod{\pi^m \Lambda}.$$

Thus $m+s$ input digits suffice to determine m output digits of the projected packet.

Proof. Write $x - y = \pi^{m+s} z$. Since $\pi^s E(z) \in \Lambda$,

$$E(x-y) = \pi^m(\pi^s E(z)) \in \pi^m \Lambda.$$

□

The theorem gives a precision budget for delayed separation. A packet with weight s can be reconstructed at the requested output precision by retaining s additional input digits.

8 Exact lattice separation

The exact denominator belongs to the pair consisting of the rational packet decomposition and the integral lattice.

Definition 8.1 (Lattice packet data)**.** Let

$$V = \bigoplus_{\alpha \in I} V_\alpha$$

be a finite direct sum over K, with packet projectors E_α. Let $\Lambda \subseteq V$ be an $\mathcal{O}$ lattice. Put

$$\Lambda_\alpha = \Lambda \cap V_\alpha, \qquad \Lambda_{\text{split}} = \bigoplus_\alpha \Lambda_\alpha,$$

and define the gluing module

$$G_{\Lambda,\mathcal{P}} = \Lambda / \Lambda_{\text{split}}.$$

The separation weight of E_α is

$$s_\Lambda(E_\alpha) = \min\{s \geq 0 : \pi^s E_\alpha \Lambda \subseteq \Lambda\}.$$

The global separation weight is

$$s_\Lambda(\mathcal{P}) = \max(\{0\} \cup \{s_\Lambda(E_\alpha) : \alpha \in I\}).$$

For a finitely generated torsion $\mathcal{O}$ module G, write $\exp_\pi(G)$ for the least s such that $\pi^s G = 0$.

The gluing module $G_{\Lambda,\mathcal{P}}$ is a finitely generated torsion $\mathcal{O}$ module, hence has finite length, because Λ_{split} and Λ are full lattices in the same vector space. To see that the split lattice is full, clear denominators of bases of the rational summands. Each $\Lambda \cap V_\alpha$ then spans V_α, so their direct sum spans V.

Theorem 8.2 (Gluing module and exact separation weight). *With the notation of definition 8.1, the map*

$$\Phi : G_{\Lambda,\mathcal{P}} \longrightarrow \bigoplus_{\alpha \in I} E_\alpha \Lambda / \Lambda_\alpha, \qquad [x] \longmapsto (E_\alpha x + \Lambda_\alpha)_\alpha$$

is injective, and every coordinate projection of its image is surjective. We also have

$$\boxed{\exp_\pi(G_{\Lambda,\mathcal{P}}) = s_\Lambda(\mathcal{P}).}$$

If

$$G_{\Lambda,\mathcal{P}} \cong \bigoplus_{j=1}^{r} \mathcal{O}/\pi^{a_j}\mathcal{O}$$

with $a_1 \le \cdots \le a_r$, then

$$s_\Lambda(\mathcal{P}) = \max(\{0\} \cup \{a_j : 1 \le j \le r\}).$$

Proof. If $x \in \Lambda$ maps to zero, then $E_\alpha x \in \Lambda_\alpha$ for every α. Since

$$x = \sum_\alpha E_\alpha x,$$

we have $x \in \Lambda_{\text{split}}$. Thus Φ is injective. The coordinate map onto $E_\alpha\Lambda/\Lambda_\alpha$ is surjective by the definition of $E_\alpha\Lambda$.

Let $s = s_\Lambda(\mathcal{P})$. For every $x \in \Lambda$ and every α,

$$\pi^s E_\alpha x \in \Lambda_\alpha.$$

Hence

$$\pi^s x = \sum_\alpha \pi^s E_\alpha x \in \Lambda_{\text{split}},$$

so $\pi^s G_{\Lambda,\mathcal{P}} = 0$. This proves

$$\exp_\pi(G_{\Lambda,\mathcal{P}}) \le s.$$

If $d < s$, then for some α there is an $x \in \Lambda$ with

$$\pi^d E_\alpha x \notin \Lambda_\alpha.$$

The class $\pi^d[x]$ is therefore nonzero in the gluing module. Thus π^d does not annihilate the gluing module, and equality follows. The final formula is the usual description of the exponent through Smith normal form. □

Corollary 8.3 (Total gluing and worst precision). *If*

$$G_{\Lambda,\mathcal{P}} \cong \bigoplus_{j=1}^{r} \mathcal{O}/\pi^{a_j}\mathcal{O},$$

then

$$\operatorname{length}_{\mathcal{O}}(G_{\Lambda,\mathcal{P}}) = \sum_{j=1}^{r} a_j, \qquad s_\Lambda(\mathcal{P}) = \max(\{0\} \cup \{a_j : 1 \le j \le r\}).$$

Thus the lattice index measures the total amount of gluing, while the separation weight measures the worst precision loss in one direction.

Proof. The length and exponent of a finitely generated torsion module are read directly from its Smith decomposition. Apply theorem 8.2. □

Corollary 8.4 (Two complementary packets)**.** *Suppose*

$$V = V_1 \oplus V_2$$

with projector E onto V_1 and complementary projector $I - E$. Then

$$\Lambda/(\Lambda_1 \oplus \Lambda_2) \cong E\Lambda/\Lambda_1 \cong (I-E)\Lambda/\Lambda_2.$$

Consequently

$$s_\Lambda(E) = s_\Lambda(I-E) = \exp_\pi(\Lambda/(\Lambda_1 \oplus \Lambda_2)).$$

Proof. Map $x \in \Lambda$ to $Ex + \Lambda_1$. Its kernel consists of the x for which $Ex \in \Lambda_1$. In that case

$$(I-E)x = x - Ex \in \Lambda \cap V_2 = \Lambda_2,$$

so the kernel is $\Lambda_1 \oplus \Lambda_2$. The map is surjective by definition. The complementary map is handled in the same way. The equality of weights follows from theorem 8.2. □

Corollary 8.5 (Integral splitting criterion)**.** *Every packet projector preserves Λ if and only if*

$$\Lambda = \bigoplus_{\alpha} (\Lambda \cap V_\alpha).$$

Equivalently,

$$s_\Lambda(\mathcal{P}) = 0 \quad \Longleftrightarrow \quad G_{\Lambda,\mathcal{P}} = 0.$$

Proof. If every projector preserves Λ, then

$$x = \sum_{\alpha} E_\alpha x$$

expresses every $x \in \Lambda$ as a sum of vectors in Λ_α. The converse is immediate because each projector is the identity on one direct summand and zero on the others. The final equivalence follows from theorem 8.2. □

8.1 Refinement and separation weight

A finer rational packet system imposes more integral splitting conditions.

Theorem 8.6 (Gluing exact sequence under refinement)**.** *Let $\mathcal{Q} = (Q_\beta)$ refine $\mathcal{P} = (P_\alpha)$ on V, and let Λ be a lattice. Define*

$$\Lambda_{\mathcal{P}} = \bigoplus_\alpha (\Lambda \cap P_\alpha V), \qquad \Lambda_{\mathcal{Q}} = \bigoplus_\beta (\Lambda \cap Q_\beta V).$$

Then

$$\Lambda_{\mathcal{Q}} \subseteq \Lambda_{\mathcal{P}} \subseteq \Lambda$$

and there is a short exact sequence

$$0 \longrightarrow \Lambda_{\mathcal{P}}/\Lambda_{\mathcal{Q}} \longrightarrow \Lambda/\Lambda_{\mathcal{Q}} \longrightarrow \Lambda/\Lambda_{\mathcal{P}} \longrightarrow 0.$$

In particular,

$$\boxed{s_\Lambda(\mathcal{P}) \le s_\Lambda(\mathcal{Q}).}$$

Proof. Every fine packet space lies in its parent packet space, so every element of $\Lambda_{\mathcal{Q}}$ belongs to $\Lambda_{\mathcal{P}}$. The displayed exact sequence is the standard quotient sequence for nested submodules. The exponent of a quotient cannot exceed the exponent of the module from which it is obtained. Apply theorem 8.2 to the two gluing modules. □

Example 8.7 (Strict growth under refinement)**.** Take the standard lattice $\mathbb{Z}_2^2$ and the involution from proposition 9.1. The one packet system (I) has weight zero. Refining it into the two rational sign packets produces weight one. The coarse lattice is already split because there is only one summand. The fine eigenspaces are glued together by one dyadic digit.

Remark 8.8 (Strict growth can occur). A coarse packet family may preserve the lattice even though a fine spectral split does not. Refinement can reveal rational directions that are glued together integrally. The weight records the extra depth needed to separate them.

8.2 Exact precision delay

The separation weight has an operational meaning. It is the exact number of extra input digits needed to recover a projected packet uniformly.

Theorem 8.9 (Necessary and sufficient precision delay)**.** *Let E be a rational projector on V, let Λ be a lattice, and let*

$$s = s_\Lambda(E).$$

For every $m \ge 0$, the rule

$$[x]_{m+s} \longmapsto [Ex]_m$$

from $\Lambda/\pi^{m+s}\Lambda$ to $V/\pi^m\Lambda$ is well defined. Here m is an integer. If d is an integer with $0 \le d < s$, then for every integer $m \ge 0$ there are $x, y \in \Lambda$ such that

$$x \equiv y \pmod{\pi^{m+d}\Lambda}$$

but

$$Ex \not\equiv Ey \pmod{\pi^m\Lambda}.$$

Thus s extra digits are both sufficient and necessary for a uniform precision guarantee.

Proof. If

$$x - y = \pi^{m+s} z,$$

then

$$E(x-y) = \pi^m(\pi^s E z) \in \pi^m \Lambda.$$

This proves that the rule is well defined. Now take $d < s$. By the minimality of s, there is a $z \in \Lambda$ with

$$\pi^d E z \notin \Lambda.$$

Set

$$x = \pi^{m+d} z, \qquad y = 0.$$

Then $x \equiv y$ modulo $\pi^{m+d}\Lambda$, while

$$E(x-y) = \pi^m(\pi^d E z) \notin \pi^m \Lambda.$$

□

The central idea

The necessity statement is uniform over the lattice. A particular input may need fewer extra digits, but a smaller delay cannot recover every projected packet at the prescribed precision. This is why the least clearing exponent gives an exact precision guarantee rather than only a sufficient budget.

Example 8.10 (The same rational split with two lattices)**.** Let

$$V = Ke_1 \oplus Ke_2$$

and let E project onto Ke_1. On the split lattice

$$\Lambda_0 = \mathcal{O}e_1 \oplus \mathcal{O}e_2,$$

the weight is zero. Fix $s \geq 1$ and consider

$$\Lambda_s = \mathcal{O}e_1 + \mathcal{O}(\pi^{-s}e_1 + e_2).$$

Then

$$\Lambda_s \cap Ke_1 = \mathcal{O}e_1, \qquad \Lambda_s \cap Ke_2 = \pi^s \mathcal{O}e_2.$$

The gluing module is isomorphic to $\mathcal{O}/\pi^s\mathcal{O}$, so

$$s_{\Lambda_s}(E) = s.$$

The rational decomposition has not changed. Only the lattice has changed.

The example can be realized by an integral operator. Define

$$Ae_1 = 0, \qquad Ae_2 = \pi^s e_2.$$

In the basis

$$e_1, \quad \pi^{-s}e_1 + e_2,$$

the matrix of A is

$$\begin{pmatrix} 0 & -1 \\ 0 & \pi^s \end{pmatrix}.$$

Its eigenvalue factors have resultant equal to π^s up to a unit, and the exact projector weight on Λ_s is also s.

9 The dyadic sign split

The smallest example already shows why coefficient selectors and spectral averages must be kept distinct.

Proposition 9.1 (Sign projectors over a lattice)**.** *Let*

$$A = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}$$

act on $\mathbb{Z}_p^2$. Over $\mathbb{Q}_p$, the sign projectors are

$$E_+ = \frac{I + A}{2} = \begin{pmatrix} 1 & 1/2 \\ 0 & 0 \end{pmatrix},$$

$$E_- = \frac{I - A}{2} = \begin{pmatrix} 0 & -1/2 \\ 0 & 1 \end{pmatrix}.$$

For every odd prime p, both projectors preserve $\mathbb{Z}_p^2$. At $p = 2$,

$$s_2(E_+) = s_2(E_-) = 1.$$

The factors $x - 1$ and $x + 1$ have resultant 2.

Proof. The displayed matrices are complementary idempotents. The scalar 2 is a unit in $\mathbb{Z}_p$ for odd p, so both matrices are integral there. Over $\mathbb{Z}_2$, multiplying by 2 clears the denominators, while neither projector preserves the standard lattice. Thus both weights are one. The resultant of the two linear factors is their root difference, which is 2. □

Modulo 2, the two eigenvalues become equal. The rational sign packets remain distinct over $\mathbb{Q}_2$, but the standard lattice does not split into their intersections until one more dyadic digit is retained.

Proposition 9.2 (Integral character averages away from the group order)**.** *Let $\mathcal{O}$ be a discrete valuation ring, let N be a unit in $\mathcal{O}$, and suppose $\mathcal{O}$ contains a primitive Nth root of unity ω. If an integral operator U satisfies $U^N = I$, then*

$$E_j = \frac{1}{N} \sum_{k=0}^{N-1} \omega^{-jk} U^k$$

preserves every U stable $\mathcal{O}$ lattice. At primes dividing N, this formula alone gives no integral projector.

Proof. Every scalar coefficient in the displayed sum belongs to $\mathcal{O}$ because N is a unit and ω is integral. Each power of U preserves the lattice, so their $\mathcal{O}$ linear combination does as well. When N is not a unit, division by N is not an operation in $\mathcal{O}$, so the same argument is unavailable. □

At a prime dividing N, the factor $1/N$ no longer guarantees that the character average preserves the lattice. Cancellation may still make a particular projector integral. Coefficient residue selectors remain exact because they never divide by the group order.

9.1 The concrete rational sign matrix

Consider the integral involution

$$A = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}, \qquad A^2 = I.$$

Over a field of characteristic different from two, its sign projectors are

$$E_+ = \frac{I + A}{2} = \begin{pmatrix} 1 & 1/2 \\ 0 & 0 \end{pmatrix},$$

$$E_- = \frac{I - A}{2} = \begin{pmatrix} 0 & -1/2 \\ 0 & 1 \end{pmatrix}.$$

They are orthogonal idempotents and sum to I.

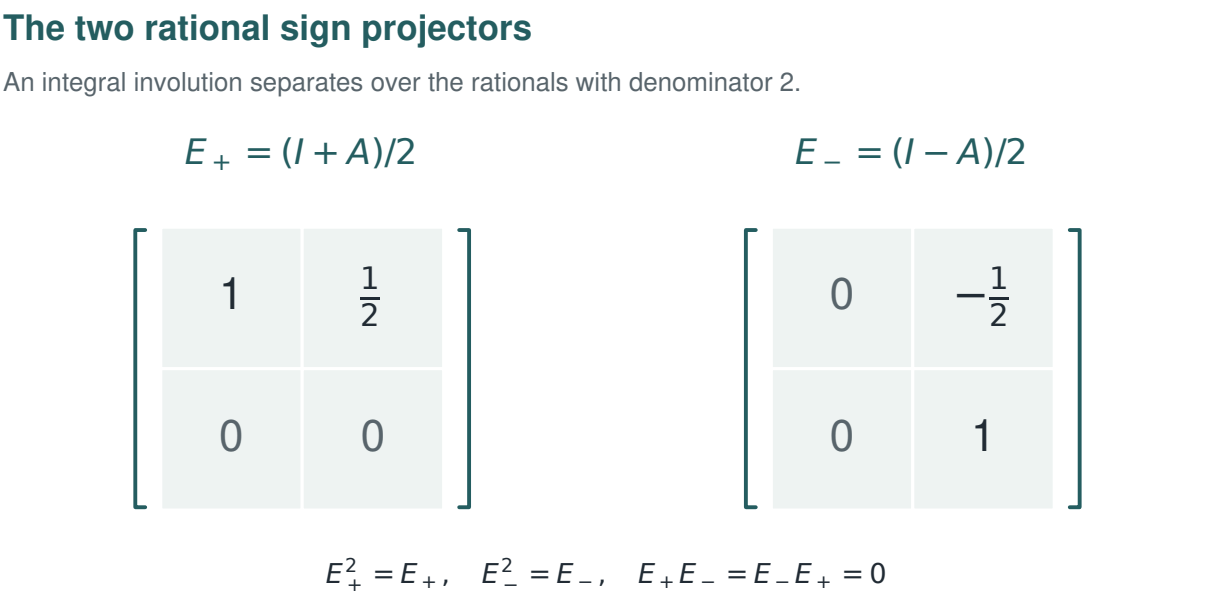

Figure 7. The rational sign projectors for an integral involution. Their denominator has 2-adic weight one.

Proposition 9.3 (Odd-adic versus dyadic behavior)**.** *For every prime $p \neq 2$, every entry of E_+ and E_- is p-integral, and each projector has exact local denominator weight zero. At $p = 2$, each projector has exact local denominator weight one. Multiplication by 2 makes it integral, while the unscaled matrix is not integral:*

$$s_{2,\mathbb{Z}_2^2}(E_+) = s_{2,\mathbb{Z}_2^2}(E_-) = 1.$$

The characteristic factors $x-1$ and $x+1$ have resultant 2. Its 2-adic valuation is one, matching both local projector weights above, and its p-adic valuation is zero at every prime $p \neq 2$.

Proof. The reduced denominators of the displayed entries are 1 or 2, which proves the local integrality and minimality statements directly. The resultant is

$$\operatorname{Res}(x-1, x+1) = 2.$$

Thus $v_2(2) = 1$ and $v_p(2) = 0$ for primes $p \neq 2$. □

The two characteristic factors $x-1$ and $x+1$ have the same reduction in $\mathbb{F}_2[x]$. The rational matrices E_+ and E_- themselves cannot be reduced modulo 2, because their entries contain $1/2$. Consequently the integral special fiber does not inherit their separate idempotent splitting, even though the two projectors remain distinct over $\mathbb{Q}_2$. This is the simplest model of delayed dyadic separation.

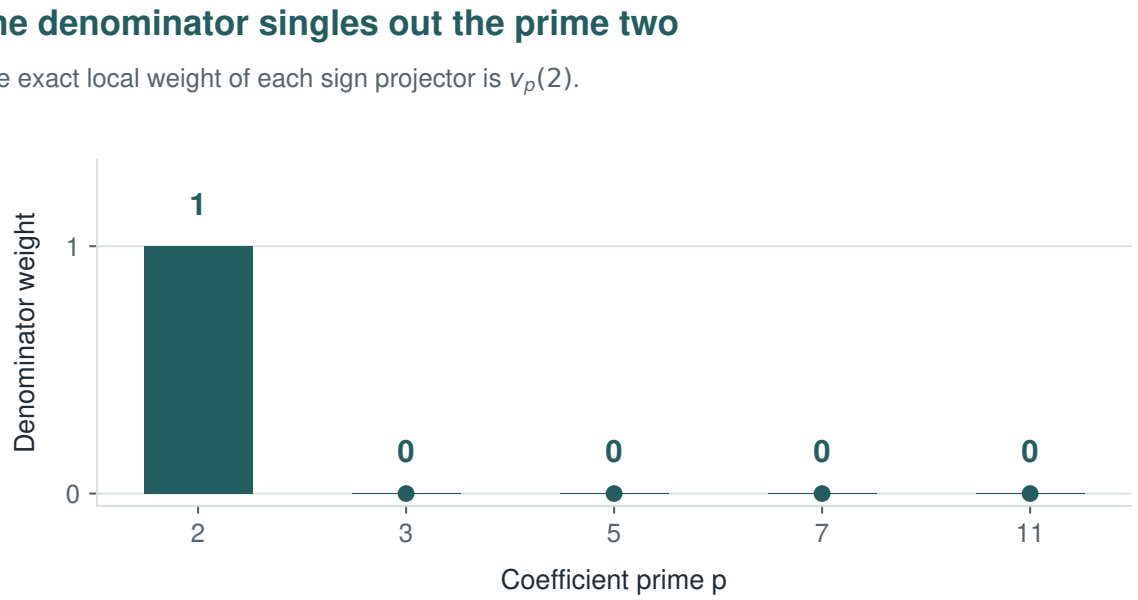

Figure 8. The denominator weight of the sign projector is nonzero only at the prime two.

9.1.1 Why coefficient packets remain available

The failure of the character formula

$$\frac{1}{2}(I \pm A)$$

to be integral does not invalidate coefficient selectors such as even and odd residue extraction. It shows that two distinct constructions must be distinguished:

integral address selector	$\neq$	character-average spectral projector

when the group order is not a unit. The first can remain exact over $\mathbb{Z}_2$. The second can acquire a denominator weight.

10 Smith normal form and congruence lifting

The gluing module gives the exact common denominator of packet projectors. Smith normal form gives the corresponding coordinate by coordinate solvability and branching rule.

Standard Fact 10.1 (Smith normal form over a discrete valuation ring)**.** Let $M \in M_{m,n}(\mathcal{O})$. There are invertible matrices

$$U \in \mathrm{GL}_m(\mathcal{O}), \qquad V \in \mathrm{GL}_n(\mathcal{O})$$

such that

$$UMV = \mathrm{diag}(\pi^{s_1}, \dots, \pi^{s_r}, 0, \dots, 0),$$

where

$$0 \le s_1 \le \cdots \le s_r$$

and r is the rank over K. The exponents are uniquely determined. See [6].

Proposition 10.2 (Computing a packet weight from an inclusion matrix)**.** *Choose an $\mathcal{O}$ basis of Λ and an $\mathcal{O}$ basis of Λ_{split}. Let B be the matrix of the inclusion*

$$\Lambda_{\mathrm{split}} \hookrightarrow \Lambda.$$

If the Smith form of B is

$$\mathrm{diag}(\pi^{a_1}, \dots, \pi^{a_n}), \qquad 0 \le a_1 \le \cdots \le a_n,$$

then

$$G_{\Lambda,\mathcal{P}} \cong \bigoplus_{j=1}^{n} \mathcal{O}/\pi^{a_j}\mathcal{O}, \qquad s_\Lambda(\mathcal{P}) = \max(\{0\} \cup \{a_j : 1 \le j \le n\}).$$

Proof. The gluing module is the cokernel of the inclusion matrix B. Smith normal form gives its invariant factors. The weight formula follows from theorem 8.2. □

Theorem 10.3 (Smith weighted congruence solve)**.** *Let $M \in M_{m,n}(\mathcal{O})$ have Smith exponents $s_1, \dots, s_r$. Assume the residue field is finite of cardinality q, fix $L \ge 1$, and consider*

$$Mx \equiv b \pmod{\pi^L}.$$

Put

$$\tilde{b} = Ub$$

for a Smith matrix U as in standard fact 10.1. The congruence is solvable if and only if

$$\tilde{b}_i \equiv 0 \pmod{\pi^{\min(s_i, L)}} \qquad (1 \le i \le r)$$

and

$$\tilde{b}_i \equiv 0 \pmod{\pi^L} \qquad (r < i \le m).$$

When it is solvable, the number of solutions in $(\mathcal{O}/\pi^L\mathcal{O})^n$ is

$$\boxed{q^{(n-r)L + \sum_{i=1}^{r} \min(s_i, L)}.}$$

Proof. Set $x = Vy$. Multiplying the congruence by U reduces it to independent equations

$$\pi^{s_i} y_i \equiv \tilde{b}_i \pmod{\pi^L} \qquad (1 \le i \le r)$$

and zero equations in the remaining rows. Multiplication by π^{s_i} on $\mathcal{O}/\pi^L\mathcal{O}$ has image equal to the elements divisible by $\pi^{\min(s_i,L)}$ and kernel of size

$$q^{\min(s_i,L)}.$$

Each of the $n - r$ unused variables is free and contributes q^L choices. Multiplying the independent counts gives the formula. □

Corollary 10.4 (Obstruction and branching data)**.** *The transformed entries of $\tilde{b}$ that fail the stated divisibility conditions are the complete finite congruence obstructions. When all obstructions vanish, the Smith exponents determine the number of solution branches at depth L.*

Proof. This is exactly the solvability and counting statement of theorem 10.3 written in invariant coordinates. □

Example 10.5 (Three weighted directions)**.** Take $p = 2$, $L = 6$, and the diagonal weights

$$(0, 1, 3).$$

The right side

$$(1, 2, 8)$$

is admissible. The three coordinate kernels have sizes

$$1, \quad 2, \quad 8,$$

so there are 16 solutions. Replacing the final entry 8 by 4 violates the required divisibility by 2^3 and makes the system unsolvable.

10.1 Concrete diagonal fibers over integer quotients

Let M be a matrix over a DVR. Smith normal form gives invertible matrices U, V such that

$$UMV = \operatorname{diag}(\pi^{s_1}u_1, \dots, \pi^{s_r}u_r, 0, \dots, 0),$$

where each u_i is a unit and

$$0 \le s_1 \le \cdots \le s_r.$$

The exponents s_i are directional lifting weights.

Theorem 10.6 (Concrete Smith-weighted congruence solve)**.** *Let $p > 1$ and consider the diagonal system over $(\mathbb{Z}/(p^L)\mathbb{Z})^d$*

$$\operatorname{diag}(p^{s_1}, \dots, p^{s_d})x = b \pmod{p^L}.$$

The system is solvable if and only if

$$p^{\min(s_i,L)} \mid (b_i)_{\mathrm{val}}$$

for every i, where $(b_i)_{\mathrm{val}}$ is the canonical natural representative. Conditional on this admissibility condition, the number of solutions is

$$\boxed{p^{\sum_{i=1}^{d} \min(s_i, L)}.}$$

If any coordinate is inadmissible, the solution set is empty and its cardinality is zero.

Proof. Lean proves the one-coordinate arithmetic directly over $\mathbb{Z}/p^L\mathbb{Z}$ for every $p > 1$:

$$(\exists x \in \mathbb{Z}/p^L\mathbb{Z} : \quad p^s x = b \pmod{p^L}) \quad \Longleftrightarrow \quad p^{\min(s,L)} \mid b_{\mathrm{val}},$$

where b_{val} is the canonical natural representative, and every admissible fiber has exactly $p^{\min(s,L)}$ elements. The coordinates are independent, so the product equivalence gives the displayed global count. If one coordinate fiber is empty, the global fiber is empty. Lean proves both the global solvability equivalence and the conditional count, including cardinality zero on the inadmissible branch. □

For an arbitrary DVR $\mathcal{O}$ with residue field cardinality q, the analogous formula

$$q^{\sum_i \min(s_i, L)}$$

follows from the solvability and fiber count for each coordinate. The formal correspondence records direct proofs of this DVR coordinate arithmetic and the rectangular transport as separate targets. The inherited abstract product interface remains available when the coordinate facts are supplied as certificates. A Smith form and its changes of basis are inputs to the transport statement. It does not provide an extracted diagonalization routine. See [8, 5].

If a Smith form is rank deficient, a literal zero diagonal factor requires the corresponding target coordinate to vanish modulo p^L and then contributes all p^L possible coordinate values. In the concrete quotient it can equivalently be represented by any weight $s_i \geq L$, since $p^{s_i} = 0$ in $\mathbb{Z}/(p^L)\mathbb{Z}$. The theorem then gives exactly that condition and factor. The numbered theorem takes the diagonal data as its input.

Example 10.7. At $p = 2$, depth $L = 6$, and weights $(0, 1, 3)$, the right side $(1, 2, 8)$ is admissible. The coordinate kernels have sizes

$$1, 2, 8,$$

so the system has 16 solutions. Replacing 8 by 4 in the final coordinate violates the divisibility condition and makes the system unsolvable.

How to read the result

The gluing calculation takes the largest Smith weight because every packet must be separated to the requested precision. The congruence calculation retains the individual directional weights. A coordinate with weight s_i contributes a solvability threshold and $\min(s_i, L)$ to the branching exponent. The independent coordinate counts multiply, so these truncated weights add in the exponent.

11 Linear refinement defects

Exact coordinate refinement describes two representations of the same object. In an application, the coarse operator may instead be chosen to model coarse dynamics. An intertwining defect measures the mismatch between applying the operator before or after passing to coarse coordinates.

Let X_f and X_c be vector spaces or Banach spaces over a common field, and let

$$C : X_f \longrightarrow X_c$$

be a linear map, and let

$$T_f \in \mathrm{End}(X_f), \qquad T_c \in \mathrm{End}(X_c).$$

Define

$$\Delta = CT_f - T_c C.$$

The central idea

There are two routes from a fine state to a coarse result. One applies the fine operator and then maps the result to the coarse space. The other maps the state first and then applies the coarse operator. The defect is the difference between these routes. Its vanishing says that the chosen operators are compatible with the comparison map. The norm estimates below combine the size of this defect with the norms of the surrounding operators.

Theorem 11.1 (Power defect identity)**.** *For every integer $n \geq 1$,*

$$CT_f^n - T_c^n C = \sum_{k=0}^{n-1} T_c^{n-1-k} \Delta T_f^k.$$

Proof. The statement is clear for $n = 1$. For the induction step, write

$$CT_f^{n+1} - T_c^{n+1} C = (CT_f^n - T_c^n C)T_f + T_c^n (CT_f - T_c C)$$

and apply the induction hypothesis. □

Corollary 11.2 (Power norm bound)**.** *For bounded operators between Banach spaces,*

$$\|CT_f^n - T_c^n C\| \leq \|\Delta\| \sum_{k=0}^{n-1} \|T_c\|^{n-1-k} \|T_f\|^k.$$

Proof. Apply the triangle inequality and submultiplicativity to theorem 11.1. □

Corollary 11.3 (Norm bound)**.** *For a submultiplicative operator norm,*

$$\|CT_f^n - T_c^n C\| \leq \|\Delta\| \sum_{k=0}^{n-1} \|T_c\|^{n-1-k} \|T_f\|^k.$$

If $\|T_f\|, \|T_c\| \leq \rho$, then

$$\boxed{\|CT_f^n - T_c^n C\| \leq n\rho^{n-1} \|\Delta\|.}$$

Corollary 11.4 (Polynomial defect)**.** *For*

$$p(z) = \sum_{n=0}^{N} a_n z^n,$$

we have

$$Cp(T_f) - p(T_c)C = \sum_{n=1}^{N} a_n \sum_{k=0}^{n-1} T_c^{n-1-k} \Delta T_f^k.$$

Proof. The constant terms cancel because $CI = IC$. Apply theorem 11.1 to every positive power and sum. □

Theorem 11.5 (Resolvent defect identity)**.** *If $z - T_f$ and $z - T_c$ are invertible, then*

$$C(z - T_f)^{-1} - (z - T_c)^{-1}C = (z - T_c)^{-1}\Delta(z - T_f)^{-1}.$$

Proof. Multiply the claimed identity on the left by $z - T_c$ and on the right by $z - T_f$. The left side becomes

$$(z - T_c)C - C(z - T_f) = CT_f - T_cC = \Delta.$$

Multiplying back by the two resolvents proves the formula. □

11.1 Inverse witnesses from one side and norm control

For continuous linear maps, the same identity gives the certified norm bound

$$\boxed{\|CR_f - R_cC\| \le \|R_c\|\,\|\Delta\|\,\|R_f\|,}$$

from a left inverse witness for the coarse scalar shift and a right inverse witness for the fine scalar shift. These witnesses suffice for the displayed identity. On their own, they need not define inverses on both sides and hence need not define resolvents. If $\Delta = 0$, Lean also proves, for every finite polynomial p, the exact compatibility

$$\boxed{C\,p(T_f) = p(T_c)\,C,}$$

in both the algebraic setting and the setting of continuous linear maps. Thus all powers and polynomial actions intertwine with coarse reconstruction. The stated inverse witnesses also intertwine. In particular, genuine resolvents do so when the scalar shifts are invertible. This is the linear prototype of the more general theory of refinement defects reserved for Chapter III.

11.2 Analytic functional calculus

Theorem 11.6 (Holomorphic functional calculus defect)**.** *Let X_f and X_c be complex Banach spaces, and let $C : X_f \to X_c$, T_f, and T_c be bounded complex-linear maps. Let h be holomorphic on an open set U containing both spectra. Let Γ be an admissible finite rectifiable Cauchy cycle in U and in both resolvent*

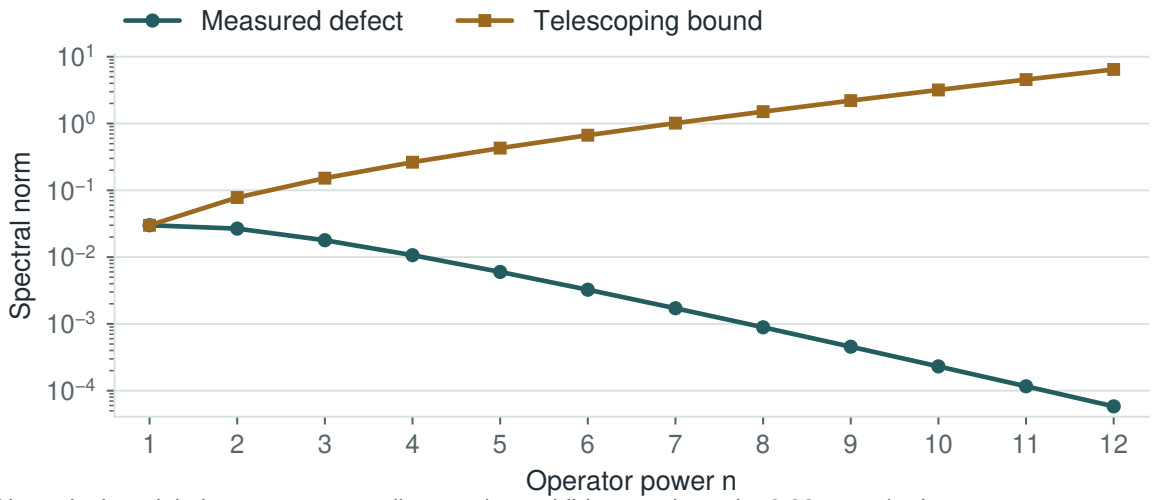

Figure 9. A controlled defect for one step and its telescoping norm bound under repeated operator application.

sets, with winding number one on the union of the spectra and zero outside U. The length of a cycle counts multiplicities. Then

$$Ch(T_f) - h(T_c)C = \frac{1}{2\pi i}\int_\Gamma h(z)(z - T_c)^{-1}\Delta(z - T_f)^{-1}\,dz.$$

Consequently,

$$\|Ch(T_f) - h(T_c)C\| \le \frac{\operatorname{length}(\Gamma)}{2\pi}\sup_{z\in\Gamma}|h(z)|\,\|\Delta\| \times \sup_{z\in\Gamma}\|(z - T_c)^{-1}\|\sup_{z\in\Gamma}\|(z - T_f)^{-1}\|.$$

Proof. The assertion is immediate if either space is zero. Otherwise, use the rectifiable-cycle form of the holomorphic functional calculus in [1, Chapter VII, §4, Theorem 4.1, formula (4.5), and Proposition 4.6]. For each operator T, compare Γ with a positive simple system around its spectrum. Their difference has zero winding outside $U \setminus \sigma(T)$, so Theorem 4.1 applied to the resolvent-valued integrand identifies the two integrals. Consequently,

$$h(T) = \frac{1}{2\pi i}\int_\Gamma h(z)(z - T)^{-1}\,dz.$$

Subtract the two formulas after composing with C, then use theorem 11.5 inside the integral. The norm estimate follows from the standard contour bound. □

Theorem 11.7 (Exponential defect identity). *Let $C : X_f \to X_c$, T_f, and T_c be bounded linear maps between Banach spaces over a common field. For real t, use real or complex spaces. For complex t, use complex spaces and complex-linear maps. Then*

$$Ce^{tT_f} - e^{tT_c}C = \int_0^t e^{(t-s)T_c}\Delta e^{sT_f}\,ds,$$

where the integral is taken along the straight segment from 0 to t when t is complex. For real $t \geq 0$,

$$\|Ce^{tT_f} - e^{tT_c}C\| \leq \|\Delta\| \int_0^t \|e^{(t-s)T_c}\|\|e^{sT_f}\|\,ds.$$

Proof. For real t, differentiate

$$F(s) = e^{(t-s)T_c}Ce^{sT_f}.$$

We obtain

$$F'(s) = e^{(t-s)T_c}\Delta e^{sT_f}.$$

Integration from 0 to t gives the identity. The complex statement follows by the same calculation along the straight segment. The norm bound follows from the integral formula. □

11.3 Several refinement levels

Let

$$C_\ell : X_{\ell+1} \longrightarrow X_\ell$$

be linear maps for $0 \leq \ell < L$, and let $T_\ell \in \mathrm{End}(X_\ell)$. Put

$$\Delta_\ell = C_\ell T_{\ell+1} - T_\ell C_\ell.$$

For $a < b$, write

$$C_{a,b} = C_a C_{a+1} \cdots C_{b-1},$$

with $C_{a,a} = I$.

Theorem 11.8 (Multilevel defect decomposition). *The total defect from level L to level zero is*

$$C_{0,L}T_L - T_0 C_{0,L} = \sum_{\ell=0}^{L-1} C_{0,\ell}\Delta_\ell C_{\ell+1,L}.$$

For bounded maps,

$$\|C_{0,L}T_L - T_0 C_{0,L}\| \leq \sum_{\ell=0}^{L-1} \|C_{0,\ell}\|\|\Delta_\ell\|\|C_{\ell+1,L}\|.$$

Proof. Insert the intermediate terms

$$C_{0,\ell}T_\ell C_{\ell,L}$$

for $0 \le \ell \le L$. Consecutive differences telescope. The difference between the terms indexed by $\ell + 1$ and ℓ is

$$C_{0,\ell}(C_\ell T_{\ell+1} - T_\ell C_\ell)C_{\ell+1,L}.$$

Summing gives the identity. The norm estimate follows from the triangle inequality. □

How to read the result

The multilevel formula keeps track of where each mismatch enters. A defect at one level is composed with the comparison maps needed to reach the input and output levels. The norm estimate therefore depends on both the local defects and the maps that carry them through the hierarchy. Controlling local mismatches alone does not control the total error if those maps amplify them.

Example 11.9 (A visible one step defect)**.** Let $X_f = \Bbbk^2$, let $X_c = \Bbbk$, and let

$$C(x_1, x_2) = x_1.$$

Take

$$T_f = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \qquad T_c = (a).$$

Then

$$\Delta = CT_f - T_c C = (0, b).$$

The coarse operator is exactly compatible with the fine operator precisely when the discarded coordinate does not feed into the retained coordinate. The entry c does not appear in the one step defect because it moves information in the opposite direction. It can still affect later powers through the terms in theorem 11.1.

Corollary 11.10 (Exact compatibility)**.** *If every one step defect Δ_ℓ vanishes, then*

$$C_{0,L}p(T_L) = p(T_0)C_{0,L}$$

for every polynomial p. The analogous resolvent, holomorphic, and exponential identities also hold whenever the relevant expressions are defined.

Proof. The total one step defect vanishes by theorem 11.8. Apply corollary 11.4 and theorems 11.5 to 11.7. □

12 Worked realizations in the common operator language

12.1 Signal polyphase coordinates

Let $x = (x_n)_{n\in\mathbb{Z}} \in c_{00}(\mathbb{Z}; R)$ and let the seed be δ_0 under the bilateral shifts $(S^r\delta_0)_n = \delta_{n,r}$. This makes the algebraic span and every displayed sum finite. The N packets are

$$x_j[m] = x[Nm + j].$$

Synthesis interleaves these sequences. A linear filter with a finite impulse response that is invariant under shifts becomes an $N \times N$ matrix of transfer blocks. Refining from N to M with $N \mid M$ splits each

coarse phase into its descendants without changing the reconstructed signal. The same formulas extend to standard sequence completions when the synthesis series converges. This is the usual polyphase viewpoint from multirate filter banks [10].

12.2 Sparsity of transfer blocks

A banded operator need not remain banded after residue reordering, but its nonzero couplings become a structured packet graph. With the convention $(S_r x)_n = x_{n-r}$, the only active transfer is

$$P_{N,j+r} S_r P_{N,j},$$

with indices taken modulo N. More general finite stencils produce a finite set of active phase differences.

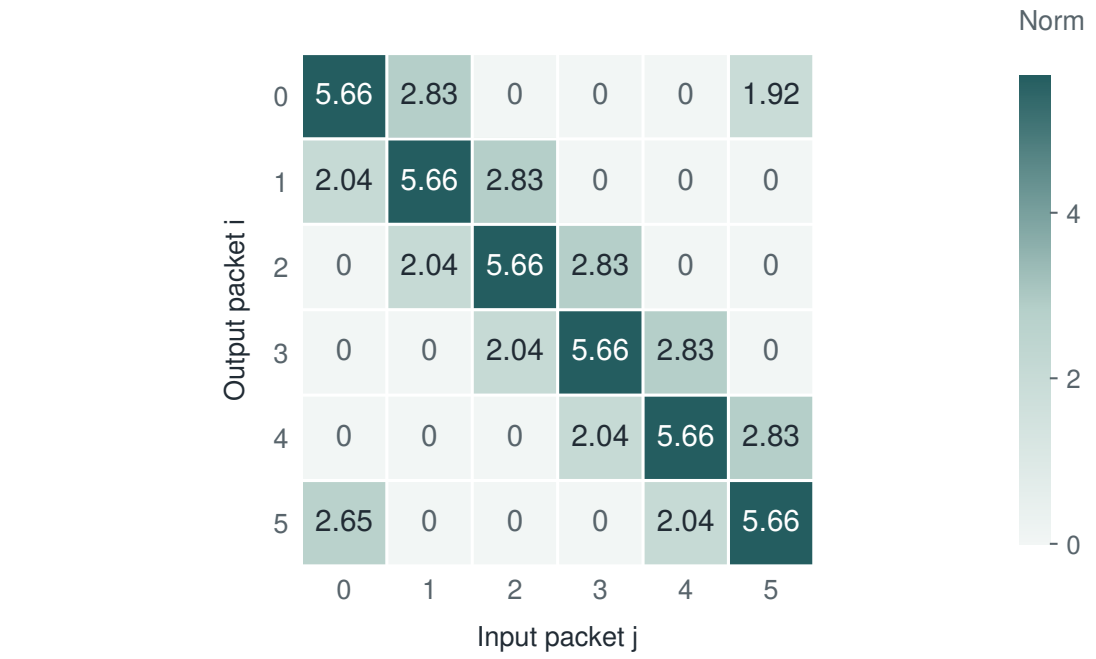

Figure 10. Norms of packet blocks for a finite stencil. The original operator is exactly reconstructed from a sparse transfer pattern.

12.3 A short realization in Smith chart coordinates

How to read the result

The Smith chart used here is a coordinate diagram for impedance and reflection. It is different from the Smith normal form used earlier to study integral congruences. The connection within this chapter is the way a change of coordinates makes an action easier to describe. Here a rotation in reflection coordinates becomes a fractional linear map in impedance coordinates. The sampled phase orbit is a geometric example and does not supply another linear projector decomposition.

Let Z and $Z_0 \neq 0$ be complex impedances, put $z = Z/Z_0$, and assume $z \neq -1$. Write

$$\Gamma = \frac{z-1}{z+1}.$$

On the open reflection disk $|\Gamma| < 1$, multiplication by any phase ω_N^k stays in the disk and has a finite inverse-chart image. The phase action is

$$\Gamma \mapsto \omega_N^k \Gamma.$$

Outside the open disk, the same chart formula requires $1 - \omega_N^k \Gamma \neq 0$. Pulling the phase action back on this domain gives

$$T_{N,k}(z) = \frac{(1+\omega_N^k)z + (1-\omega_N^k)}{(1-\omega_N^k)z + (1+\omega_N^k)}.$$

For $N = 2$ and $k = 1$,

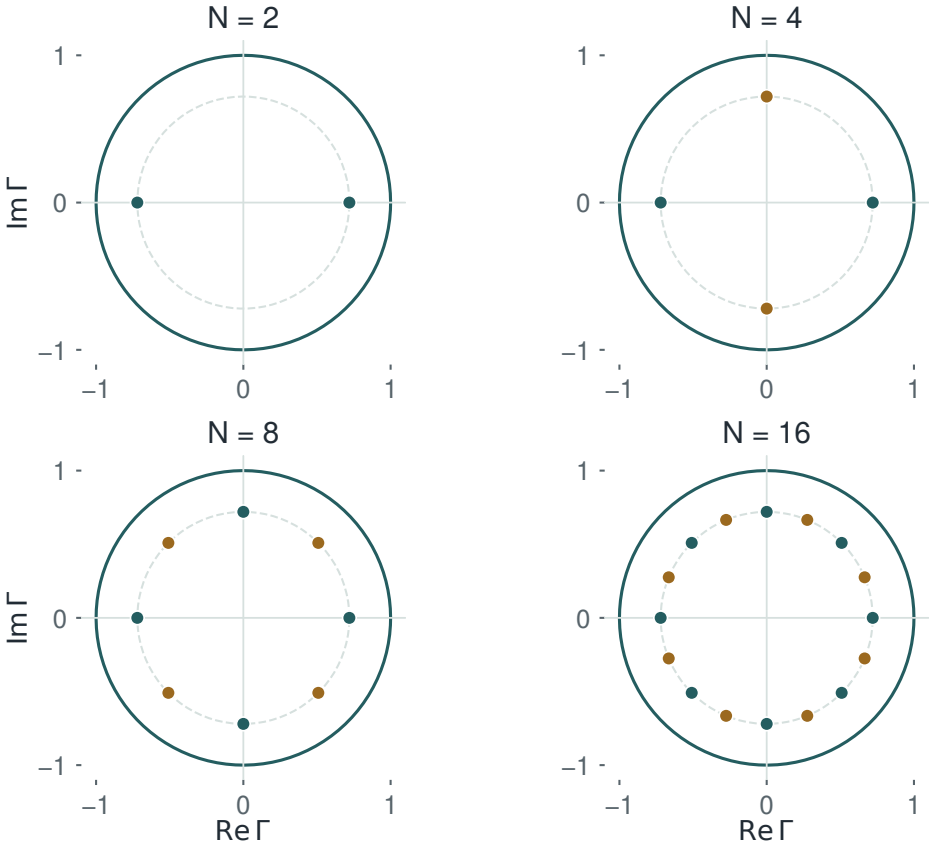
$$T_{2,1}(z) = \frac{1}{z}, \qquad z \neq 0, -1.$$

Thus the nontrivial action at the first phase level exchanges normalized impedance and admittance. Calling these values "packets" is geometric terminology for the sampled orbit. It does not assert that the two values form linear idempotent ranges. Higher refinements at powers of 2 sample the same reflection circle at progressively finer electrical phases. Compare the standard Smith chart conventions in [7].

The symmetric weight

$$w_{\mathrm{Smith}}(\Gamma) = \frac{1}{|1-\Gamma|^2} + \frac{1}{|1+\Gamma|^2}$$

indicates where small errors in reflection coordinates produce large impedance or admittance errors.



13 Finite computational certificates

The following results and tables record finite checks of the implementation. They do not certify the general lattice or analytic statements in Lean. The accompanying verification files record the execution evidence and tested ranges.

All numerical work in this chapter is finite and reproducible. It tests the Python implementation of identities proved above or checked against certificates. It does not replace those arguments or the Lean kernel checks. The recorded implementation run covers 48 tests, including contracts for invalid input, refinement transitivity, aggregation of transfer blocks, Fourier/DFT agreement, Smith fiber counts by exhaustive enumeration, and consistency of the stored JSON and CSV records.

Nested polyphase samples

Reflection coordinates retain their geometry at every dyadic refinement.

Every sample has |Γ| = 0.72. Gold marks points added at N = 4, 8, or 16.

Figure 11. Nested phase orbits at powers of 2 on the Smith reflection disk. The full treatment of the Smith chart is deferred to the signal chapter.

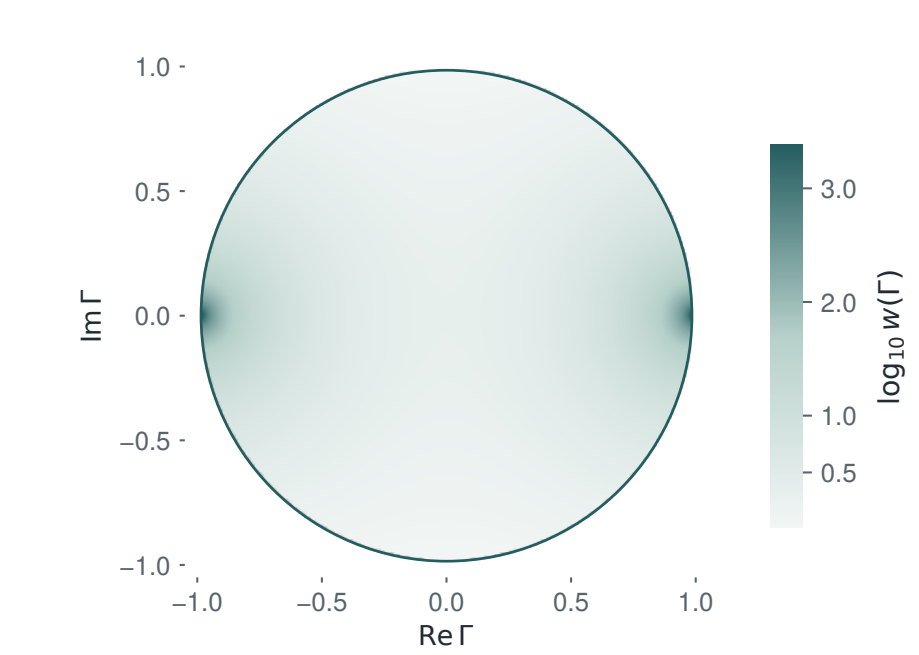


Figure 12. A symmetric refinement weight concentrated near the boundary points for open and short circuits.

Table 1. Representative numerical and symbolic checks.

Check	Result
Packet synthesis residuals for moduli $2, 3, 4, 6, 8, 12$	0
Nested refinement residuals for $2 \to 4$, $2 \to 8$, $3 \to 6$, $3 \to 12$, $4 \to 8$, $4 \to 12$, $6 \to 12$	0
CRT residuals for dyadic and odd moduli for 4×3, 8×3, 4×5, 8×5	0
Maximum finite Fourier projector residual	6.60×10^{-15}
Weighted inverse residual modulo 2^{10}	0
Weighted inverse residual modulo 3^8	0
Weighted inverse residual modulo 5^7	0
Difference between filtered and direct modular inverses	0
Transfer zeta coefficients versus direct walk enumeration through weight 30	exact match
Dyadic sign projector resultant weight	$v_2(2) = 1$
Sign projector resultant weight at the odd prime 3	$v_3(2) = 0$
Power defect telescoping identity residual	at most 6.94×10^{-18}
Resolvent defect identity residual	1.09×10^{-17}
Smith $N = 2$ phase versus $z \mapsto 1/z$	residual below 1.4×10^{-16}

Numerical Certificate 13.1 (Weighted inverse)**.** For the tested diagonal-plus-transfer matrices, the filtered inverse agrees exactly with direct modular inversion at all tested precisions:

$$2^{10}, \qquad 3^{8}, \qquad 5^{7}.$$

The maximum modular residual is zero in every case.

Numerical Certificate 13.2 (Transfer zeta)**.** The rational function

$$\frac{-t^3}{t^9 - t^7 - t^6 - t^5 + 2t^4 + t^3 + t^2 - 1}$$

was expanded through degree 30. Every coefficient agrees with direct weighted-walk enumeration.

Numerical Certificate 13.3 (Dyadic separation)**.** The code verifies exactly that the two rational sign projectors are idempotent, orthogonal, and complementary, that scaling by 2 makes both integral, and that the same projectors are already integral modulo every tested odd prime.

14 Scope and limits

The exact statements above have several deliberate boundaries.

First, refinement changes coordinates while preserving reconstruction. If a numerical method discards fine packets, the resulting error must be estimated separately.

Second, the weighted inverse is linear. A nonlinear map creates higher order interactions among packet coordinates. Those interactions are not contained in the path formula of theorem 5.2.

Third, a resultant is only a denominator bound. The exact weight depends on the lattice and is given by theorem 8.2. The two examples in examples 7.4 and 8.10 show that the same eigenvalue separation can give different integral packet weights.

Fourth, the dyadic sign example is a model rather than a classification of all phenomena at the prime two. Character averages, trace splittings, quadratic refinements, and deformation projectors must each be checked on their own lattices.

Finally, the defect formulas do not prove that a chosen coarse operator is a good approximation. They say exactly how a known one step defect propagates. A useful approximation theorem must also bound that defect in the problem under study.

A Notation table

Symbol	Meaning
$P_{\ell,\alpha}$	packet projector at refinement level ℓ
I_ℓ	packet address set at level ℓ
$\beta \succ \alpha$	fine packet β is a child of coarse packet α
$\mathcal{A}_\ell, \mathcal{S}_\ell$	packet analysis and synthesis maps
$J_{\ell+1,\ell}$	exact coordinate refinement map
$C_{\ell,\ell+1}$	exact coordinate regrouping from fine to coarse
$T^{(\ell)}_{\beta\alpha}$	transfer block $P_{\ell,\beta} T P_{\ell,\alpha}$

Symbol	Meaning
$P_{N,j}$	residue or phase selector for address $j \pmod N$
$w(e)$	positive filtration weight of a transfer edge
$W(\gamma)$	cumulative weight of a transfer word or graph walk
$A(t)$	polynomial weighted adjacency matrix
$Z_{s,t}(t)$	weighted transfer-zeta function from vertex s to vertex t
$s_{\pi,\Lambda}(E)$	separation weight of a rational projector on the chosen lattice, when a clearing exponent exists
Δ	linear refinement defect for one step $CT_f - T_cC$

B Algorithmic forms

B.1 Residue analysis and synthesis

```
def analyze_residues(x, N):
    require N > 0
    return [x[j::N] for j in range(N)]

def synthesize_residues(packets):
    N = len(packets)
    require packet lengths fit one N-way interleaving
    y = empty(sum(len(p) for p in packets))
    for j, packet in enumerate(packets):
        y[j::N] = packet
    return y
```

The verified contract is synthesize(analyze$(x, N)) = x$. The Lean counterpart uses packet coordinates restricted to projector ranges and proves both inverse laws. The finite Python routine checks the concrete array realization.

B.2 Weighted inverse at finite precision

```
Dinv = inverse(D)                       # certified on both sides
edge[e] = Dinv @ H_edge[e]
require Dinv @ H == sum(edge[e] for e in edges)
require edge[e] lies in filtration[weight[e]]
m = certified_lower_bound(weight)       # 1 <= m <= weight[e]
N = (L + m - 1) // m                    # so L <= m*N
S = 0
for n in range(N):
    for word in edge_tuples(edges, n):
        if sum(weight[e] for e in word) < L:
            S += (-1)**n * ordered_product(edge[e] for e in word)
return q_L(S @ Dinv)
```

Lean proves that the mapped pruned sum is exactly the mapped finite geometric inverse. The lower bound m gives $m|\gamma| \le W(\gamma)$, so $L \le mN$ derives $q_L(A^N) = 0$ from the filtration certificate and makes the returned value an inverse on both sides of $q_L(D + H)$. The Lean lemma $L \le m\lceil L/m \rceil$ justifies the displayed executable cutoff for $m > 0$. Taking $m = 1$ and $N = L$ gives the unconditional cutoff

for positive weights. The Python implementation checks the DVR matrix specialization against direct modular inversion.

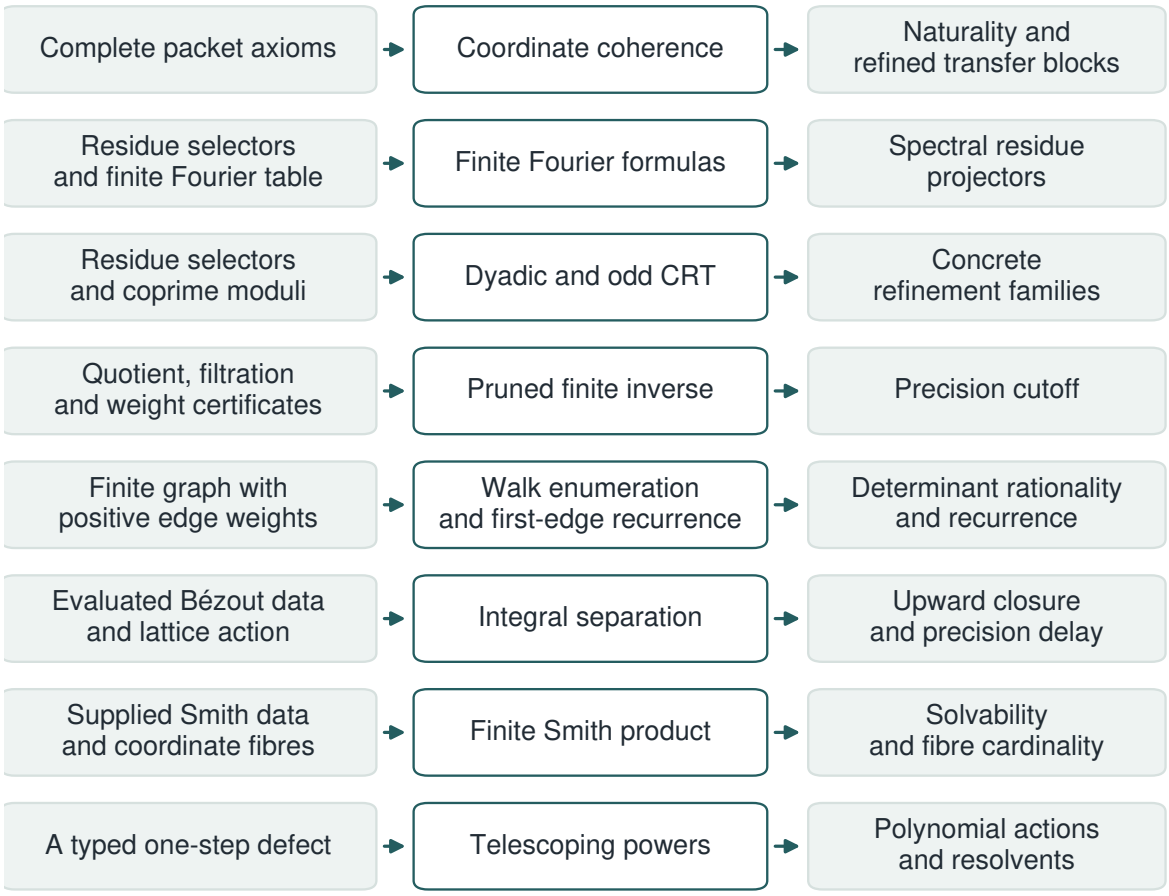
B.3 Walk construction for transfer zeta

```
def coefficient(G, start, target, n):
    total = 0
    for length in range(n + 1):
        for word in edge_tuples(G, length):
            if is_walk(word, start, target) and weight(word) == n:
                total += 1
    return total

A[i,j] = sum(t**weight(e) for distinct edges e from i to j)
T = I - A
Q = det(T)
H = adjugate(T)
P = H[start, target]
assert Q.coeff(0) == 1
Z = coefficient_series(G, start, target)
prove Q * Z == P
```

Positive weights make the coefficient loop finite because every contributing word has length at most n. Lean proves the enumeration correct, derives its recurrence from the first edge, proves $(I - A)Z = I$, constructs the determinant/adjugate inverse, and identifies the two matrices by inverse uniqueness. Thus the normalized $QZ = P$ identity and its induced recurrence follow from finite graph data. The Python companion repeats the exact symbolic construction as an executable check. The Lean proof does not use it as an oracle.

C Proof dependency map



The proof order is:

complete packet axioms $\Rightarrow$ finite-packet uniqueness and coordinate coherence
$\Rightarrow$ coordinate naturality and refined transfer blocks,
residue selectors and a finite Fourier table $\Rightarrow$ Fourier formulas,
coprime moduli $\Rightarrow$ dyadic–odd formulas,
quotient, filtration, and edge-weight certificates $\Rightarrow$ explicit pruned inverse,
finite positive-weight graph $\Rightarrow$ semantic enumeration and first-edge recurrence
$\Rightarrow$ det / adj rationality and recurrence,
minimal evaluated Bézout data and inverse-unit lattice action
$\Rightarrow$ separation bound, upward closure, and precision delay,
concrete $\mathbb{Z}/p^L\mathbb{Z}$ coordinate fibres $\Rightarrow$ finite Smith product count,
one-step typed defect $\Rightarrow$ powers, polynomial actions, and witnessed resolvents.

The walk branch for transfer zeta is logically independent of operator inversion. Its rationality conclusion follows from finite graph data without a supplied $QZ = P$ premise. Likewise, CRT factorization follows directly from residue selectors and coprimality. It does not require the abstract refinement

Distinct proof branches

Each row identifies its own inputs and the conclusions they support.

The walk series is independent of operator inversion. General Smith and Bézout constructions remain upstream inputs to their certificate branches.

Figure 13. The dependency structure of Chapter II. Coordinate coherence, residue/CRT, weighted inversion, automatic finite-graph transfer rationality, and integral separation are distinct branches with explicit inputs.

theorem, although it supplies a concrete refinement family. General Smith diagonalization and the construction of polynomial Bézout/resultant data remain inputs to the formalized branches that use those certificates.

D Formal coverage and computational scope

This chapter develops common refinements, complete filtered inversion, lattice gluing, rectangular Smith congruences, and analytic and multilevel defects. It also includes the specializations, finite graph construction, worked realizations, and three algorithm specifications associated with the foundational formal contract.

Formal correspondence. The formal project is `formal/current/`. Its correspondence contains 81 source records, including 53 proof-level items. Chapter-wide targets and foundational records are kept separately, with exact source and proof hashes. The map and the Lean guide report each item's recorded status and verification checks.

Formal coverage. 53 of 53 proof-level source records have kernel checked, semantically accepted scope. No partial or pending proof records are listed in this correspondence. These are source-record counts under their stated hypotheses, not counts of independent discoveries.

The rectifiable analytic endpoints use a representation whose velocity length is bounded by the original geometric length. This inequality supplies the manuscript estimate. Equality of the two lengths is not required. The accepted correspondence identifies the exact canonical endpoints and their hypotheses.

The inherited Lean contract has 25 rows: 21 canonical numbered items, one Smith-phase identity, and three algorithm specifications. That foundational contract has its own source identity and scope. The chapter-wide correspondence separately records the exact statements, proof targets, source hashes, and execution evidence. A row may use several declarations, and several source labels may refer to one written theorem. These are distinct counting units.

The source archive preserves the foundational sources and their reports. Each verification record applies only to the source hashes and statement scopes it identifies. Preservation alone does not certify a changed statement.

The worked plates give exact models. The formal companion in the back matter explains the chapter-wide proof scope and the foundational declaration-level contract. Illustrations and finite checks support understanding and implementation. Universal claims depend on their written proofs and the exact formal statements where coverage is recorded.

The twenty-four worked plates follow this account of the proof scope. Their statement references identify the mathematical text of Chapter II.

E Visual atlas

Twenty-four worked plates follow the main constructions through explicit vectors, matrices, weighted walks, and congruence fibers. Their labels Plate II.1 to Plate II.24 stay fixed across the integrated atlas and the standalone guide. Each plate names the corresponding statement and its printed page in this monograph.

Three routes through the atlas

Exact coordinates. Read Plate II.1 to Plate II.8, then the finite filter in Plate II.20.
Weights and arithmetic. Read Plate II.9 to Plate II.19. The first group follows weighted operator words and graph walks. The second follows denominator clearing and Smith congruences.
Realizations and defects. Read Plate II.20 to Plate II.24. These plates separate the Smith impedance chart from Smith normal form, trace error propagation, and connect the examples to the formal contract.

The matrices and finite ranges shown here are explicit models. The general proofs remain in the preceding sections. A picture or finite computation does not extend the hypotheses of a theorem or the coverage of a Lean declaration.

How to use this volume

Twenty-four worked pages and twenty-two exact model figures accompany Chapter II and its formal companion. Integer, rational, modular and symbolic calculations determine the figures. The preserved Python model sources and their explicit finite verification ranges are included in the source package.

A route through the examples

The labels Plate II.1 through Plate II.24 identify worked pages independently of PDF pagination. Each page names its corresponding statement in the final mathematical text. The formal companion distinguishes chapter-wide coverage from the foundational contract.

Plate II.1 Three kinds of resolution
Plate II.2 An atlas of the refinement layer
Plate II.3 Follow one coefficient through the tower
Plate II.4 Regrouping is not averaging
Plate II.5 The operator changes coordinates too
Plate II.6 Selectors survive without division
Plate II.7 A Fourier certificate you can inspect
Plate II.8 One address, two independent residues
Plate II.9 Which words can survive precision five?
Plate II.10 An inverse computed in both orders
Plate II.11 The residual tells you when to stop
Plate II.12 Walks are not simple paths
Plate II.13 A finite graph produces its denominator
Plate II.14 Separate before dividing
Plate II.15 Where the dyadic digit is lost
Plate II.16 One extra digit is necessary
Plate II.17 See every Smith fiber modulo eight
Plate II.18 Transport the whole solution fiber
Plate II.19 Precision exposes directional freedom
Plate II.20 Filter first or split first: same output
Plate II.21 Two Smith constructions, different roles
Plate II.22 A small defect can grow under powers
Plate II.23 Resolvents amplify errors near poles
Plate II.24 Read the certificates with the pictures

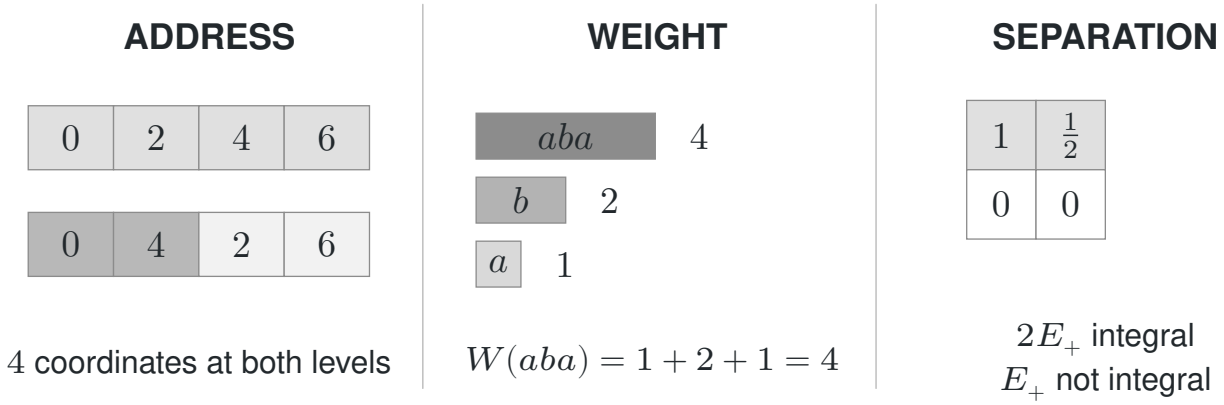
Three reading routes

Exact coordinates: Plate II.3 to Plate II.8, followed by the finite filter in Plate II.20. **Precision and arithmetic:** Plate II.9 to Plate II.19. **Realizations and defects:** Plate II.20 to Plate II.24.

How to read an ordered product

In a written matrix word ab, the rightmost map b acts first. Directed walks may instead be listed in chronological edge order, as in the traditional text's block-path formula. Follow the convention stated with the example.

What the figures establish



The models expose the mechanisms and their boundaries. Exact finite checks validate the displayed instances. Universal statements keep the hypotheses and proofs given in the mathematical text. Lean coverage is recorded by the chapter-wide correspondence and the foundational theorem map. Each compiler claim belongs to the source and logs identified by its verification record.

Plate II.1 / CHAPTER II / A WORKED VISUAL GUIDE

Three kinds of resolution

Chapter II, mathematical text: Definition 3.4, Theorem 5.10, Theorem 7.7

Chapter II asks three different questions that can all sound like "increase the resolution." This guide separates them, then follows small objects far enough that the distinctions can be computed rather than merely named.

Three different operations. On the left, all coefficients survive a regrouping. In the middle, an integer weight controls which operator words can matter modulo a chosen power. On the right, a rational projector needs a denominator cleared before integral precision can be recovered.

Address resolution

A coefficient such as x_6 can sit in the even packet, then the residue-2 packet modulo 4, then the residue-6 packet modulo 8. Its value does not become more accurate. Its *address becomes more specific*, while the full object remains exactly reconstructible.

Arithmetic precision

An operator word with total filtration weight at least L vanishes in the specified depth-L quotient. Increasing L can make additional words relevant. This is a change in the precision of the ring in which the answer is required, not a lossless rearrangement of one fixed list.

Separation precision

For the integral involution used later, $E_+ = (I + A)/2$ is an exact rational projector but not an integral one at 2. One extra input digit suffices to recover the projected difference to the requested precision. The packet is present over the fraction field even when its integral separation is delayed.

> **Read this as:** Keep three quantities distinct: the packet address, the precision cutoff, and the denominator weight. Finer addresses do not automatically improve arithmetic precision or remove a spectral denominator.

Plate II.2 / ORIENTATION / SYMBOLS WITH JOBS

An atlas of the refinement layer

Chapter II, mathematical text: Definition 3.2, Definition 3.4, Definition 7.6

The same letter can have different roles in different realizations. The table fixes the roles used here. Every small matrix in the guide is explicitly supplied. No diagonalization or classification theorem is inferred from a picture.

Object	Role	Worked instance
$P_{N,j}$	Retain coefficients with address j modulo N.	Even/odd masks, then mod-4 and mod-8 masks.
$\mathcal{A}_N, \mathcal{S}_N$	Split into range-restricted packet vectors, then sum them.	A permutation/interleaving of eight coordinates.
J, C	Exact refinement and regrouping. In the defect section, C may instead be any supplied coarsening map.	A permutation in Plate II.5 and a shear in Plate II.22.
T_{ba}	Input packet a, output packet b: $P_b T P_a$.	Blocks of a finite cyclic filter.
D, H, A	$T = D + H = D(I + A)$, with $A = D^{-1}H$.	Explicit integral 2×2 matrices.
$w(e), W(\gamma)$	Positive certified edge gain and its additive word weight.	$w(a) = 1$, $w(b) = 2$.
L	Precision depth in a quotient such as $\mathbb{Z}/2^L\mathbb{Z}$.	$L = 5$ gives arithmetic modulo 32.
$A(t), Z(t)$	Polynomial graph adjacency and unsigned walk-count series.	Two parallel edges remain distinct.
E, Λ, s	A rational projector, a specified lattice, and a clearing exponent.	E_+ has local weight 1 at 2.
(s_i)	Directional weights of a supplied Smith diagonal.	$(1, 2)$ modulo 8 or $(0, 1, 3)$ across depths.
Δ	The failure of an independently chosen operator to intertwine: $CT_f - T_c C$.	One nonzero entry $1/16$.

Suggested reading routes

For exact coordinates, read Plate II.3 through Plate II.8, then the finite filter on Plate II.20. For weighted inversion and counting, read Plate II.9 through Plate II.13. For arithmetic separation and congruence fibers, read Plate II.14 through Plate II.19. The final pages distinguish nonlinear chart geometry, error propagation, and the formal contract.

> **Read this as:** Operator words carry signed matrix values. Graph walks carry unsigned counts. Smith normal form concerns linear congruences. The Smith impedance chart on Plate II.21 is a different, nonlinear construction.

Plate II.3 / MODEL A / LOSSLESS ADDRESS REFINEMENT

Follow one coefficient through the tower

Chapter II, mathematical text: Theorem 3.3, Theorem 4.6

Take a vector $x = (x_0, \dots, x_{15})$. A packet is not a single summary number: it retains every coefficient at its selected addresses. For example,

$$P_{2,0}x = (x_0, 0, x_2, 0, \dots, x_{14}, 0).$$

The rail below lists the addresses in each packet. Its display order groups descendants under their parents. The matrix example on Plate II.5 instead uses increasing residue order.

	$r=0$								$r=1$							
$N=2$	0	2	4	6	8	10	12	14	1	3	5	7	9	11	13	15
					16											
	$r=0$				$r=2$				$r=1$				$r=3$			
$N=4$	0	4	8	12	2	6	10	14	1	5	9	13	3	7	11	15
					16											
	$r=0$		$r=4$		$r=2$		$r=6$		$r=1$		$r=5$		$r=3$		$r=7$	
$N=8$	0	8	4	12	2	10	6	14	1	9	5	13	3	11	7	15
					16											

Each cell is an address n; its coefficient travels with it.

Every row contains all sixteen addresses exactly once. A heavier boundary separates packet ranges. The numbers are coefficient addresses, not new coefficient values. There is no interpolation, averaging, or omitted high-frequency tail.

The address 6 is even, is 2 modulo 4, and is 6 modulo 8. Its coefficient therefore lies in the successive ranges

$$P_{8,6}X \subseteq P_{4,2}X \subseteq P_{2,0}X.$$

The corresponding identities hold as operators:

$$P_{2,0} = P_{4,0} + P_{4,2}, \qquad P_{4,2} = P_{8,2} + P_{8,6}.$$

Applying either composite parent selector to $P_{8,6}x$ leaves it unchanged. Applying the odd selector kills it. This is absorption between a parent and a child, rather than an approximate resemblance between nearby scales.

Why the reconstruction is unique

If a vector is a sum of components in disjoint packet ranges, apply the projector for one range. All other components vanish and the selected component remains. Thus every child component is recovered uniquely from the sum.

> **Read this as:** Refinement is a sharper address book for the same coefficients. The total number of free coordinates does not change.

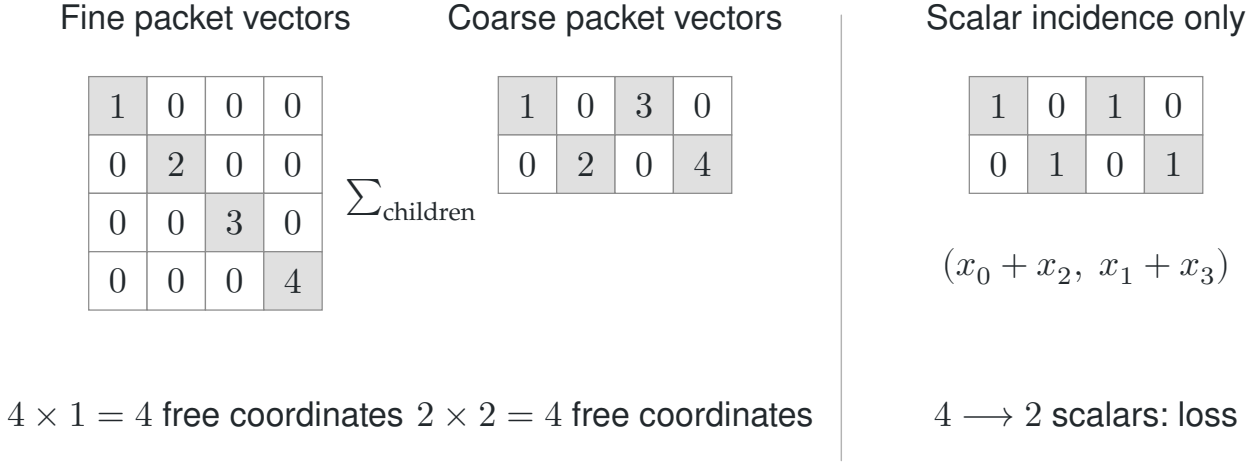


Plate II.4 / MODEL A / THE MEANING OF COARSENING

Regrouping is not averaging

Chapter II, mathematical text: Definition 3.4, Theorem 3.5

The word *coarsening* can suggest compression. In the exact coordinate theorem it means regrouping complete packet vectors. Replacing each packet by one scalar sum is a different operation and really does lose information.

For $x = (1, 2, 3, 4)$, the fine packets are the four coordinate-supported vectors. Regrouping gives $(1, 0, 3, 0)$ and $(0, 2, 0, 4)$. Every original coordinate remains available in one of these two vectors.

The left and middle panels store the same four independent coordinates. The right panel instead applies a 2×4 numerical incidence matrix to four scalar entries. That is not the range-restricted exact coordinate map.

Define

$$X_N^{\mathrm{pkt}} = \bigoplus_j P_{N,j} X, \qquad \mathcal{A}_N x = (P_{N,j} x)_j, \qquad \mathcal{S}_N (x_j)_j = \sum_j x_j.$$

Completeness and mutual annihilation give both inverse laws. Consequently,

$$J = \mathcal{A}_4 \mathcal{S}_2, \qquad C = \mathcal{A}_2 \mathcal{S}_4, \qquad CJ = I, \quad JC = I.$$

The larger list of fine packets has smaller individual packet spaces.

A kernel witnesses genuine information loss

For the scalar incidence matrix B drawn on the right,

$$B(1, 0, -1, 0)^{\mathsf{T}} = 0.$$

The zero vector and $(1, 0, -1, 0)$ therefore have the same two scalar summaries. No inverse can recover the original four scalars from that output alone.

> **Read this as:** Ask what each packet stores. A list of full packet vectors can be exactly invertible. A list of packet means or totals generally is not.

Plate II.5 / MODEL A / COHERENCE AND NATURALITY

The operator changes coordinates too

Chapter II, mathematical text: Theorem 3.5, Theorem 3.8

Use a finite periodic carrier $X = \mathbb{Q}^8$ for this example. Let $Se_j = e_{j+1 \bmod 8}$ and let

$$T = I + 2S + S^2.$$

This is a concrete cyclic model, not an unannounced boundary convention for the finitely supported signal on Plate II.20. Write R_N for the permutation that groups coordinates in increasing residue order modulo N.

$\widehat{T}_2$

1	·	·	1	·	·	·	2
1	1	·	·	2	·	·	·
·	1	1	·	·	2	·	·
·	·	1	1	·	·	2	·
2	·	·	·	1	·	·	1
·	2	·	·	1	1	·	·
·	·	2	·	·	1	1	·
·	·	·	2	·	·	1	1

$J_{4,2}$

1	·	·	·	·	·	·	·
·	·	1	·	·	·	·	·
·	·	·	·	1	·	·	·
·	·	·	·	·	·	1	·
·	1	·	·	·	·	·	·
·	·	·	1	·	·	·	·
·	·	·	·	·	1	·	·
·	·	·	·	·	·	·	1

$\widehat{T}_4$

1	·	·	·	·	1	·	2
·	1	·	·	1	·	2	·
2	·	1	·	·	·	·	1
·	2	·	1	·	·	1	·
1	·	2	·	1	·	·	·
·	1	·	2	·	1	·	·
·	·	1	·	2	·	1	·
·	·	·	1	·	2	·	1

$$J_{4,2}\widehat{T}_2 = \widehat{T}_4 J_{4,2}$$

Actual 8×8 matrices. Dots are zero entries. The other entries are exact integers. Heavy lines mark the packet blocks: size four at level two and size two at level four.

The reordered operators and change of coordinates are

$$\widehat{T}_N = R_N T R_N^{-1}, \qquad J_{4,2} = R_4 R_2^{-1}.$$

Multiplication cancels the intermediate coordinate maps:

$$J_{4,2}\widehat{T}_2 = \widehat{T}_4 J_{4,2}, \qquad J_{8,4}J_{4,2} = J_{8,2}.$$

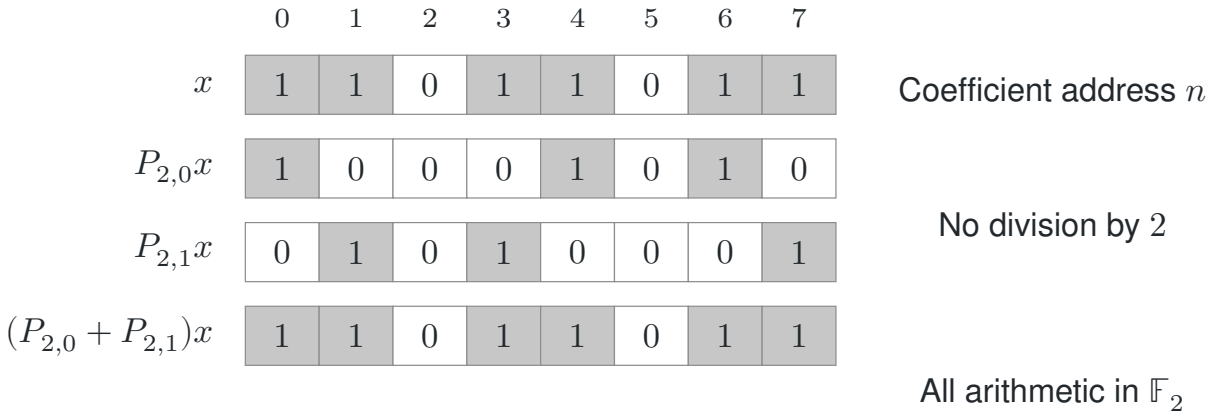
Thus it makes no difference whether the operator is applied before or after a consistent coordinate change. One must transport the operator, not merely reuse the same numerical matrix under a new ordering.

Refined blocks still reconstruct the same map

A coarse block expands as

$$P_b T P_a = \sum_{\beta \succ b,\, \alpha \succ a} P_\beta T P_\alpha.$$

The terms are maps embedded in the original source and target spaces. Adding their norms, or adding their matrix entries after forgetting the embeddings, is not this operator identity.



> **Read this as:** The fine matrix contains a different block organization of the same operator. An independently guessed coarse matrix is a separate approximation problem, measured later by a defect.

Plate II.6 / MODEL A / RESIDUE MASKS IN CHARACTERISTIC TWO

Selectors survive without division

Chapter II, mathematical text: Proposition 4.2

Work first in $\mathbb{F}_2$, where $1+1=0$. The eight coefficients below are just a finite display of a coefficient sequence. The even and odd projectors are diagonal masks with entries zero and one.

Each nonzero input coefficient is retained by exactly one mask. Reconstruction is exact over $\mathbb{F}_2$. No average and no root of unity is used.

For a general coefficient ring and a positive integer N, the definition is

$$(P_{N,j}x)_n = \begin{cases} x_n, & n \equiv j \pmod N, \\ 0, & \text{otherwise.} \end{cases}$$

An address belongs to one residue class, so applying two masks either keeps that same coefficient or kills it. This proves

$$P_{N,i}P_{N,j} = \delta_{ij}P_{N,j}, \qquad \sum_j P_{N,j} = I.$$

The argument is coordinatewise and does not require the coefficients to form a field.

Why the usual even/odd average is a different formula

Over a field of characteristic not two, parity extraction can be represented using $F(z)$ and $F(-z)$ and division by 2. In characteristic two, $-z = z$ and $2 = 0$, so that formula cannot be used. The coefficient mask, however, still distinguishes even from odd *exponents*.

This distinction also explains the later involution example. Failure to reduce a rational spectral projector containing $1/2$ does not make every integral coefficient-address selector disappear.

> **Read this as:** The basic object is the address selector. A Fourier average is one possible realization of it and has additional algebraic hypotheses.

Plate II.7 / MODEL A / AN EXACT NINE-ENTRY TABLE

A Fourier certificate you can inspect

Chapter II, mathematical text: Theorem 4.3

Take $N = 3$ and work in $\mathbb{F}_7$. Set

$$\omega = 2, \qquad \omega^{-1} = 4, \qquad \eta = 3^{-1} = 5.$$

Here $2^3 = 1$ and neither 2 nor 2^2 is one. The unnormalized geometric sums are the entries in the first matrix.

$\sum_k 4^{jk} 2^{rk} \pmod 7$ $\qquad$ $P_j(z^r) : \ 5 = 3^{-1} \pmod 7$

3	0	0
0	3	0
0	0	3

$\times 5$

1	0	0
0	1	0
0	0	1

$$\omega = 2, \quad \omega^3 = 1$$

$$\omega^{-1} = 4, \quad \eta = 5$$

$$j, r \in \{0, 1, 2\}$$

In $\mathbb{F}_3 \times \mathbb{F}_3$: order two does not imply orthogonality.

$$\omega = (-1, 1), \quad \eta = (2, 2), \quad \eta(1 + \omega) = (0, 1) \neq (0, 0)$$

All entries are exact residues modulo seven. Multiplying the diagonal value 3 by 5 produces 1. The lower calculation is a genuine failed Fourier certificate in a different coefficient ring.

On the monomial z^n, define $UF(z) = F(2z)$. The proposed projector acts by

$$5 \sum_{k=0}^{2} 4^{jk} 2^{nk}.$$

The identity $2^3 = 1$ makes this depend only on n mod 3. The nine-entry table therefore establishes the formula for every exponent once periodicity is used, rather than requiring a separate test at every coefficient.

Order alone is not sufficient over every ring

In $\mathbb{F}_3 \times \mathbb{F}_3$, the element $(-1, 1)$ has order two, but one component is a trivial character. Its nontrivial Fourier sum does not vanish in that component. Thus an element of order N in a ring with zero divisors is not, by itself, the full orthogonality certificate.

> **Read this as:** The finite table is a checkable sufficient input. Over a field, a primitive root supplies it. Over a more general ring, inspect the actual table instead of inferring orthogonality from order alone.

Plate II.8 / MODEL A / THE DYADIC AND ODD RECTANGLE

One address, two independent residues

Chapter II, mathematical text: Corollary 4.9

Because 4 and 3 are coprime, a residue modulo 12 is specified by a column $a = n \bmod 4$ and a row $b = n \bmod 3$. Each cell contains the unique combined address.

$$a = n \bmod 4$$

	$a=0$	$a=1$	$a=2$	$a=3$
$b=0$	0	9	6	3
$b=1$	4	1	10	7
$b=2$	8	5	2	11

$$b = n \bmod 3$$

$$(a,b) = (3,1) \iff n = 7 \pmod{12}$$

$$7,\ 19,\ 31, \ldots$$

$$P_{12,7} = P_{4,3}P_{3,1}$$

The twelve cells are a permutation of $0, \ldots, 11$, not twelve extra degrees of freedom. The selected cell contains every integer congruent to 7 modulo 12.

An explicit reconstruction formula is

$$n \equiv 9a + 4b \pmod{12},$$

because 9 is one modulo four and zero modulo three, while 4 has the opposite pair of residues. For $(a,b) = (3,1)$ this gives $31 \equiv 7$.

Applying the two masks in either order gives

$$P_{12,7} = P_{4,3}P_{3,1} = P_{3,1}P_{4,3}.$$

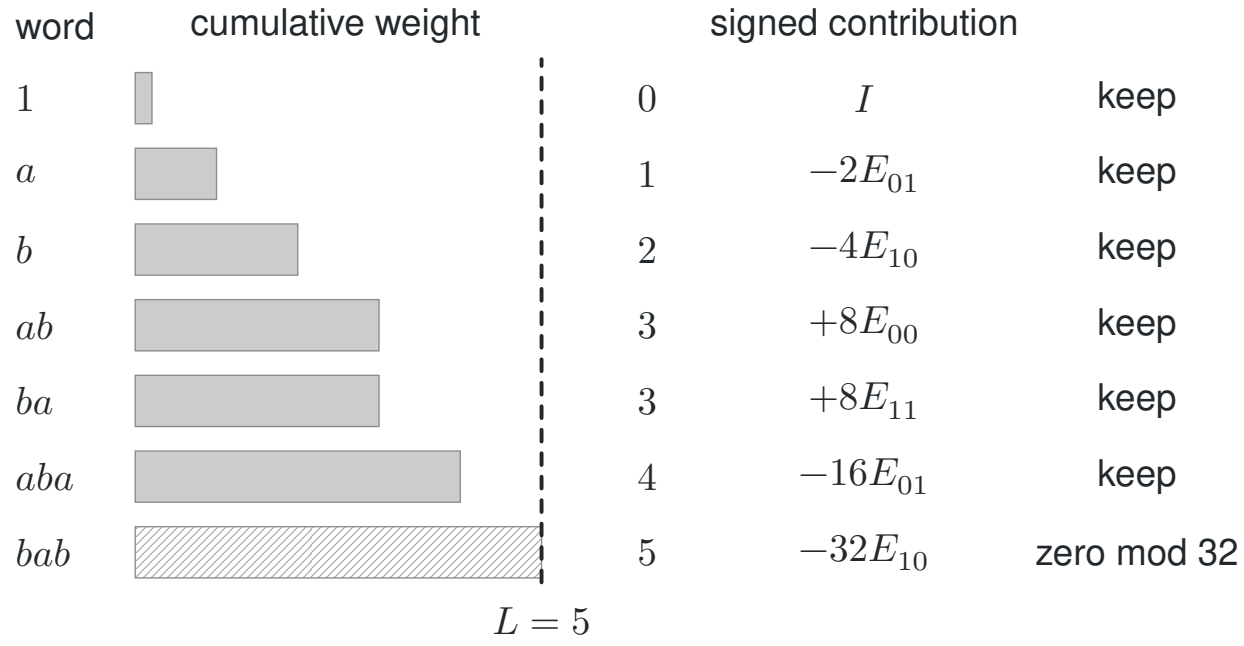
More generally, an address survives exactly when it satisfies both congruences. The coprime reconstruction identifies this intersection with one combined residue class.

The hypothesis can be seen failing

Replace 4 and 3 by 4 and 6. The requirements $n \equiv 0 \pmod 4$ and $n \equiv 1 \pmod 6$ are incompatible: the first makes n even and the second makes it odd. A full rectangular address product no longer exists. Compatible pairs must agree modulo the greatest common divisor.

> **Read this as:** CRT separates address coordinates. It does not claim that dyadic and odd spectral projectors have the same denominator weights or the same lifting behavior.

Plate II.9 / MODEL B / ORDERED TRANSFERS IN A FILTERED RING



Which words can survive precision five?

Chapter II, mathematical text: Theorem 5.10, Corollary 5.11

Let E_{ij} send the jth basis vector to the ith. In integral 2×2 matrices set

$$a = 2E_{01}, \qquad b = 4E_{10}, \qquad A = a + b.$$

Their certified dyadic weights are 1 and 2. At precision $L = 5$, every word of weight at least five vanishes modulo 32.

All nonzero retained terms of the signed inverse sum, followed by the first discarded nonzero word. The empty word contributes I. Other words of weight below five can still be zero because $a^2 = b^2 = 0$.

The words are *written matrix products*: in ab, the map b acts first. Therefore

$$ab = 8E_{00}, \qquad ba = 8E_{11}, \qquad aba = 16E_{01}.$$

The two products ab and ba cannot be identified merely because they have equal weight. Both their order and their source/target information matter.

The pruning rule supplies a sufficient reason for a term to vanish. It is not an assertion that every word below the threshold contributes nontrivially. Packet incompatibility and algebraic relations can remove additional words.

> **Read this as:** Length controls the sign. Cumulative weight controls precision. The ordered matrix product controls the actual contribution. None of these three can replace the others.

Plate II.10 / MODEL B / A COMPLETE MODULO-32 CALCULATION

An inverse computed in both orders

Chapter II, mathematical text: Theorem 5.10, Corollary 5.11

Keep the matrices from Plate II.9 and choose

$$D = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad D^{-1} = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}, \quad T = D(I + A) = \begin{pmatrix} 5 & 3 \\ 4 & 1 \end{pmatrix}.$$

The six retained contributions sum to

$$S = I - a - b + ab + ba - aba = \begin{pmatrix} 9 & -18 \\ -4 & 9 \end{pmatrix}.$$

The required inverse is $K = SD^{-1}$ in the quotient, not $D^{-1}S$.

T		K		$TK \pmod{32}$		$KT \pmod{32}$	
5	3	9	5	1	0	1	0
4	1	28	13	0	1	0	1

$$S = \begin{pmatrix} 9 & -18 \\ -4 & 9 \end{pmatrix}, \qquad K = SD^{-1} \pmod{32}$$

The displayed K uses canonical residues from 0 to 31. Both left and right products are the identity modulo 32. These are exact modular equalities, not floating-point residuals.

One can verify the claim without trusting the word expansion:

$$TK = \begin{pmatrix} 129 & 64 \\ 64 & 33 \end{pmatrix} \equiv I, \qquad KT = \begin{pmatrix} 65 & 32 \\ 192 & 97 \end{pmatrix} \equiv I \pmod{32}.$$

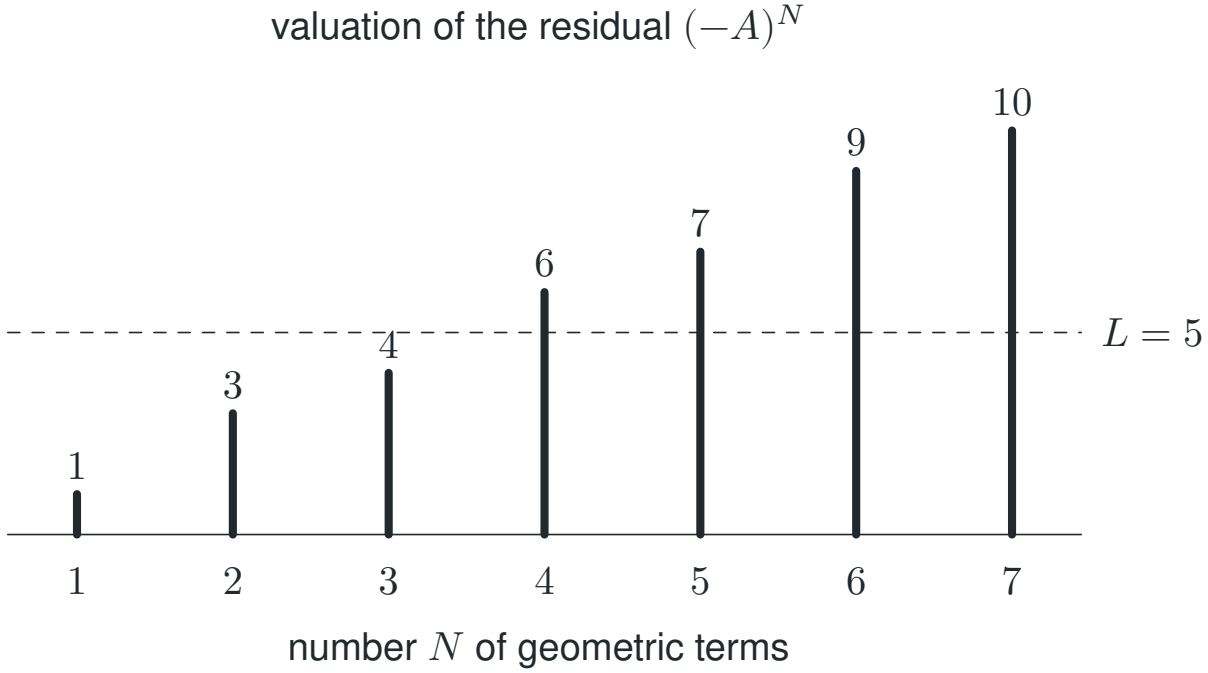
The cancellation of the exterior factor D explains the order. Since $T = D(I + A)$, multiply its inverse by D^{-1} on the *right* of the inverse of $I + A$.

What the finite theorem does not require

There is no claim here that the same integer series converges in the ordinary real matrix norm. The quotient kills all sufficiently deep products, so a finite sum suffices. The complete normed-ring theorem is a separate result with its own strict contraction hypothesis.

> **Read this as:** A correct noncommutative formula must work on both sides and preserve the order of its factors. Here the entire result can be checked by two integer matrix products.

Plate II.11 / MODEL B / A CERTIFIED CUTOFF, NOT A HEURISTIC



The residual tells you when to stop

Chapter II, mathematical text: Theorem 5.10, Corollary 5.11, Section B.2

For $S_N = \sum_{k=0}^{N-1} (-A)^k$, telescoping gives

$$(I + A)S_N = S_N(I + A) = I - (-A)^N.$$

Thus the exact residual is known. To certify precision L, it is enough to show that every residual entry is divisible by 2^L.

The plotted values are the minimum dyadic valuations of the nonzero entries of $(-A)^N$. The dashed line is the requested cutoff $L = 5$. This is an exact valuation profile, not a measured numerical convergence curve.

In this particular model, $A^2 = 8I$. Therefore

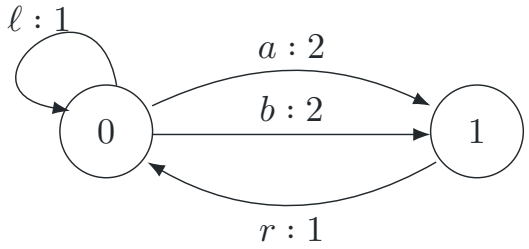
$$v_2(A^{2k}) = 3k, \qquad v_2(A^{2k+1}) = 3k + 1,$$

where the matrix valuation means the minimum entry valuation. Three geometric terms leave a residual of valuation four and do not suffice modulo 32. Four terms leave valuation six and do suffice.

The generic positive-weight estimate is more conservative. If every edge weight is at least $m > 0$, a word of length N has weight at least mN. Hence the cutoff

$$N = \left\lceil \frac{L}{m} \right\rceil$$

is sufficient. Here the certified minimum weight is $m = 1$, so the generic choice is five. The extra identity $A^2 = 8I$ justifies stopping at four in this example.



> **Read this as:** A structural identity may improve a cutoff. An observed small real norm or an arbitrarily larger claimed minimum edge weight does not supply that certificate.

Plate II.12 / MODEL C / A GRAPH WITH PARALLEL EDGES

Walks are not simple paths

Chapter II, mathematical text: Theorem 6.6

Consider the directed graph below. The loop ℓ has weight one, the two distinct edges a, b from 0 to 1 each have weight two, and the return edge r has weight one.

Edge labels carry positive integer weights.

All walks from 0 to 1 of weight 5

$\ell\ell\ell a$	$\ell\ell\ell b$
ara	arb
bra	brb

Every word on the right is read chronologically from left to right as an edge traversal. This is intentionally different from the right-to-left action of a written operator product in Plate II.9.

A walk may revisit a vertex and reuse an edge. At total weight five there are six walks from 0 to 1. Two use three loops followed by either a or b. Four travel to 1, return to 0, and travel to 1 again, with two independent choices of parallel edge.

Their multiplicities enter the polynomial adjacency matrix:

$$A(t) = \begin{pmatrix} t & 2t^2 \\ t & 0 \end{pmatrix}.$$

The coefficient 2 remembers the two distinct edges. Replacing it by 1 would count a different graph.

The first-edge decomposition

Let $a_n(s,t)$ count walks of total weight n from s to t. Removing the first edge gives

$$a_n(s,t) = \mathbf{1}_{s=t,\, n=0} + \sum_{\substack{e:\, \mathrm{source}(e)=s \\ w(e)\le n}} a_{n-w(e)}(\mathrm{target}(e), t).$$

The empty walk is allowed precisely on the diagonal at weight zero. Positive weights ensure that every contributing walk has length at most n, so enumeration at each fixed weight is finite.

> **Read this as:** The graph series counts unsigned walks, including repetitions and parallel-edge multiplicity. It does not count simple paths, and it does not know whether an associated operator product vanishes or cancels.

Plate II.13 / MODEL C / AUTOMATIC RATIONALITY AND RECURRENCE

A finite graph produces its denominator

Chapter II, mathematical text: Theorem 6.6, Corollary 6.7

For the graph on Plate II.12, compute the determinant and adjugate rather than guessing a recurrence:

$$I - A(t) = \begin{pmatrix} 1-t & -2t^2 \\ -t & 1 \end{pmatrix}, \quad Q(t) = 1 - t - 2t^3, \quad \operatorname{adj}(I-A)_{0,1} = 2t^2.$$

Since $Q(0) = 1$, its inverse exists as a formal power series with integer coefficients.

$$Z_{0,1}(t) = \frac{2t^2}{1 - t - 2t^3}$$

n	0	1	2	3	4	5	6	7	8	9	10	11	12
a_n	0	0	2	2	2	6	10	14	26	46	74	126	218

$$a_8 = a_7 + 2a_5 = 14 + 2 \cdot 6 = 26$$

The coefficients are independently computed by the first-edge recurrence and checked against the rational series through weight 24. Literal edge-walk enumeration supplies a third check through weight 10.

From $QZ_{0,1} = 2t^2$ one obtains

$$a_0 = a_1 = 0, \quad a_2 = 2, \qquad a_n = a_{n-1} + 2a_{n-3} \quad (n \geq 3).$$

The numerator is responsible for the initial exception. Omitting it would incorrectly force the entire series to vanish.

Three boundaries of this calculation

This is a *formal* series identity. No analytic convergence at a chosen real or complex value of t is needed. The canonical determinant need not be the minimal denominator after cancellation. Finally, positive weights prevent infinitely many walks at a fixed weight: a single weight-zero loop would already give the infinitely many distinct walks $1, \ell, \ell^2, \ldots$ at weight zero.

> **Read this as:** Finite positive-weight graph data determine a rational series and an eventual recurrence. The proof does not begin by assuming a certificate $QZ = P$ that already contains that conclusion.

Plate II.14 / MODEL D / AN EVALUATED BÉZOUT CERTIFICATE

Separate before dividing

Chapter II, mathematical text: Theorem 7.5, Definition 7.6

Use the integral involution

$$A = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}, \qquad A^2 = I.$$

With $F = A - I$ and $G = A + I$, the identities

$$-F + G = 2I, \qquad FG = 0$$

are an explicit evaluated Bézout certificate. Here all the required commutations follow because these operators are polynomials in the same matrix.

A

1	1
0	-1

$N = I + A$

2	1
0	0

$E_+ = N/2$

1	$\frac{1}{2}$
0	0

$$N^2 = 2N$$

$$E_+^2 = E_+$$

$$E_+(1,0) = (1,0), \qquad E_+(-1,2) = (0,0)$$

The denominator-free numerator is quasi-idempotent: $N^2 = 2N$. Division by the nonzero scalar 2 gives an idempotent over the fraction field. It does not yet make the projector integral on the selected lattice.

The numerator $N = G$ acts by 2 on $\ker(A - I)$ and by zero on $\ker(A + I)$. Thus

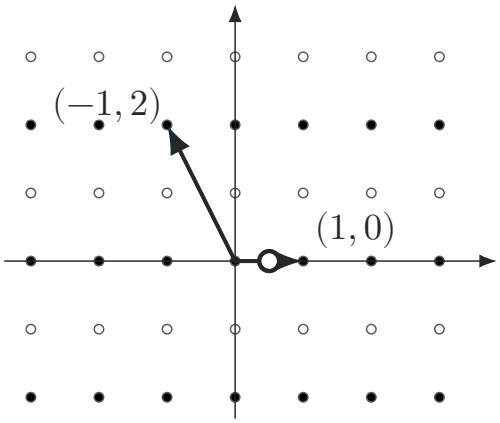
$$E_+ = \frac{1}{2}N = \begin{pmatrix} 1 & 1/2 \\ 0 & 0 \end{pmatrix}$$

is the required separator. The complementary projector is $E_- = I - E_+$.

A denominator bound need not be minimal

The same projector can be presented with the inflated certificate $-2F + 2G = 4I$. Its numerator is $2G$ and its normalization is still E_+. This supplies a two-digit clearing bound at 2, although one digit is enough. Thus the valuation of a supplied certificate gives an upper bound, not automatically the least possible weight.

For the original sign factors the concrete resultant is $\mathrm{Res}(x-1, x+1) = 2$ and the bound is sharp. That equality is special to this displayed calculation, not a universal minimality theorem for every resultant certificate.



> **Read this as:** First check the evaluated identities and the numerator. Then normalize in the fraction field. Finally ask what denominator is needed on the particular lattice.

Plate II.15 / MODEL D / THE EIGENLATTICE HAS INDEX TWO

Where the dyadic digit is lost

Chapter II, mathematical text: Proposition 9.3

The eigenspaces are spanned by $(1,0)$ and $(-1,2)$. Their integral eigenvectors do not form an integral basis of $\mathbb{Z}^2$. The change-of-basis determinant is two.

$$E_+(0,1) = (\tfrac{1}{2}, 0)$$

$$B = \begin{pmatrix} 1 & -1 \\ 0 & 2 \end{pmatrix}, \quad \det B = 2$$

Filled: $B\mathbb{Z}^2 = \{(x,y) : y \text{ is even}\}$

Unfilled: the other lattice coset.

B^{-1} is integral at odd primes, not at 2.

A picture of the ordinary integer lattice, not a drawing of the topology of $\mathbb{Q}_2$. Filled dots have even second coordinate. Unfilled dots lie in the other coset. The hollow point at $(1/2, 0)$ records the image of an integral vector under E_+.

Write

$$B = \begin{pmatrix} 1 & -1 \\ 0 & 2 \end{pmatrix}, \qquad AB = B\,\mathrm{diag}(1,-1), \qquad E_+ = B\,\mathrm{diag}(1,0)B^{-1}.$$

The index-two eigenlattice explains the denominator in B^{-1} and in the projector. Over the localized lattice $\Lambda_p = \mathbb{Z}^2_{(p)}$, the number 2 is a unit for every odd prime p. Hence the local denominator weight is zero there and one at $p = 2$.

This is a *local* assertion. Odd localization does not change the fact that the displayed eigenvectors span an index-two sublattice inside the ordinary integer lattice.

The special fiber does not retain the rational splitting

Modulo two, $x - 1 = x + 1$ and A becomes a nontrivial unipotent matrix. The entries $1/2$ in $E_\pm$ cannot be reduced modulo two. By contrast, the coefficient selectors on Plate II.6 use only zero and one and remain available.

> **Read this as:** The obstruction is in integral separation, not in the existence of the two rational eigenspaces. The lattice is part of the question.

Plate II.16 / MODEL D / A SHARP EXAMPLE OF PRECISION DELAY

One extra digit is necessary

Chapter II, mathematical text: Theorem 7.7, Proposition 9.3

The projector acts by

$$E_+(x, y) = (x + y/2, 0).$$

Its factor $1/2$ can consume one dyadic digit. The claim concerns differences: if the inputs agree modulo $2^{m+1}\Lambda$, their projected differences lie in $2^m\Lambda$.

input pair	difference	same mod 8?	E_+ difference	same mod 8?
$0, (0, 8)$	$(0, 8)$	yes	$(4, 0)$	no
$0, (0, 16)$	$(0, 16)$	yes	$(8, 0)$	yes

$$m = 3: \quad 3 \text{ input digits fail; } 4 \text{ input digits suffice.}$$

For $m = 3$, inputs differing by $(0, 8)$ agree modulo eight, but their projected outputs differ by $(4, 0)$ and do not. Raising the input agreement to modulo sixteen makes the projected outputs agree modulo eight.

The example works at every positive depth:

$$E_+(0, 2^m) = (2^{m-1}, 0) \notin 2^m\Lambda, \qquad E_+(0, 2^{m+1}) = (2^m, 0) \in 2^m\Lambda.$$

Thus a zero-delay promise fails, while one extra input digit is sufficient. This witnesses sharpness for the specified projector and lattice.

The general calculation is just as short

If $\pi^s E\Lambda \subseteq \Lambda$ and $x - y = \pi^{m+s}v$, then

$$E(x - y) = \pi^m(\pi^s Ev) \in \pi^m\Lambda.$$

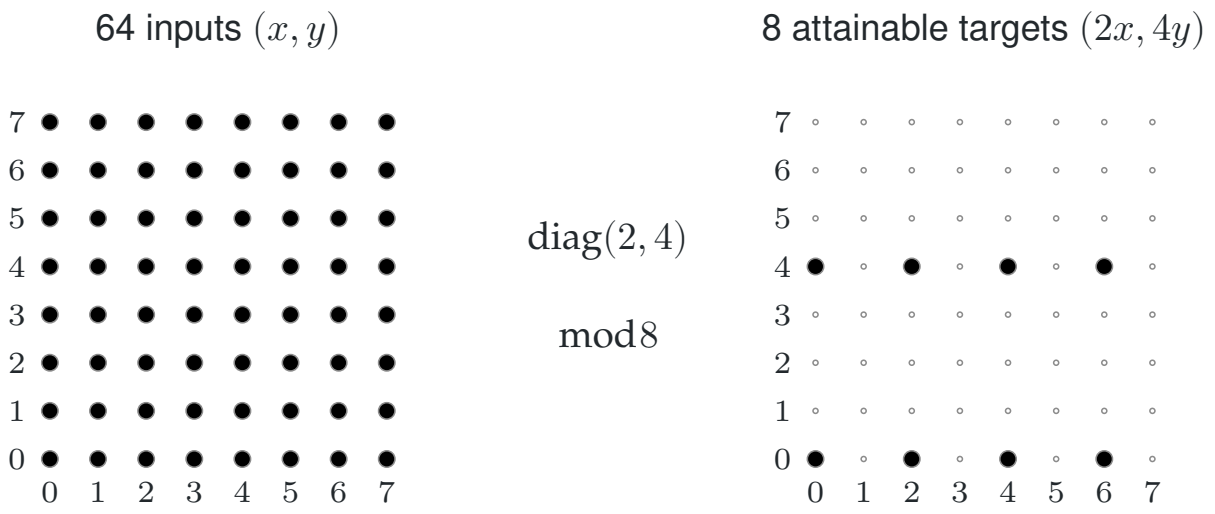
No rounding procedure is hiding in this identity. Nor does it authorize reducing E modulo π when its entries are nonintegral. Individual projected points may lie in a fractional lattice. The theorem controls their difference at the stated integral scale.

Accuracy and branching are different views

The later Smith example records how many inputs share one output at finite depth. Here we ask how accurately an input must be known to determine a projected output difference. Both involve directional divisibility, but they are different questions.

> **Read this as:** The phrase “one lost digit” has an exact meaning: both a sufficiency theorem and an explicit pair of inputs showing that a smaller delay fails.

Plate II.17 / MODEL E / TWO DIRECTIONAL WEIGHTS



See every Smith fiber modulo eight

Chapter II, mathematical text: Theorem 10.6

Consider the actual map of finite sets

$$(\mathbb{Z}/8\mathbb{Z})^2 \longrightarrow (\mathbb{Z}/8\mathbb{Z})^2, \qquad (x, y) \longmapsto (2x, 4y).$$

The first coordinate of the output must be even. The second must be zero or four. Those are precisely the attainable targets in the right panel.

Every filled target has exactly $2 \cdot 4 = 8$ preimages.

All sixty-four input points and all sixty-four possible target addresses are shown. The eight filled target points are the image. Every attainable target has exactly eight preimages. The other fifty-six targets have none.

For a specific attainable target $(2, 4)$,

$$2x \equiv 2 \pmod 8 \iff x \in \{1, 5\}, \qquad 4y \equiv 4 \pmod 8 \iff y \in \{1, 3, 5, 7\}.$$

The coordinate choices are independent, giving $2 \cdot 4 = 8$ solutions. The entire carrier is partitioned consistently:

$$8 \text{ attainable targets} \times 8 \text{ inputs per target} = 64.$$

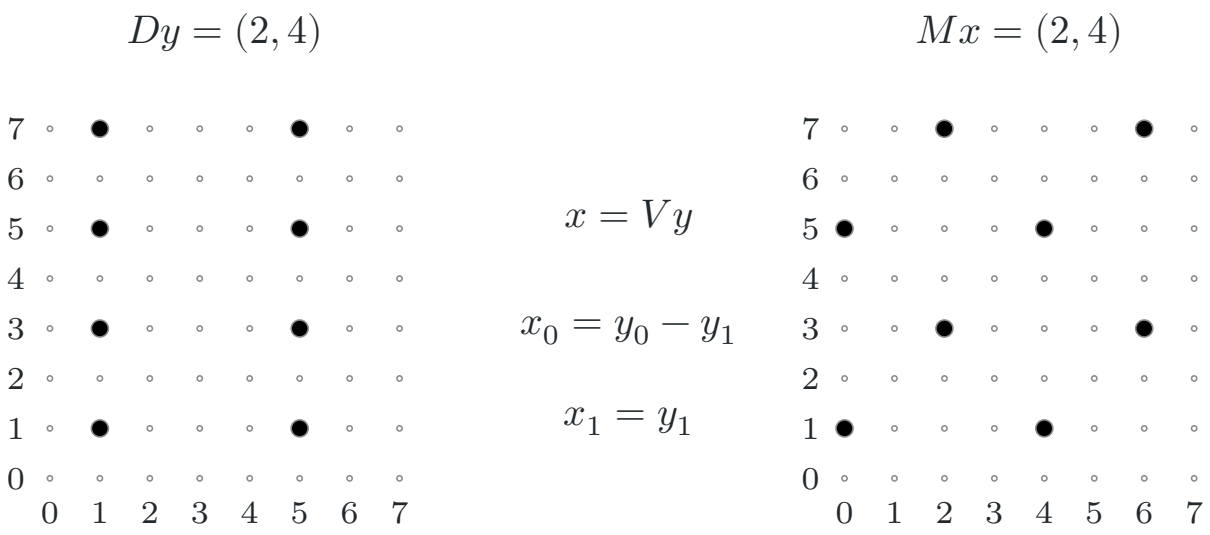
For an inadmissible target, such as $(1, 4)$ or $(2, 2)$, the fiber is empty. The same nonzero cardinality formula must not be applied to it.

The arithmetic behind the picture

Multiplication by p^s modulo p^L has kernel size $p^{\min(s,L)}$. Its image consists exactly of residues whose canonical representatives are divisible by that same power. The displayed model has $p = 2$, $L = 3$ and weights $(1, 2)$.

> **Read this as:** A directional weight has two consequences: a divisibility condition on the target and a conditional multiplicity of inputs. Solvability comes before counting.

Plate II.18 / MODEL E / EXPLICIT SMITH COORDINATES



Transport the whole solution fiber

Chapter II, mathematical text: Theorem 10.6

The preceding diagonal system is connected to a nondiagonal one by the unimodular change of variables

$$M = \begin{pmatrix} 2 & 2 \\ 0 & 4 \end{pmatrix}, \quad V = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}, \quad MV = \operatorname{diag}(2,4) = D.$$

Since $\det V = 1$, $x = Vy$ is bijective modulo eight. Thus $Mx = b$ is equivalent to $Dy = b$.

The eight solutions are permuted, not created or discarded.

The eight solutions for the target $(2,4)$, before and after the coordinate shear. Coordinates are residues in $\{0,\dots,7\}$. No interpolation on this modular grid is intended.

For example, the diagonal solution $y = (1,3)$ corresponds to

$$x = Vy = (-2,3) \equiv (6,3) \pmod 8,$$

and $M(6,3)^{\mathsf{T}} = (18,12)^{\mathsf{T}} \equiv (2,4)^{\mathsf{T}}$. Applying the inverse shear recovers the original solution.

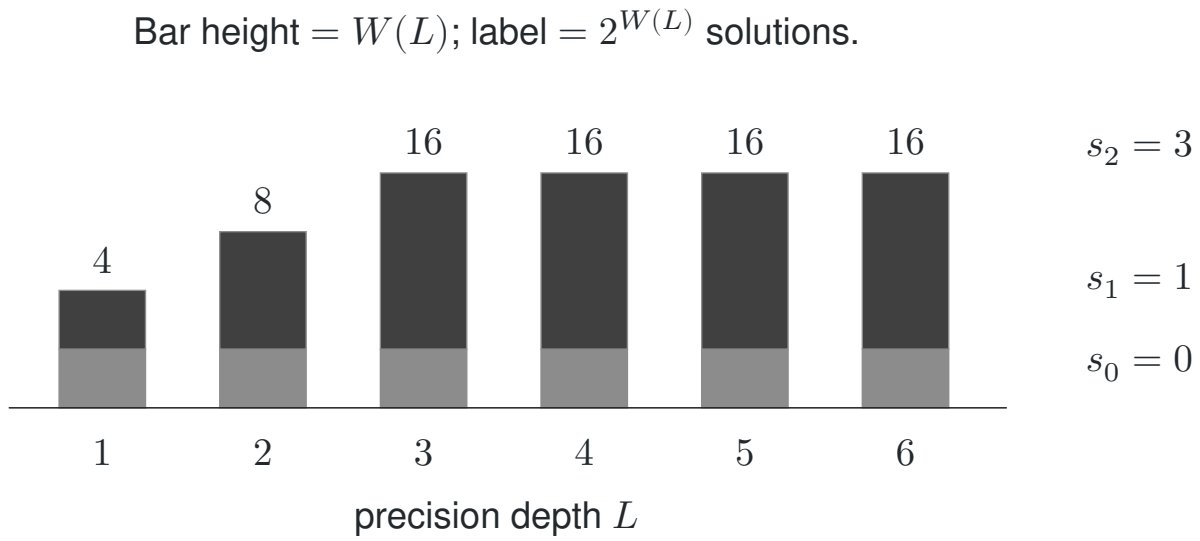
Two boundary cases worth keeping visible

A unit diagonal coordinate has exactly one solution for every target. A literal zero coordinate has all eight possible inputs when its target is zero, and no input when the target is nonzero. A zero coordinate is not inverted or silently omitted.

The displayed diagonalization is verified by multiplication. The theorem takes diagonal data as input. A Smith normal form for an arbitrary matrix or general DVR requires a separate structure theorem.

> **Read this as:** An invertible change of coordinates transports existence, every solution, and the fiber count. The target must be transformed as prescribed when checking admissibility.

Plate II.19 / MODEL E / A FIBER BUDGET AT EACH DEPTH



Precision exposes directional freedom

Chapter II, mathematical text: Theorem 10.6

Take $p = 2$ and the supplied diagonal weights $(s_0, s_1, s_2) = (0, 1, 3)$. At depth L, an admissible target has

$$2^{W(L)} \text{ solutions}, \qquad W(L) = \min(0, L) + \min(1, L) + \min(3, L).$$

Each direction contributes only the amount visible at the current depth.

The stacked height records the exponent $W(L)$. The label above each bar records the actual number of solutions. The zero-weight direction contributes no branching. This is a finite cardinality calculation, not an information-theoretic assumption about random inputs.

The values are

L	1	2	3	4	5	6
$W(L)$	2	3	4	4	4	4
# solutions	4	8	16	16	16	16.

Once $L \geq 3$, the nonzero weights have been fully exposed and the admissible fiber cardinality stabilizes at sixteen. The input space still grows as 2^{3L}. The number of attainable targets grows accordingly.

At depth six, $(1, 2, 8)$ is admissible and gives sixteen solutions. Replacing the last coordinate by four makes the target inadmissible and gives zero solutions, even though the weights and depth are unchanged.

What changes with a zero diagonal factor?

A literal zero factor contributes L, not a fixed eventual weight, and requires a zero target coordinate. Its fiber therefore keeps growing with the modulus. That case must not be mistaken for a finite nonzero Smith weight.

Read this as: The scalar sum of weights gives the count, but the separate weights give the admissibility conditions. Keeping only a determinant valuation can hide which target coordinate fails.

Plate II.20 / MODEL F / A FINITE POLYPHASE REALIZATION

Filter first or split first: same output

Chapter II, mathematical text: Section B.1

Use the finitely supported signal $x = (1, 2, 3, 4, 5, 6)$ and the filter $h = (1, 2, 1)$. Outside the displayed support, the input is zero. Let $e_m = x_{2m}$ and $o_m = x_{2m+1}$.

x	1	2	3	4	5	6		
$h * x$	1	4	8	12	16	20	17	6
y_{even}	1	8	16	17				
y_{odd}	4	12	20	6				

$h = (1, 2, 1)$

zero extension

no periodic wrap

Exact integer convolution, including both output tail coefficients. The two bottom rows are the even and odd output phases. Interleaving them reconstructs the full eight-term output.

If w denotes one delay on a phase sequence, the filter becomes

$$\begin{pmatrix} y_{\text{even}} \\ y_{\text{odd}} \end{pmatrix} = \underbrace{\begin{pmatrix} 1+w & 2w \\ 2 & 1+w \end{pmatrix}}_{H_{\text{phase}}(w)} \begin{pmatrix} e \\ o \end{pmatrix}.$$

The cross-phase delay is not optional. A unit shift sends an odd sample to the next even position, while it sends an even sample to the odd position in the same phase block.

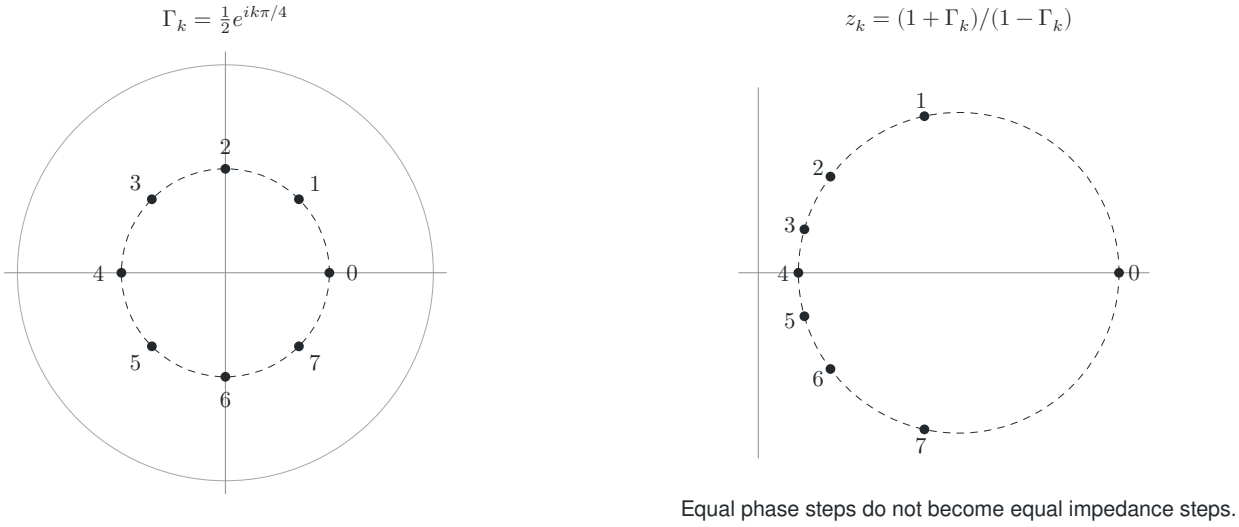
Here $e = 1 + 3w + 5w^2$ and $o = 2 + 4w + 6w^2$, so direct polynomial multiplication gives

$$y_{\text{even}} = 1 + 8w + 16w^2 + 17w^3, \qquad y_{\text{odd}} = 4 + 12w + 20w^2 + 6w^3.$$

This is the same result as ordinary convolution followed by residue extraction. No numerical transform or limiting argument is needed because every sequence is finitely supported.

> **Read this as:** A phase matrix is not just a sparsity pattern. Its delay factors carry the information about quotient and remainder needed when a shift crosses a phase boundary.

Plate II.21 / MODEL G / A NONLINEAR PHASE ORBIT



Two Smith constructions, different roles

Chapter II, mathematical text: Section 12.3, Smith-phase identity (p. 43)

Smith *normal form* concerns linear congruences. The Smith *impedance chart* uses the nonlinear coordinate change

$$\Gamma = \frac{z-1}{z+1}, \qquad z = \frac{1+\Gamma}{1-\Gamma}.$$

They share a name, not a mathematical definition. Sample the reflection circle at the exact algebraic points $\Gamma_k = \frac{1}{2}e^{ik\pi/4}$.

Equal phase steps do not become equal impedance steps.

Matching labels identify the same point in the two coordinates. All eight points are computed algebraically. Only their placement on the page is rendered numerically. The outer left circle is $|\Gamma| = 1$, not part of the sampled radius-$1/2$ orbit.

The half-turn $\Gamma \mapsto -\Gamma$ gives

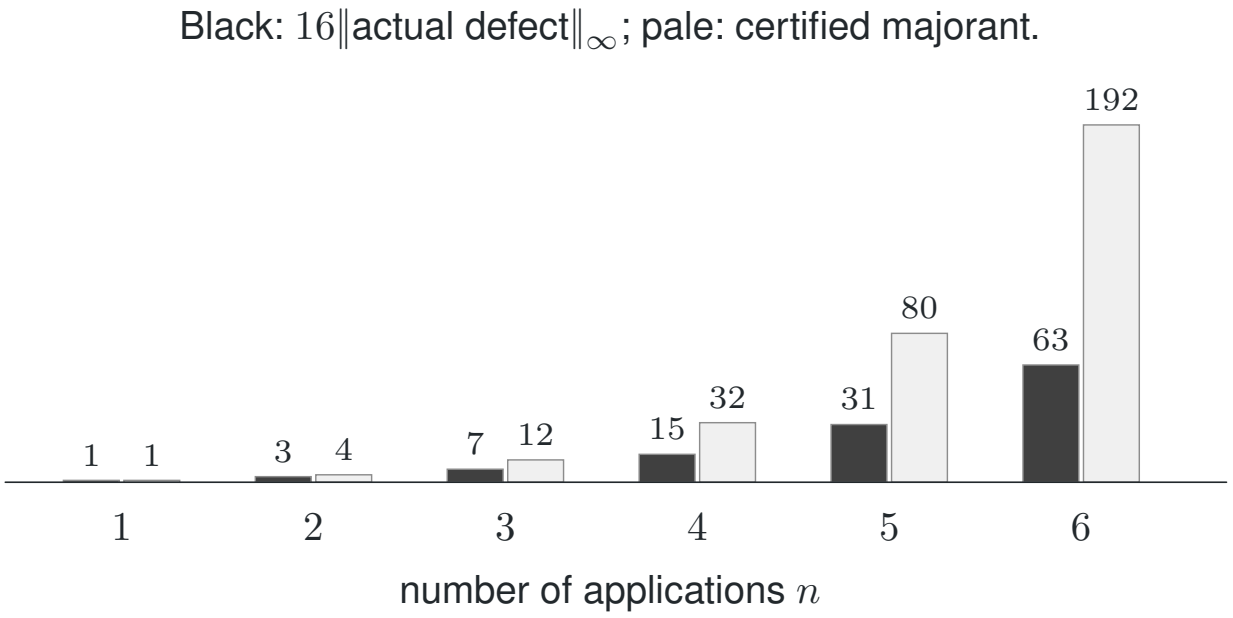
$$z \longmapsto \frac{1}{z}, \qquad z \neq 0, -1.$$

Thus the labels 0 and 4 are 3 and $1/3$. Label 2 is $(3+4i)/5$, and the opposite point is its reciprocal. The domain restrictions come from the forward and inverse coordinate denominators.

These sampled phase points are not linear idempotent ranges. Refining from two to four to eight samples inserts more points on the same orbit. This does not imply a linear packet decomposition of impedance values.

> **Read this as:** The chart is a geometric realization of phase action. Its nonlinear coordinate sensitivity near $\Gamma = \pm 1$ is not the Smith congruence-fiber count and not a new linear projector theorem.

Plate II.22 / MODEL H / EXACT TELESCOPING, EXPLICIT GROWTH



A small defect can grow under powers

Chapter II, mathematical text: Theorem 11.1, Corollary 11.3

Choose an invertible coordinate shear but independently keep the same numerical operator at both levels:

$$C = \begin{pmatrix} 1 & \varepsilon \\ 0 & 1 \end{pmatrix}, \quad T_f = T_c = \operatorname{diag}(1, 2), \quad \varepsilon = \frac{1}{16}.$$

Then $\Delta = CT_f - T_c C = \varepsilon E_{01}$. Exact coordinate invertibility has not forced these independently selected operators to intertwine.

Actual defects and certified upper bounds in the induced infinity norm, both divided by ε. All heights are exact integers. The upper estimate is valid but need not be tight.

Direct multiplication gives

$$CT_f^n - T_c^n C = \varepsilon(2^n - 1)E_{01}.$$

The general telescoping formula explains every contribution:

$$CT_f^n - T_c^n C = \sum_{k=0}^{n-1} T_c^{n-1-k} \Delta T_f^k.$$

Since both operator norms are two, the source theorem bounds the error by $n2^{n-1}\varepsilon$. It does not promise a small error uniformly in n merely because ε is small.

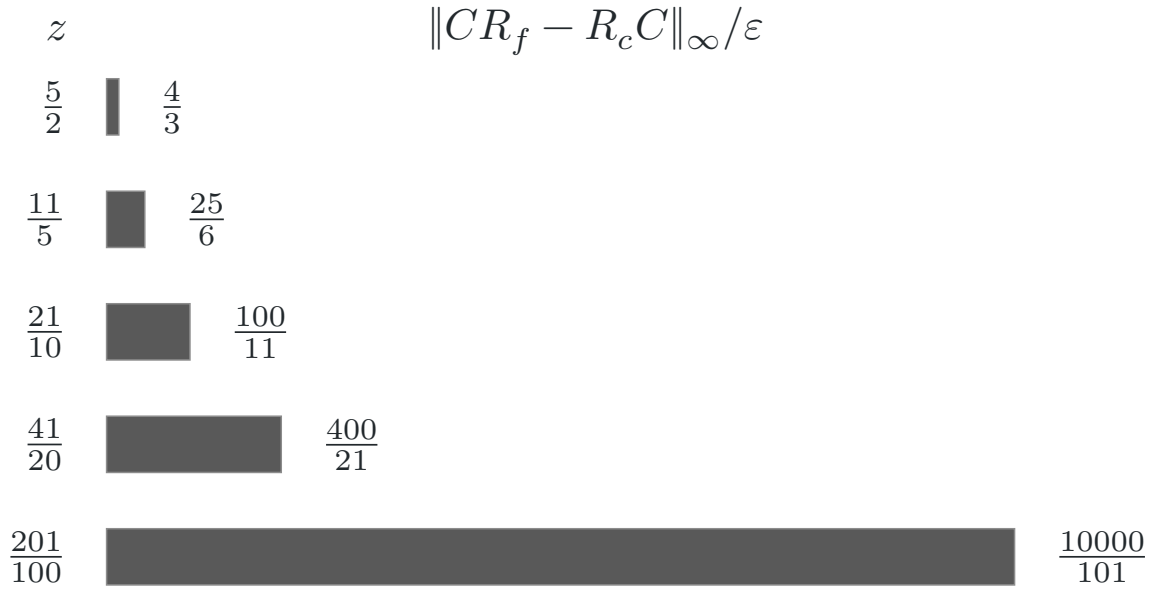
Had we chosen the transported operator $T_c' = CT_f C^{-1}$, the defect would be zero and every polynomial action would intertwine exactly. That is a different choice of coarse operator, not a stronger conclusion from the faulty one.

> **Read this as:** Separate coordinate coherence from operator consistency. A defect from one step is propagated by the dynamics on both sides. The telescoping identity tells you exactly how.

Plate II.23 / MODEL H / A DOMAIN-SENSITIVE COMPARISON

Resolvents amplify errors near poles

Chapter II, mathematical text: Theorem 11.5



For the same model, take $z \notin \{1, 2\}$ and form the actual inverse matrices

$$R_f = (zI - T_f)^{-1}, \qquad R_c = (zI - T_c)^{-1}.$$

Their off-diagonal intertwining error is

$$CR_f - R_c C = R_c \Delta R_f = \frac{\varepsilon}{(z-1)(z-2)} E_{01}.$$

Both inverse hypotheses matter. Neither resolvent is asserted at a pole.

Exact rational samples; the point $z = 2$ itself is excluded.

The bars show exact amplification factors for five rational choices $z > 2$. Rows are separate samples, not equally spaced positions on the z axis. The coefficient $\varepsilon = 1/16$ has been divided out.

At $z = 3$ the amplification factor is only $1/2$. At $z = 201/100$, it is $10000/101$, so a small one-step defect can create a much larger resolvent defect. This follows from the exact formula rather than from unstable floating-point subtraction of two nearly singular inverses.

The certified general norm estimate is

$$\|CR_f - R_c C\| \le \|R_c\| \, \|\Delta\| \, \|R_f\|.$$

The chapter also proves a version using one-sided witnesses: a left inverse for the coarse shift and a right inverse for the fine shift suffice for the algebraic identity. That does not turn arbitrary one-sided witnesses into a claim of two-sided resolvent existence.

> **Read this as:** A small local defect is meaningful only together with control of the surrounding operators or inverses. Near a pole, the domain and amplification factors are part of the theorem, not technical decoration.

Plate II.24 / PROOF BOUNDARY / HOW TO USE THIS GUIDE

Read the certificates with the pictures

Formal evidence: chapter-wide correspondence and the 25-row foundational contract

The foundational formal contract has twenty-five items: twenty-one numbered definitions and results in the main text, one Smith-phase identity, and three algorithm specifications. The source archive preserves its evidence. The broader constructions have a separate correspondence and replay record. The table below describes the foundational interfaces. The chapter-wide map identifies the broader constructions. The models illustrate the mathematics, and their finite checks have recorded ranges.

Formal coverage. 53 of 53 proof-level source records have kernel checked, semantically accepted scope. No partial or pending proof records are listed in this correspondence. These are source-record counts under their stated hypotheses, not counts of independent discoveries.

Inherited interface	Inputs and checked scope	Boundary of that interface
Exact refinement	Complete projector families and a parent map when formulas relating parents to children are used.	A canonical refinement for every arbitrary pair of decompositions.
Fourier realization	A finite orthogonality table, or field/root hypotheses that provide it.	Orthogonality from multiplicative order alone over every ring.
Weighted inversion	A two-sided inverse of D, a multiplicative filtration, and positive certified gains.	Convergence in every possible complete filtered algebra.
Graph rationality	A finite multigraph with positive weights, together with its actual determinant and adjugate.	Simple-path counts, analytic convergence everywhere, or operator noncancellation.
Spectral separation	Evaluated Bézout identities and explicit lattice-preservation data.	Automatic construction or minimality of every resultant certificate.
Smith congruences	Concrete diagonal data modulo p^L, with $p > 1$.	An automatically constructed general-DVR Smith normal form.
Linear defects	Actual typed maps and the stated inverse or norm witnesses.	Small propagated errors independent of time or distance from a pole.

Reproduce the explanatory calculations

The preserved model source contains **118 named exact checks**. Each finite range is recorded in the file `EXACT_CHECKS.json`. They cover masks, CRT labels, modular inverse products, graph enumeration, rational recurrences, lattice denominators, complete finite fibers, phase identities, and defect formulas. Graphics are generated from those same exact model definitions. Numerical placement of geometric points is only a rendering step.

The computational report records 48 passing Python tests, 118 exact visual checks, 22 byte-matching regenerated vector plates, 13 regenerated PDF/PNG figure pairs, and nine matching numerical summary rows. Each record retains its tested range and source identity. Lean replay and source coverage are documented separately.

Read this as: Use the guide to understand what a theorem says and why its hypotheses matter. Use the theorem map and preserved proof sources to identify the precise formal result. Neither a picture nor a finite test expands that result's scope.

CHAPTER III

Projector Resolved Seed Calculus III

Typed transfer, nonlinear packets, and obstruction theory

The preceding constructions provide the linear setting. This chapter studies nonlinear coordinates and the limits of their extension.

Typed operations extend the linear language to nonlinear coordinates, analytic packet jets and obstruction theory. The analytic supplement develops the continuous packet-jet claims.

IN THIS CHAPTER

Mathematical text 178

Scope

Expanded ordinary proofs and the bounded Lean core have different coverage. The packet Taylor estimates, counting arguments and later extensions retain their stated ordinary-proof status. Arbitrary differentiability is not asserted.

The next chapter develops a cyclic analytic family through coefficient selection, transport and spectral data.

How to use this volume

Begin with typed edge words and exact coordinate transport. A chosen connection introduces defects, holonomy, and packet obstruction witnesses. Part II develops nonlinear packet jets, tree expansions, correction complexes, filtered lifting, elimination, and smooth transport.
Part I develops the finite algebraic core under its declaration-level formal contract. Part II gives the nonlinear and analytic development with ordinary proofs. The accompanying formal development verifies exact nonlinear coordinates, continuous packet jets on actual projector ranges, and the decorated composition and structural support laws in Lean. The integral Taylor remainder and the later analytic and obstruction results retain their ordinary proof status. Formal coverage stays attached to the identified declarations. The visual atlas at the end of this volume provides twenty-four worked plates. The separate Lean guide explains the formal contract and its evidence.

Overview

Finite projector packets turn linear transfer into typed walks and arbitrary maps into exact coordinate representations. Canonical coordinate transport satisfies an exact cocycle law. A chosen connection can fail to compose, producing holonomy and packet obstruction witnesses. Nonlinear packet jets lead to higher composition, convergent rooted tree expansions, graded operations, and nonlinear refinement defects. A specified correction map produces a canonical cokernel obstruction. Relative exact sequences, mapping cones, Hilbert splitting, nonlinear correction, and filtered lifting describe how these obstructions behave. Exact elimination produces Schur formulas, and finite transport reduces gluing to fundamental cycle holonomy. For smooth orthogonal packet families, direct packet rotations converge in operator norm to canonical unitary transport. The finite formal contract and the broader ordinary proof development retain their separate scopes throughout.

The chapter presents the mathematical development together with worked examples, a visual atlas, and a separate guide to the formal proof evidence. The packet norm estimate distinguishes the actual range jet from its ambient extension. The support statements keep external packet profiles and intermediate composition witnesses explicitly typed. The formal companion gives the exact source and scope of each formal verification.

Part I Finite typed transfer and the formal contract

The finite algebraic core supplies the algebraic foundation and a contract for its individual declarations. Here, "roadmap" and "outside the contract" describe the scope of the finite Lean formalization. Ordinary mathematical results in Part II may lie beyond that scope. The finite contract covers thirty result environments. The source contract has 41 mapping rows because it also includes definitions and other interfaces.

The formal companion records the exact Lean and Mathlib dependencies [3, 17], compilation, kernel replay, and axiom checks. References to declarations from Chapters I–II retain their explicitly inherited status. The companion distinguishes the finite algebraic contract from the additional packet-coordinate and analytic interfaces.

1 Purpose and formal status

Chapter I fixed typed seeds, operator grammars, exact projector packets, generated hulls, and reconstruction [13]. Chapter II added coherent refinement coordinates, weighted transfer, arithmetic separation, and linear defect identities [14]. The present chapter begins the next layer: explicit edge words, optional connection data, and obstructions within individual packets.

Canonical coordinate transport and a connection play different mathematical roles. Canonical transport compares two exact descriptions of the *same* ambient object and is forced by analysis and synthesis. A connection chooses transports that may carry extra modeling, discretization, or gauge information. Canonical transport obeys a cocycle theorem. A connection may fail to obey a cocycle, and that failure is meaningful data. Keeping separate notation lets us distinguish the automatic coherence of exact coordinates from the possible holonomy of a chosen connection.

1.1 Statement labels

Every substantial theorem, lemma, corollary, proposition, definition, API, and roadmap item carries one or more of the three labels below. When separate clauses use a Chapter III result and an inherited bridge, the statement carries both applicable labels. Illustrative examples do not require a label.

S1. Lean-backed in Chapter III: the displayed scope is no stronger than the named compiled declaration in the identified Chapter III module.

S2. Inherited Lean-backed: the displayed result is supplied by the stated formal contract of Chapter I or Chapter II.

S3. Roadmap only: the text states a future interface or theorem target and is excluded from the completion denominator.

Boundary 1.1 (Finite theorem denominator). The completion denominator of the finite algebraic contract consists of the thirty result environments in Part I. Of these, 26 resolve to compiled Chapter III declarations and four resolve to the stated Chapters I–II contracts. The authoritative theorem map names the exact declarations used by each statement. The kernel audit checks those targets and their supporting theorems. The namespace gate requires every declaration in the compiled Komorebi.PaperIII

namespace to pass its checks. Roadmap items are excluded from the denominator and remain visibly marked.

2 Finite typed packet graphs

2.1 Orientation and matrix convention

Let V be a finite packet type, E a finite edge type, and R a semiring. A directed multigraph is a pair of endpoint functions

$$\mathrm{src}, \mathrm{tgt} : E \longrightarrow V.$$

Parallel edges remain distinct elements of E. Rows are targets and columns are sources. Thus an edge $e : i \to j$ is represented by a matrix supported at row j, column i.

Definition 2.1 (Packet graph and scalar edge system)**.** For $a, b \in V$ and $r \in R$, define

$$\mathrm{packetMatrix}(a, b; r)_{yx} = \begin{cases} r, & y = b \text{ and } x = a, \\ 0, & \text{otherwise.} \end{cases}$$

An edge system is a coefficient function $c : E \to R$. Its elementary edge operator and total transfer operator are

$$L_e = \mathrm{packetMatrix}(\mathrm{src}(e), \mathrm{tgt}(e); c(e)), \qquad T = \sum_{e \in E} L_e.$$

Formal contract: finite algebraic core.

`Komorebi.PaperIII.EdgeOperators.PacketGraph;Komorebi.PaperIII.EdgeOperators.PacketGraph.packetMatrix;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp`

Words are written in execution order. In $L_f L_e$, the rightmost operator L_e acts first. For a written word $(e_1, \dots, e_n)$, e_1 acts first and the operator product is $L_{e_n} \cdots L_{e_1}$.

Reading the execution order

Read the edge list in the order of execution. The matrix product writes later actions farther to the left. The target packet of one edge must equal the source packet of the next before multiplication can contribute. Over a noncommutative semiring, this order also fixes the order of the scalar coefficients.

Lemma 2.2 (Declared support)**.** *For every edge e, $(L_e)_{yx} = 0$ unless $y = \mathrm{tgt}(e)$ and $x = \mathrm{src}(e)$.*

Formal contract: finite algebraic core.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_eq_zero_off_support`

Theorem 2.3 (Typed interface annihilation)**.** *If $\mathrm{tgt}(e) \neq \mathrm{src}(f)$, then*

$$L_f L_e = 0.$$

Formal contract: finite algebraic core.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_mul_edgeOp_eq_zero`

Proof. For a matrix entry (y, x),

$$(L_f L_e)_{yx} = \sum_{z \in V} (L_f)_{yz} (L_e)_{zx}.$$

A potentially nonzero summand would require simultaneously $z = \mathrm{src}(f)$ and $z = \mathrm{tgt}(e)$, contrary to the hypothesis. □

Theorem 2.4 (Collapse of a matched edge pair). *If* $\mathrm{tgt}(e) = \mathrm{src}(f)$, *then*

$$L_f L_e = \mathrm{packetMatrix}(\mathrm{src}(e), \mathrm{tgt}(f); c(f)c(e)).$$

Together with theorem 2.3, this gives both cases for the composition of two edge operators.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_mul_edgeOp_of_composable`

Proof. The sum defining the matrix product has exactly one potentially nonzero intermediate index, namely $\mathrm{tgt}(e) = \mathrm{src}(f)$. At that index the coefficients occur in operator order as $c(f)c(e)$, and the outer source and target are $\mathrm{src}(e)$ and $\mathrm{tgt}(f)$. □

Boundary 2.5 (Current fiber scope). The compiled Chapter III model above has one scalar coordinate per packet. For a family of modules $(X_i)_{i \in V}$, an intrinsic edge map would instead have type $\ell_e : X_{\mathrm{src}(e)} \to X_{\mathrm{tgt}(e)}$, and its totalization on $\bigoplus_i X_i$ would be $\iota_{\mathrm{tgt}(e)} \ell_e \pi_{\mathrm{src}(e)}$. The same support proof applies, but this generalization with dependent fibers is not attributed to the compiled Chapter III modules for scalar edge systems.

Figure 1 summarizes the support convention and shows how composable words differ from words with a broken interface. The next section uses this distinction.

3 Operator words and directed walks

3.1 Typed words

Definition 3.1 (Composable word and execution operator). A finite word $w = (e_1, \dots, e_n)$ is composable when

$$\mathrm{tgt}(e_r) = \mathrm{src}(e_{r+1}) \qquad (1 \le r < n).$$

Set

$$L_w = L_{e_n} \cdots L_{e_1}, \qquad L_\emptyset = I.$$

This definition records the written order of execution even though matrix composition is read right to left.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.Composable;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp`

Theorem 3.2 (First broken interface). *If a word begins* $(e, f, \dots)$ *and* $\mathrm{tgt}(e) \neq \mathrm{src}(f)$, *then its word operator is zero.*

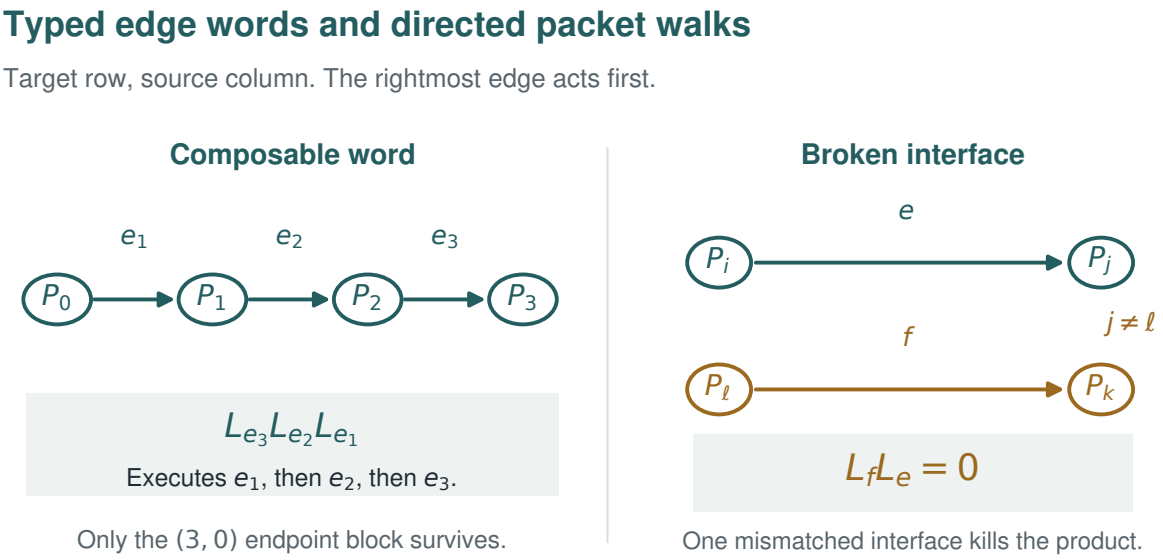

Figure 1. Rows record target packets and columns record source packets. This convention fixes execution order. Composable words collapse to endpoint blocks, while one broken packet interface annihilates the entire operator product.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_eq_zero_of_first_break`

Theorem 3.3 (Noncomposable words vanish)**.** *If w is not composable, then $L_w = 0$.*

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_eq_zero_of_not_composable`

Proof. Choose the first broken adjacent pair. The corresponding consecutive factor is zero by theorem 2.3, and associativity absorbs that zero into the complete product. The Lean proof implements the same argument by induction on the list. □

3.2 The checked recursive expansion

Definition 3.4 (Recursive word expansion)**.** Define

$$\mathcal{W}_0 = I, \qquad \mathcal{W}_{n+1} = T\mathcal{W}_n.$$

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordExpansion`

Theorem 3.5 (Transfer power equals recursive word expansion). *For every $n \in \mathbb{N}$,*

$$T^n = \mathcal{W}_n.$$

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_eq_wordExpansion`

Proof. The zero case is the identity matrix. If $T^n = \mathcal{W}_n$, then the left-successor power convention gives $T^{n+1} = TT^n = T\mathcal{W}_n = \mathcal{W}_{n+1}$. □

Remark 3.6. The formal module also defines an explicit sum over tuples $w : \mathrm{Fin}(n) \to E$ and a second sum in which noncomposable tuples are replaced by zero. It proves that the recursive matrix, the explicit tuple sum, and the sum filtered by composability agree. The separate declarations make the finite enumeration claim directly checkable.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.explicitWordExpansion;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.walkExpansion;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordExpansion_eq_explicitWordExpansion;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.explicitWordExpansion_eq_walkExpansion`

3.3 Exact expansion from words to walks

For a nonempty composable word $w = (e_1, \dots, e_n)$, define its reverse coefficient product

$$c^{\leftarrow}(w) = c(e_n)c(e_{n-1}) \cdots c(e_1).$$

The reversal is essential over a noncommutative semiring.

Lemma 3.7 (One word is one endpoint block). *If $w = (e_1, \dots, e_n)$ is nonempty and composable, then*

$$L_w = \mathrm{packetMatrix}(\mathrm{src}(e_1), \mathrm{tgt}(e_n); c^{\leftarrow}(w)).$$

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.reverseCoefficient;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.terminalTarget;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_eq_packetMatrix_of_composable`

Proof. Induct on n. The case $n = 1$ is the definition of L_e. Suppose the formula holds for the prefix $(e_1, \dots, e_n)$ and append f. Composability gives $\mathrm{tgt}(e_n) = \mathrm{src}(f)$. Multiplying the two packet matrices leaves one intermediate index and changes the coefficient to $c(f)c(e_n) \cdots c(e_1)$, with source $\mathrm{src}(e_1)$ and target $\mathrm{tgt}(f)$. □

Write $\mathrm{Walk}_n(i, j)$ for the finite set of composable edge tuples of length n whose first source is i and whose final target is j. For $n = 0$, it has one empty walk when $i = j$ and is empty otherwise. Assign the empty walk the coefficient 1.

The empty walk

The empty walk records doing nothing at a chosen packet. It contributes only to a diagonal entry. Thus the convention for length zero matches the identity matrix and lets the walk sum include every nonnegative power.

Theorem 3.8 (Finite operator expansion from words to walks). *For every $n \in \mathbb{N}$,*

$$\boxed{T^n = \sum_{w \in E^n} L_w = \sum_{w \in E^n} \begin{cases} L_w, & w \text{ composable}, \\ 0, & w \text{ not composable}. \end{cases}}$$

Parallel edges occur as distinct summands.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_eq_explicitWordExpansion;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_eq_walkExpansion`

Proof. Induction and finite distributivity give

$$\left(\sum_{e \in E} L_e\right)^n = \sum_{(e_1,\dots,e_n) \in E^n} L_{e_n} \cdots L_{e_1}.$$

Every noncomposable summand is zero by theorem 3.3, so inserting the composability filter does not change the sum. In Lean, tuple concatenation and the successor sum are handled by `tupleWordOp_snoc` and `explicitWordExpansion_succ`. The two bridge equalities then yield the displayed theorem. □

Corollary 3.9 (Endpoint coefficient walk sum). *For all $n \in \mathbb{N}$ and $i, j \in V$,*

$$\boxed{(T^n)_{ji} = \sum_{w \in \mathrm{Walk}_n(i,j)} c^{\leftarrow}(w).}$$

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.Connects;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.endpointWalkCoefficientSum;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_apply_eq_sum_walks`

Proof. Take the (j, i) entry in theorem 3.8. By lemma 3.7, a surviving word contributes $c^{\leftarrow}(w)$ exactly when its endpoints are i and j, and contributes zero otherwise. At $n = 0$, the identity matrix gives the unique empty diagonal walk. □

Corollary 3.10 (Reachability obstruction at fixed length). *If* $\mathrm{Walk}_n(i, j) = \emptyset$, *then* $(T^n)_{ji} = 0$.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_apply_eq_zero_of_no_walk`

Proof. This is immediate from the empty sum in the preceding corollary. □

Corollary 3.11 (Orbit support obstruction). *Let $S \subseteq V$, and let $x \in R^V$ be supported on S. If j is not reachable by a directed path from any vertex of S, then*

$$(T^n x)_j = 0 \qquad \text{for every } n \in \mathbb{N}.$$

Hence the orbit under T of x cannot generate a vector with a nonzero coordinate at j.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.Reachable;Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_mulVec_apply_eq_zero_of_unreachable_support`

Inherited formal contract: Chapters I–II.
`Komorebi.PacketNaturalityCompletion.Reachability.algebraicOrbitHull_le_reachable_support;Komorebi.PacketNaturalityCompletion.Reachability.unreachable_nonzero_packet_obstruction`

Proof. Expand $(T^n x)_j = \sum_i (T^n)_{ji} x_i$. Terms with $i \notin S$ vanish by the support of x, and terms with $i \in S$ vanish by corollary 3.10. The final claim follows because the j-coordinate also vanishes on every finite linear combination of orbit vectors. □

4 Canonical exact coordinate transport

4.1 The Chapter III frame model

Let every chart a carry a linear frame equivalence $F_a : M \xrightarrow{\sim} M$. The formal Chapter III module defines transport from a to b by

$$J_{b \leftarrow a} = F_b^{-1} F_a.$$

This frame formula means *synthesize in chart a, then analyze in chart b.*

Theorem 4.1 (Exact frame transport is coherent). *For every a, b, c,*

$$J_{a \leftarrow a} = \mathrm{id}, \qquad J_{a \leftarrow b} J_{b \leftarrow a} = \mathrm{id}, \qquad J_{c \leftarrow b} J_{b \leftarrow a} = J_{c \leftarrow a},$$

and therefore

$$J_{a \leftarrow c} J_{c \leftarrow b} J_{b \leftarrow a} = \mathrm{id}.$$

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.exactTransport_self;Komorebi.PaperIII.Transport.exactTransport_roundTrip;Komorebi.PaperIII.Transport.exactTransport_cocycle;Komorebi.PaperIII.Transport.exactTransport_triangleLoop`

Proof. Every identity is cancellation of adjacent $F_r F_r^{-1}$ factors. The Lean definitions use `LinearEquiv.trans`. The displayed formulas use the equivalent right-to-left notation for function composition fixed in this chapter. □

Theorem 4.2 (Every finite canonical path telescopes). *Let $p = (a_0, a_1, \dots, a_n)$ be any finite vertex list and put*

$$J_p = J_{a_n \leftarrow a_{n-1}} \cdots J_{a_1 \leftarrow a_0}, \qquad J_{(a_0)} = \mathrm{id}.$$

Then

$$J_p = J_{a_n \leftarrow a_0}.$$

In particular, if $a_n = a_0$, *then* $J_p = \mathrm{id}$.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.pathEndpoint;Komorebi.PaperIII.Transport.exactPathTransport;Komorebi.PaperIII.Transport.exactPathTransport_eq_endpoint;Komorebi.PaperIII.Transport.exactPathTransport_loop`

Proof. Induct on the list of successive vertices and apply the cocycle in theorem 4.1 at each step. If the endpoint is the start, the endpoint transport is the identity. □

4.2 Exact packet coordinates

The graph model above resolves a fixed scalar matrix. Coordinate transport is a separate construction. Let X be an R-module, and let

$$\mathcal{P}^a = (P_i^a)_{i \in I_a}$$

be a finite complete family of pairwise orthogonal linear idempotents:

$$P_i^a P_j^a = \delta_{ij} P_i^a, \qquad \sum_{i \in I_a} P_i^a = I_X.$$

Define the exact packet coordinate module

$$\mathrm{Coord}(\mathcal{P}^a) = \left\{ (x_i)_{i \in I_a} : P_i^a x_i = x_i \right\}.$$

Its analysis and synthesis maps are

$$\mathcal{A}_a(x) = (P_i^a x)_i, \qquad \mathcal{S}_a((x_i)_i) = \sum_i x_i.$$

Completeness and orthogonality give

$$\mathcal{S}_a \mathcal{A}_a = \mathrm{id}_X, \qquad \mathcal{A}_a \mathcal{S}_a = \mathrm{id}_{\mathrm{Coord}(\mathcal{P}^a)}.$$

What a packet coordinate contains

A packet coordinate is a whole vector fixed by its projector. Analysis splits an ambient vector into these components, and synthesis adds them back. The transport between exact systems keeps the ambient vector and changes its packet presentation.

Definition 4.3 (Canonical exact coordinate transport)**.** For two exact packet systems on the same ambient module, define

$$J^X_{b \leftarrow a} = \mathcal{A}_b \mathcal{S}_a : \mathrm{Coord}(\mathcal{P}^a) \longrightarrow \mathrm{Coord}(\mathcal{P}^b).$$

The arrow points from the source coordinate system a to the target coordinate system b.

Inherited formal contract: Chapters I–II.

`Komorebi.PaperII.NestedRefinement.refineCoordinates;Komorebi.PaperII.NestedRefinement.coordinateRefinementEquiv`

Theorem 4.4 (Identity, inverse, and cocycle for canonical transport)**.** *For any exact packet systems a, b, c on X,*

$$J^X_{a\leftarrow a} = \mathrm{id}, \qquad \left(J^X_{b\leftarrow a}\right)^{-1} = J^X_{a\leftarrow b}, \qquad J^X_{c\leftarrow b} J^X_{b\leftarrow a} = J^X_{c\leftarrow a}.$$

Inherited formal contract: Chapters I–II.

`Komorebi.PaperII.NestedRefinement.refineCoordinates_self;Komorebi.PaperII.NestedRefinement.coarsenCoordinates_refineCoordinates;Komorebi.PaperII.NestedRefinement.refineCoordinates_coarsenCoordinates;Komorebi.PaperII.NestedRefinement.refineCoordinates_comp;Komorebi.PaperII.NestedRefinement.coordinateRefinementEquiv_trans`

Proof. Insert $\mathcal{S}_b\mathcal{A}_b = \mathrm{id}_X$:

$$J^X_{c\leftarrow b} J^X_{b\leftarrow a} = \mathcal{A}_c \mathcal{S}_b \mathcal{A}_b \mathcal{S}_a = \mathcal{A}_c \mathcal{S}_a = J^X_{c\leftarrow a}.$$

The identity statement is $\mathcal{A}_a\mathcal{S}_a = \mathrm{id}$. Setting $c = a$ in the cocycle gives $J^X_{a\leftarrow b} J^X_{b\leftarrow a} = \mathrm{id}$. Interchanging a and b gives the other composition, so the two transports are inverses. □

If $F : X \to Y$ is linear and $\mathcal{P}^a, \mathcal{P}^b$ are source packet systems while $\mathcal{Q}^r, \mathcal{Q}^s$ are target packet systems, put

$$\widehat{F}_{r\leftarrow a} = \mathcal{A}^Y_r F \mathcal{S}^X_a.$$

Theorem 4.5 (Canonical coordinate naturality)**.** *The exact coordinate representation preserves typed composition and satisfies*

$$J^Y_{s\leftarrow r} \widehat{F}_{r\leftarrow a} = \widehat{F}_{s\leftarrow b} J^X_{b\leftarrow a}.$$

Inherited formal contract: Chapters I–II.

`Komorebi.PaperII.NestedRefinement.coordinateOperator_comp;Komorebi.PaperII.NestedRefinement.coordinateOperator_naturality`

Proof. Both sides reduce to $\mathcal{A}^Y_s F \mathcal{S}^X_a$ after inserting the appropriate synthesis–analysis identity. The composition law is the same calculation with the middle ambient module inserted. □

Corollary 4.6 (Canonical triangle holonomy is trivial)**.** *For every triple a, b, c,*

$$J^X_{a\leftarrow c} J^X_{c\leftarrow b} J^X_{b\leftarrow a} = \mathrm{id}.$$

Inherited formal contract: Chapters I–II.

`Komorebi.PaperII.NestedRefinement.refineCoordinates_comp;Komorebi.PaperII.NestedRefinement.refineCoordinates_self`

Boundary 4.7 (Refinement is not reduction). Although Chapter II uses the name *refineCoordinates*, J is an equivalence between two complete coordinate presentations. It neither truncates packets nor projects to a smaller state space. Any lossy restriction, interpolation, or learned identification is extra data and cannot inherit theorem 4.4 without proof.

5 A distinct noncanonical connection API

5.1 The minimal compiled API

The compiled Chapter III API assumes only normalization at each chart. All chart transports act on one module M, so chart labels distinguish routes but not Lean types.

Definition 5.1 (Noncanonical connection normalized at each chart)**.** A minimal connection is a family

$$\Gamma_{b\leftarrow a} \in \mathrm{Aut}_R(M) \qquad (a, b \in B)$$

with only

$$\Gamma_{a\leftarrow a} = \mathrm{id}_M.$$

Neither inversion on reversed edges nor the cocycle law is a field of the structure.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.Connection`

At a triple (a, b, c), the compiled cocycle predicate is

$$\Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a} = \Gamma_{c\leftarrow a}.$$

Flatness means this equality holds for every triple. The formal multiplicative relative defect and triangle holonomy are

$$D^{\times}_{c,b,a} = (\Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a})\Gamma^{-1}_{c\leftarrow a}, \qquad H_{c,b,a} = \Gamma_{a\leftarrow c}\Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a}.$$

The defect is based at the target c. The holonomy is based at a.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.Connection.CocycleAt;Komorebi.PaperIII.Transport.Connection.Flat;Komorebi.PaperIII.Transport.Connection.cocycleDefect;Komorebi.PaperIII.Transport.Connection.triangleHolonomy`

Theorem 5.2 (Checked flatness consequences)**.** *For the minimal connection API, flatness implies*

$$D^{\times}_{c,b,a} = \mathrm{id}_M, \qquad H_{c,b,a} = \mathrm{id}_M$$

for every a, b, c.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.Connection.cocycleDefect_eq_refl_of_flat;Komorebi.PaperIII.Transport.Connection.triangleHolonomy_eq_refl_of_flat`

Proof. Flatness replaces the two-edge route in $D^{\times}$ by the direct route, which cancels its inverse. For H, flatness first collapses $a \to b \to c$ to $a \to c$, then collapses $a \to c \to a$ to the normalized transport $a \to a$. □

Proposition 5.3 (The minimal API admits nontrivial holonomy)**.** *There is a connection on three points over $\mathbb{Q}$ for which transport $0 \to 1$ is multiplication by 2, every other transport between distinct endpoints is the identity, and*

$$H_{2,1,0}(1) = 2.$$

In particular $H_{2,1,0} \neq \mathrm{id}$.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.twistedThreePointConnection;Komorebi.PaperIII.Transport.twisted_triangleHolonomy_apply_one;Komorebi.PaperIII.Transport.twisted_triangleHolonomy_ne_refl`

Boundary 5.4 (Why the minimal defect and loop are distinct). Without reverse-edge inversion, $\Gamma_{a\leftarrow c}$ need not equal $\Gamma^{-1}_{c\leftarrow a}$. Therefore the multiplicative relative defect $D^{\times}_{c,b,a}$ and triangle holonomy $H_{c,b,a}$ are different comparisons. The formal module proves that global flatness trivializes both. It does not identify them for an arbitrary connection.

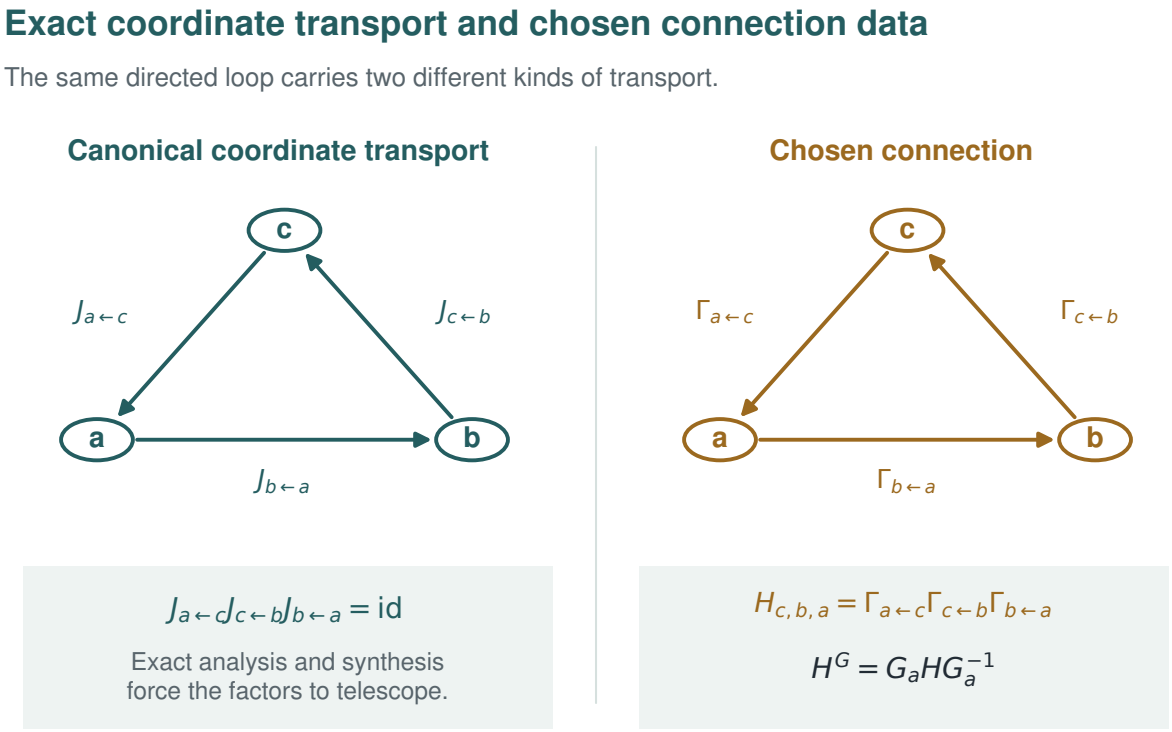

Figure 2. Exact coordinate transport and connection transport are distinct. The canonical loop telescopes to the identity. A chosen connection may carry nontrivial holonomy, which transforms by conjugation under gauge.

Figure 2 records this separation visually: the exact coordinate route telescopes, whereas the chosen connection route may carry a nonidentity loop.

Coordinate transport and connection choice

Canonical transport compares exact coordinate descriptions of the same object. Its loops telescope. A connection supplies a separate family of comparison maps, so its loops can carry information about that choice. The distinction keeps coordinate identities separate from connection assumptions.

5.2 A stronger reversible pair API

Let R be a commutative ring, let B be a type of charts or refinement states, and let each C_a be an R-module. The chart type is not assumed finite. The following definition is deliberately not derived from analysis and synthesis.

Definition 5.5 (Normalized reversible connection)**.** A normalized reversible connection is a family of linear equivalences

$$\Gamma_{b\leftarrow a} : C_a \xrightarrow{\sim} C_b \qquad (a, b \in B)$$

such that

$$\Gamma_{a\leftarrow a} = \mathrm{id}, \qquad \Gamma_{a\leftarrow b} = \Gamma_{b\leftarrow a}^{-1}.$$

No cocycle equation is included in the structure.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.ReversibleConnection`

This adds heterogeneous fibers and inversion on reversed edges to the homogeneous minimal connection. The connection is still a separate choice of maps, rather than a definition of canonical coordinate transport.

Definition 5.6 (Calibration and flatness)**.** When the C_a are exact packet coordinates of one ambient module, the connection is *canonically calibrated* if

$$\Gamma_{b\leftarrow a} = J_{b\leftarrow a} \quad \text{for every } a, b.$$

It is *flat* if

$$\Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a} = \Gamma_{c\leftarrow a} \quad \text{for every } a, b, c.$$

The canonical connection is flat. A general flat connection is proved in theorem 6.3 to be related to it by a gauge change.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.ReversibleConnection.CocycleAt;Komorebi.PaperIII.Transport.ReversibleConnection.Flat;Komorebi.PaperIII.Transport.ReversibleConnection.canonicalConnection;Komorebi.PaperIII.Transport.ReversibleConnection.canonicalConnection_flat`

The words *calibrated* and *flat* have only the algebraic meanings displayed above.

Remark 5.7 (A connection on a chart graph). One may specify Γ_e only on the oriented edges of a chart graph, together with inverse maps on reversed edges. Path transport and loop holonomy below still make sense. A direct cocycle defect for (a, b, c), however, requires a declared direct transport from a to c. The pairwise API in definition 5.5 keeps this comparison total.

5.3 Cocycle defect and triangle holonomy

The commutative ring hypothesis makes subtraction of linear maps available from this point through section 7.

Definition 5.8 (Cocycle defect)**.** For $a, b, c \in B$, define the additive cocycle defect

$$\Delta_{c,b,a} = \Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a} - \Gamma_{c\leftarrow a} \in \mathrm{Hom}_R(C_a, C_c).$$

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.cocycleDefect`

The manuscript subscript order is target, intermediate, source. The Lean arguments are supplied in traversal order `(a,b,c)`.

Definition 5.9 (Triangle holonomy)**.** The triangle holonomy based at a is

$$H_{c,b,a} = \Gamma_{a\leftarrow c}\Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a} \in \mathrm{Aut}_R(C_a).$$

It traverses $a \to b \to c \to a$.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.triangleHolonomy;Komorebi.PaperIII.Transport.ReversibleConnection.triangleObstruction`

Holonomy is attached to the chosen connection Γ, never to an unspecified coordinate change.

Theorem 5.10 (Identity between defect and holonomy)**.** *For every triple* (a, b, c)*,*

$$\boxed{H_{c,b,a} - \mathrm{id}_{C_a} = \Gamma_{a\leftarrow c}\Delta_{c,b,a}.}$$

Consequently,

$$\Delta_{c,b,a} = 0 \quad \Longleftrightarrow \quad H_{c,b,a} = \mathrm{id}_{C_a}.$$

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.triangleHolonomy_sub_id;Komorebi.PaperIII.Transport.ReversibleConnection.cocycleDefect_eq_zero_iff_triangleHolonomy_eq_refl`

Proof. Using reversibility,

$$\begin{aligned}\Gamma_{a\leftarrow c}\Delta_{c,b,a} &= \Gamma_{a\leftarrow c}\Gamma_{c\leftarrow b}\Gamma_{b\leftarrow a} - \Gamma_{a\leftarrow c}\Gamma_{c\leftarrow a}\\ &= H_{c,b,a} - \mathrm{id}_{C_a}.\end{aligned}$$

Left composition by the equivalence $\Gamma_{a\leftarrow c}$ is injective, which gives the equivalence of the two vanishing statements. □

Corollary 5.11 (Canonical transport has zero connection defect)**.** *If* $\Gamma_{b\leftarrow a} = J_{b\leftarrow a}$*, then*

$$\Delta_{c,b,a} = 0, \qquad H_{c,b,a} = \mathrm{id}$$

for all triples.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.canonicalTransport_zero_connectionDefect;Komorebi.PaperIII.Transport.ReversibleConnection.canonicalTransport_triangleHolonomy_eq_refl`

Proof. The defect vanishes by the canonical cocycle in theorem 4.4. Apply theorem 5.10. □

5.4 Paths and endpoint independence

Definition 5.12 (Connection transport along a path)**.** For a vertex sequence $p = (a_0, a_1, \dots, a_n)$, define

$$\Gamma_p = \Gamma_{a_n \leftarrow a_{n-1}} \cdots \Gamma_{a_1 \leftarrow a_0}, \qquad \Gamma_{(a_0)} = \mathrm{id}_{C_{a_0}}.$$

If $a_n = a_0$, then Γ_p is the holonomy of the loop p.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.pathTransport;Komorebi.PaperIII.Transport.ReversibleConnection.VertexPath;Komorebi.PaperIII.Transport.ReversibleConnection.indexedPathTransport`

Products follow path order: the first traversed edge acts on the right.

Proposition 5.13 (Flat pair transport collapses to endpoints)**.** *If Γ is flat, then every path satisfies*

$$\Gamma_p = \Gamma_{a_n \leftarrow a_0}.$$

In particular, every loop has identity holonomy.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.pathTransport_eq_direct_of_flat;Komorebi.PaperIII.Transport.ReversibleConnection.indexedPathTransport_eq_direct_of_flat;Komorebi.PaperIII.Transport.ReversibleConnection.indexedLoopTransport_eq_refl_of_flat`

Proof. Induct on the path length. Appending a_{n+1} left-multiplies the inductive expression by $\Gamma_{a_{n+1} \leftarrow a_n}$, and flatness replaces the two factors by $\Gamma_{a_{n+1} \leftarrow a_0}$. For a loop, normalization gives $\Gamma_{a_0 \leftarrow a_0} = \mathrm{id}$. □

Remark 5.14. The converse *trivial holonomy implies flatness* depends on which loops are present in an API defined on a chart graph. In the complete pair API, triviality of every triangle holonomy is equivalent to flatness by theorem 5.10. No theorem about topological simple connectivity is being invoked.

6 Gauge covariance and comparison with canonical transport

Definition 6.1 (Gauge change)**.** A gauge is a family of automorphisms $G_a \in \mathrm{Aut}_R(C_a)$. It acts on a connection by

$$\Gamma^G_{b \leftarrow a} = G_b \Gamma_{b \leftarrow a} G_a^{-1}.$$

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.ReversibleConnection.Gauge;Komorebi.PaperIII.Transport.ReversibleConnection.gauge`

A gauge changes coordinate representatives at each chart. The chart graph stays the same.

Theorem 6.2 (Gauge covariance)**.** *The defect and triangle holonomy transform as*

$$\Delta^G_{c,b,a} = G_c \Delta_{c,b,a} G_a^{-1}, \qquad H^G_{c,b,a} = G_a H_{c,b,a} G_a^{-1}.$$

Thus flatness and triviality of triangle holonomy are gauge invariant.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.ReversibleConnection.gauge_cocycleDefect;Komorebi.PaperIII.Transport.ReversibleConnection.gauge_triangleHolonomy;Komorebi.PaperIII.Transport.ReversibleConnection.gauge_flat_iff;Komorebi.PaperIII.Transport.ReversibleConnection.gauge_triangleHolonomy_eq_refl_iff`

Proof. Substitute the definition of Γ^G. Adjacent factors $G_b^{-1}G_b$ and $G_c^{-1}G_c$ cancel. In the defect, both the composite and direct terms acquire the same outer factors G_c and G_a^{-1}. In the loop, all inner factors cancel and only conjugation at the base remains. □

Theorem 6.3 (Flat connections are gauges of the canonical pair transport)**.** *Suppose the C_a are exact packet coordinate modules for one ambient module, so the canonical $J_{b\leftarrow a}$ is available. If Γ is a flat normalized reversible pair connection, choose $o \in B$ and set*

$$G_a = \Gamma_{a\leftarrow o} J_{o\leftarrow a}.$$

Then every pair transport satisfies

$$\boxed{\Gamma_{b\leftarrow a} = G_b J_{b\leftarrow a} G_a^{-1}.}$$

Formal contract: finite algebraic core.
`Komorebi.PaperIII.Transport.ReversibleConnection.flatGauge;Komorebi.PaperIII.Transport.ReversibleConnection.flat_isGaugeOfCanonical`

Proof. Reversibility gives $G_a^{-1} = J_{a\leftarrow o}\Gamma_{o\leftarrow a}$. Therefore

$$\begin{aligned} G_b J_{b\leftarrow a} G_a^{-1} &= \Gamma_{b\leftarrow o} J_{o\leftarrow b} J_{b\leftarrow a} J_{a\leftarrow o} \Gamma_{o\leftarrow a} \\ &= \Gamma_{b\leftarrow o}\Gamma_{o\leftarrow a} \\ &= \Gamma_{b\leftarrow a}. \end{aligned}$$

The first reduction uses the canonical cocycle twice. The second uses flatness of Γ. □

Boundary 6.4 (Flat does not mean calibrated). The theorem produces a gauge relating Γ to J. It does not prove $\Gamma = J$ before that gauge is chosen. Conversely, nontrivial triangle holonomy cannot be removed by a gauge, because conjugation cannot turn a nonidentity automorphism into the identity.

7 Obstruction packets: local certificates and holonomy blocks

7.1 The generic compiled certificate

Let Candidate, Packet, and Residual be arbitrary types, with a distinguished $0 \in$ Residual, and let

$$r : \mathsf{Candidate} \longrightarrow \mathsf{Packet} \longrightarrow \mathsf{Residual}$$

be a residual function.

Definition 7.1 (Solution and obstruction packet for a candidate)**.** A candidate x is a solution when

$$\mathrm{IsSolution}_r(x) \quad \Longleftrightarrow \quad \forall p,\ r(x,p) = 0.$$

An obstruction packet for x is a pair consisting of a named packet p and a certificate $r(x, p) \neq 0$.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.NonlinearObstructions.IsSolution;Komorebi.PaperIII.NonlinearObstructions.ObstructionPacket`

Theorem 7.2 (Exact logical force of a local obstruction)**.** *Every obstruction packet for x proves that x is not a solution, and*

$$\neg\,\mathrm{IsSolution}_r(x) \quad \Longleftrightarrow \quad \textit{there exists an obstruction packet for } x.$$

The reverse implication from failure to a packet witness is classical and does not require the packet type to be finite.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.NonlinearObstructions.ObstructionPacket.not_isSolution;Komorebi.PaperIII.NonlinearObstructions.obstructionPacket_of_not_isSolution;Komorebi.PaperIII.NonlinearObstructions.not_isSolution_iff_nonempty_obstructionPacket`

Proof. A purported solution would make the residual vanish at the certified packet, contradicting its nonzero field. Conversely, if no packet carries a nonzero residual, then every residual is zero and the candidate satisfies the definition of solution. □

What one obstruction certifies

The certificate answers one question: does this specified candidate satisfy every declared packet condition? One nonzero residual settles that question for this candidate. A statement that no candidate can solve the problem would require an obstruction for every candidate.

Boundary 7.3 (Candidate-specific means candidate-specific). The theorem rules out the named x. It neither constructs a solution nor shows that every candidate is obstructed. It provides no minimality, stability, computability, or classification theorem for the packet witness.

7.2 Specialization to holonomy blocks

For a reversible connection, specialize the generic residual at a fixed triangle by taking a packet label to be a pair (μ, ν) and the residual to be the corresponding block of $H - \mathrm{id}$. A nonzero block, together with its label and a proof of nonvanishing, gives an obstruction packet certificate in the sense of definition 7.1. The reconstruction theorem below supplies the further step: vanishing of all these local residuals is equivalent to the cocycle equation at that triangle.

Fix a triangle (a, b, c) and resolve the base fiber C_a by a finite complete family of idempotents $(\Pi^a_\mu)_{\mu \in I_a}$. Orthogonality may also hold, as it does for the exact range coordinate projectors below, but the compiled reconstruction theorem does not require it. In exact range coordinates, Π^a_μ is simply the projector that retains component μ and zeros the other components.

Definition 7.4 (Holonomy obstruction and packet residuals)**.** Define

$$\mathrm{Ob}_{c,b,a} = H_{c,b,a} - \mathrm{id}_{C_a}, \qquad \mathrm{Ob}^{\mu\nu}_{c,b,a} = \Pi^a_\mu \,\mathrm{Ob}_{c,b,a}\, \Pi^a_\nu.$$

The map $\mathrm{Ob}^{\mu\nu}_{c,b,a}$ is the obstruction block, or packet residual, from input packet ν to output packet μ. If it is nonzero, then (μ, ν) and that nonvanishing proof form an obstruction packet certificate. Diagonal blocks detect holonomy within one packet. Off-diagonal blocks detect packet mixing induced by holonomy.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.HolonomyBlocks.PacketResolution;Komorebi.PaperIII.HolonomyBlocks.PacketResolution.block`

The certificate records a specified holonomy defect, the label of an input and output packet, and a proof that the corresponding block is nonzero.

Theorem 7.5 (Exact reconstruction and detection by obstruction blocks)**.** *The total obstruction has the exact finite resolution*

$$\boxed{\mathrm{Ob}_{c,b,a} = \sum_{\mu,\nu \in I_a} \mathrm{Ob}^{\mu\nu}_{c,b,a}\,.}$$

Moreover, the following are equivalent:

(i) $\Delta_{c,b,a} = 0$;

(ii) $H_{c,b,a} = \mathrm{id}$;

(iii) $\mathrm{Ob}_{c,b,a} = 0$;

(iv) $\mathrm{Ob}^{\mu\nu}_{c,b,a} = 0$ *for every* μ, ν.

Formal contract: finite algebraic core.

`Komorebi.PaperIII.HolonomyBlocks.obstruction_sum_blocks;Komorebi.PaperIII.HolonomyBlocks.obstructionBlocks_zero_iff;Komorebi.PaperIII.HolonomyBlocks.obstructionDetection_equivalences`

Proof. Insert completeness on both sides:

$$\mathrm{Ob} = \left(\sum_{\mu} \Pi^a_\mu\right) \mathrm{Ob} \left(\sum_{\nu} \Pi^a_\nu\right) = \sum_{\mu,\nu} \Pi^a_\mu \,\mathrm{Ob}\, \Pi^a_\nu.$$

Thus (iv) implies (iii), and (iii) implies (iv) by composition with the projectors. Conditions (ii) and (iii) are equivalent by the definition of Ob and additive cancellation. Conditions (i) and (ii) are equivalent by theorem 5.10. □

Why both packet indices matter

For the declared finite complete resolution, reconstruction uses both packet indices. Inspecting only diagonal blocks can miss transport from one packet to another. The full family records that mixing and reconstructs the total obstruction exactly.

Figure 3 depicts the finite block resolution on both sides of the obstruction and the off-diagonal blocks that witness packet mixing.

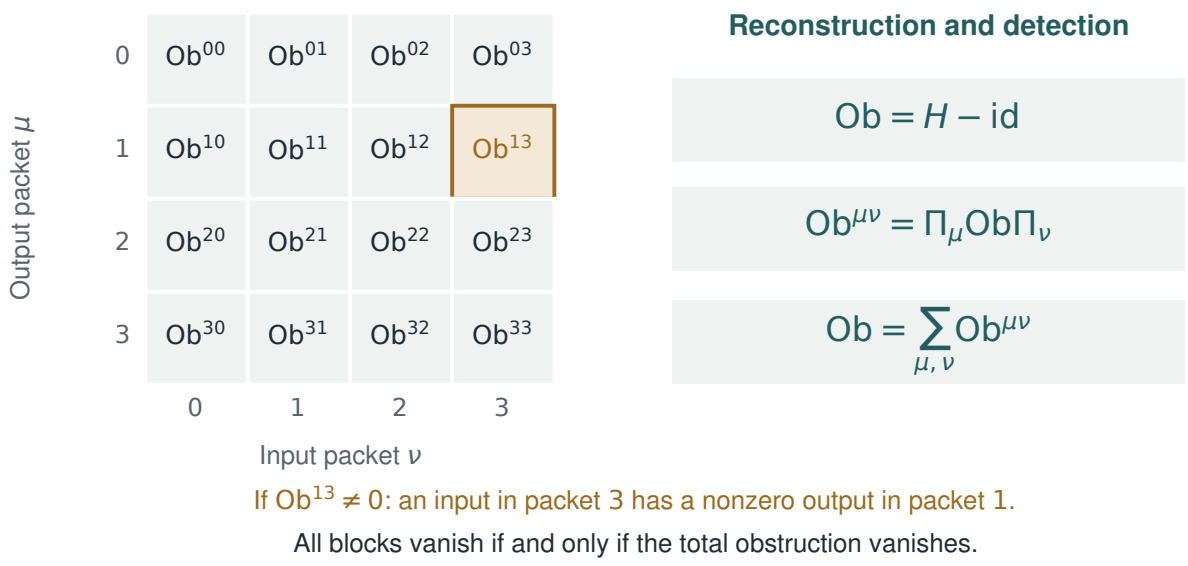

Figure 3. A finite complete packet resolution reconstructs the total holonomy obstruction from blocks indexed by input and output packets. A nonzero off-diagonal block is an exact witness of packet mixing.

Corollary 7.6 (Witness supported in one packet). *If* $\mathrm{Ob}^{\mu\nu}_{c,b,a} \neq 0$*, then there is a vector* x *supported in packet* ν *such that*

$$\Pi^a_\mu \,\mathrm{Ob}_{c,b,a}\, x \neq 0.$$

Such an x *is an exact finite witness of nonflatness.*

Formal contract: finite algebraic core.
`Komorebi.PaperIII.HolonomyBlocks.exists_packetWitness_of_obstructionBlock_ne_zero`

Proof. Classically choose y on which the nonzero linear map $\Pi^a_\mu \,\mathrm{Ob}\, \Pi^a_\nu$ is nonzero and set $x = \Pi^a_\nu y$. Idempotence gives $\Pi^a_\nu x = x$, and the required output is the chosen nonzero value. □

7.3 Gauge behavior of packet blocks

Vanishing or nonvanishing of the total triangle obstruction is gauge invariant by theorem 6.2, but a fixed packet pattern need not be. A general G_a can mix the projectors Π^a_μ.

Proposition 7.7 (Gauge covariance when packet projectors are preserved). *If* $G_a \Pi^a_\mu = \Pi^a_\mu G_a$ *for every* μ*, then*

$$\left(\mathrm{Ob}^G\right)^{\mu\nu} = G_a \,\mathrm{Ob}^{\mu\nu}\, G_a^{-1}.$$

Consequently the zero/nonzero status of each obstruction block is preserved by gauges that preserve the packet projectors.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.HolonomyBlocks.obstructionBlock_gauge_of_commutes;Komorebi.PaperIII.HolonomyBlocks.obstructionBlock_gauge_eq_zero_iff`

Proof. Use $\mathrm{Ob}^G = G_a \,\mathrm{Ob}\, G_a^{-1}$ and commute G_a and G_a^{-1} through the two packet projectors. Composition by an equivalence is injective in both directions. □

Boundary 7.8 (Packet patterns are not absolute). Without the commutation hypothesis in proposition 7.7, only the vanishing of the total obstruction is gauge invariant. The location of individual nonzero blocks may change under a gauge that mixes packets.

8 Products supported in packets and holonomy walks

The passage from words to walks also applies to products of different matrices. Let V be one finite packet type, let R be a semiring, and let $B_1, \dots, B_m \in R^{V\times V}$ be a finite sequence of possibly different packet matrices. Rows are targets and columns are sources as before.

Proposition 8.1 (Packet path expansion for different matrices)**.** *For $i, j \in V$ and $m \geq 1$, set $i_0 = i$ and $i_m = j$. Then*

$$(B_m \cdots B_1)_{ji} = \sum_{(i_1,\dots,i_{m-1})\in V^{m-1}} B_m[i_m, i_{m-1}] \cdots B_1[i_1, i_0].$$

When $m = 1$, the sum is over the unique empty tuple and its summand is $B_1[j, i]$. For $m = 0$, the product is the identity and the entry is the Kronecker delta δ_{ji}. If every $B_r[q, p]$ vanishes outside a declared relation $\mathcal{R}_r(p, q)$, then the endpoint entry is zero whenever there is no packet path compatible with the successive relations.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.EdgeOperators.heterogeneousProduct;Komorebi.PaperIII.EdgeOperators.heterogeneousPathSum;Komorebi.PaperIII.EdgeOperators.heterogeneousPacketPathExpansion;Komorebi.PaperIII.EdgeOperators.SupportedStep;Komorebi.PaperIII.EdgeOperators.SupportedPath;Komorebi.PaperIII.EdgeOperators.heterogeneousProduct_apply_eq_zero_of_no_supportedPath`

Proof. Expand each matrix product entry and distribute the finite sums. Induction on the factor list yields the displayed path sum, with the empty list evaluated as the identity matrix. If no supported intermediate packet exists, every summand contains an entry that is zero by its declared support relation. □

Boundary 8.2 (Changing packet types along a chain). The compiled theorems `heterogeneousPacketPathExpansion_two` and `heterogeneousPacketPathExpansion_three` allow different packet types at the successive stages of two- and three-factor products. The arbitrary-length theorem above permits different factors but uses one common finite packet type V. A fully dependent arbitrary-length chain of changing modules and packet types remains outside the finite algebraic contract.

Remark 8.3 (Checked specialization). When every B_r is one repeated endomorphism T, the recursive specialization to packet powers is inherited from Chapter I.

Inherited formal contract: Chapters I–II.
`Komorebi.PacketNaturalityCompletion.Packets.transferBlock_pow_eq_packetPathSum`

For a loop represented on one common finite scalar packet coordinate type, the proposition resolves its successive transport matrices into packet walks. If R is a ring, as in the reversible connection API, then $(H-I)_{ji} = H_{ji}-\delta_{ji}$. In particular, off-diagonal entries are unchanged. Thus a nonzero off-diagonal holonomy obstruction in this model with a common index type requires a transport word along the closed chart loop whose packet path runs from its input packet to its output packet. This conclusion requires declared block supports for the connection matrices. An arbitrary connection need not respect the transfer graph from section 2.

9 A minimal exact example

Example 9.1 (A scalar triangle)**.** Let $B = \{0, 1, 2\}$ and $C_0 = C_1 = C_2 = \Bbbk$ for a field $\Bbbk$. Choose $u, v, w \in \Bbbk^\times$ and set

$$\Gamma_{1\leftarrow 0}(x) = ux, \qquad \Gamma_{2\leftarrow 1}(x) = vx, \qquad \Gamma_{2\leftarrow 0}(x) = wx,$$

with reverse transports given by inverse scalars. Then

$$\Delta_{2,1,0}(x) = (vu - w)x,$$

and the triangle holonomy based at 0 is

$$H_{2,1,0}(x) = w^{-1}vux.$$

Therefore

$$H_{2,1,0} - \mathrm{id} = w^{-1}\Delta_{2,1,0}.$$

The connection is flat on this triangle exactly when $vu = w$. If the three coordinate systems are literally the same and canonical transport is used, then $u = v = w = 1$ and the obstruction vanishes. Choosing arbitrary nonzero u, v, w is a connection choice, not a consequence of changing exact packet coordinates.

Example 9.2 (A transfer walk with two steps)**.** Let a packet graph have edges $e : 0 \to 1$ and $f : 1 \to 2$, with no other edges. Then

$$T = L_e + L_f, \qquad (T^2)_{20} = c(f)c(e).$$

The products L_eL_e, L_eL_f, and L_fL_f vanish by typed mismatch. Only L_fL_e, corresponding to the walk $0 \to 1 \to 2$, contributes to the $(2, 0)$ entry. This example also fixes the noncommutative coefficient order.

10 Canonical coordinates for arbitrary maps

The analysis and synthesis identities are identities of functions, not only of linear maps. Consequently exact coordinate change does not become curved merely because the represented operation is nonlinear.

Proposition 10.1 (Exact naturality for arbitrary functions)**.** *Let $\mathcal{A}^X_a : X \xrightarrow{\sim} X_a$ and $\mathcal{A}^X_b : X \xrightarrow{\sim} X_b$ be exact coordinate equivalences for X, with inverses $\mathcal{S}^X_a$ and $\mathcal{S}^X_b$. Likewise, let $\mathcal{A}^Y_r : Y \xrightarrow{\sim} Y_r$ and $\mathcal{A}^Y_s : Y \xrightarrow{\sim} Y_s$ be*

exact coordinate equivalences for Y, with inverses $\mathcal{S}_r^Y$ and $\mathcal{S}_s^Y$. Let $F : X \to Y$ be any function, with no linearity or differentiability hypothesis. Set

$$J_{b\leftarrow a}^X = \mathcal{A}_b^X \circ \mathcal{S}_a^X, \qquad J_{s\leftarrow r}^Y = \mathcal{A}_s^Y \circ \mathcal{S}_r^Y,$$

and define

$$\widehat{F}_{r\leftarrow a} = \mathcal{A}_r^Y \circ F \circ \mathcal{S}_a^X.$$

Then

$$J_{s\leftarrow r}^Y \circ \widehat{F}_{r\leftarrow a} = \widehat{F}_{s\leftarrow b} \circ J_{b\leftarrow a}^X.$$

If $\mathcal{A}_t^Z : Z \xrightarrow{\sim} Z_t$ is another exact coordinate equivalence and $G : Y \to Z$ is any function, then exact coordinate representation also preserves composition:

$$\widehat{G \circ F}_{t\leftarrow a} = \widehat{G}_{t\leftarrow r} \circ \widehat{F}_{r\leftarrow a}.$$

Formal contract: finite algebraic core.

`Komorebi.PaperIII.Transport.exactCoordinateMap;Komorebi.PaperIII.Transport.exactCoordinateMap_comp;Komorebi.PaperIII.Transport.exactCoordinateMap_naturality`

Proof. Both sides of the naturality equation reduce to $\mathcal{A}_s^Y \circ F \circ \mathcal{S}_a^X$ using $\mathcal{S} \circ \mathcal{A} = \mathrm{id}$ in X and Y. For composition, the middle $\mathcal{S}^Y \circ \mathcal{A}^Y$ cancels in the same way. □

Boundary 10.2 (Where nonlinear defects can enter). A nonlinear *coordinate* defect cannot be blamed on the exact canonical J of definition 4.3. By proposition 10.1, that defect is identically zero. Nonzero defects require extra structure such as a noncanonical connection, truncation, approximation, restricted domains, or failure of an operation to respect a declared packet model.

11 Nonlinear operation trees: locality and the formalization frontier

11.1 The compiled foundation of unary and binary trees

Definition 11.1 (Finite grammar for operation trees)**.** For types of input labels I, constants K, unary symbols U, and binary symbols B, the finite formal grammar has four constructors:

$$\begin{aligned} t ::= \ & \mathrm{input}(i) \mid \mathrm{constant}(k) \mid \mathrm{unary}(u, t) \\ & \mid \mathrm{binary}(b, t_1, t_2). \end{aligned}$$

Given an arbitrary value type Y, evaluation takes completely explicit maps

$$I \to Y, \qquad K \to Y, \qquad U \to Y \to Y, \qquad B \to Y \to Y \to Y.$$

No algebraic, continuity, or differentiability law is imposed on these semantics.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.NonlinearObstructions.OperationTree;Komorebi.PaperIII.NonlinearObstructions.OperationTree.eval`

When I has decidable equality, let $\mathrm{inputs}(t)$ be the finite set of input labels actually occurring in t.

Theorem 11.2 (Input locality for operation trees)**.** *Let $\eta_1, \eta_2 : I \to Y$ be two input environments. If*

$$\eta_1(i) = \eta_2(i) \qquad \textit{for every } i \in \mathrm{inputs}(t),$$

then the two evaluations of t are equal under the same constant, unary, and binary semantics. In particular, if $\mathrm{inputs}(t) = \emptyset$, evaluation is independent of the input environment.

Formal contract: finite algebraic core.
`Komorebi.PaperIII.NonlinearObstructions.OperationTree.eval_congr_on_inputs;Komorebi.PaperIII.NonlinearObstructions.OperationTree.eval_eq_of_inputs_eq_empty`

Proof. Structural induction on t. The input case is the agreement hypothesis. The constant case is reflexive. The unary case applies the induction hypothesis to its child. The binary case applies it independently to the left and right subtrees, whose input sets form a union. □

Boundary 11.3 (Exact force of locality). The theorem says evaluation reads only syntactically named inputs. It does not prove that the operations are linear or nonlinear in any analytic sense, that the tree is stable, that two different trees are equivalent, or that a solution to a tree equation exists.

11.2 Typed colored extension beyond the finite contract

Definition 11.4 (Finitary colored operation signature)**.** A finitary colored signature consists of:

- a finite type V of colors;
- a type Σ of operation symbols;
- an arity $r(\sigma) \in \mathbb{N}$ for every $\sigma \in \Sigma$;

- input colors $\mathrm{in}_\sigma : \mathrm{Fin}(r(\sigma)) \to V$;
- an output color $\mathrm{out}(\sigma) \in V$.

A realization assigns a space X_v to each color and a map

$$\Phi_\sigma : \prod_{q \in \mathrm{Fin}(r(\sigma))} X_{\mathrm{in}_\sigma(q)} \longrightarrow X_{\mathrm{out}(\sigma)}.$$

Outside the finite formal contract. The intended Lean target is a dependent inductive typed tree. No such declaration is part of the finite algebraic completion contract.

Definition 11.5 (Typed operation tree and evaluation)**.** A typed operation tree is recursively either a leaf of declared color or a node labeled by σ, with one correctly colored child for each input slot of σ. Evaluation is recursive:

$$\mathrm{ev}(\mathrm{node}(\sigma; t_1, \dots, t_{r(\sigma)})) = \Phi_\sigma(\mathrm{ev}(t_1), \dots, \mathrm{ev}(t_{r(\sigma)})).$$

Outside the finite formal contract. Candidate API: `Komorebi.PaperIII.NonlinearObstructions.ColoredOperationTree` and `ColoredOperationTree.eval`. This is stronger than the compiled uncolored unary–binary grammar.

11.3 Packet labelings and the multilinear first target

Suppose every X_v has a finite complete packet family $(P_i^v)_{i \in I_v}$. A packet labeling assigns an admissible packet index to each edge or node of a typed tree. For multilinear Φ_σ, inserting

$$\mathrm{id}_{X_v} = \sum_{i \in I_v} P_i^v$$

at every input and output yields a finite sum over trees with packet labels. This is the branching analogue of inserting intermediate projectors in proposition 8.1.

Formalization target 11.6 (Finite multilinear tree expansion). The nonlinear formalization target is an exact theorem saying that the evaluation of a finite tree of multilinear nodes equals the finite sum of its packet-resolved labeled evaluations. Required proof obligations include:

(a) a dependent well-typed tree syntax;

(b) finite packet-label types at every color;

(c) an explicit convention for nullary and unary nodes;

(d) multilinearity in every input slot;

(e) preservation of the order of input slots without assuming commutativity of operations.

Outside the finite formal contract. Candidate target: `Komorebi.PaperIII.NonlinearObstructions.ColoredOperationTree.eval_eq_sum_packetLabellings`.

11.4 Connection defects at nonlinear nodes

For coordinate models of the source and target colors, an additive target coordinate space, and a chosen noncanonical connection, a pointwise node defect can be defined by

$$\mathfrak{D}^{\Gamma}_{b,a}(\Phi) = \Gamma^{Y}_{b\leftarrow a} \circ \widehat{\Phi}_a - \widehat{\Phi}_b \circ \left(\prod_q \Gamma^{X_q}_{b\leftarrow a} \right).$$

This expression compares two *chosen* routes. With canonical exact transport in every slot it vanishes by proposition 10.1.

Formalization target 11.7 (Operation-tree defect propagation). For multilinear nodes, one expects an exact finite expansion obtained by replacing one or more nodes by their defects and transporting the remaining branches. For smooth nonlinear nodes, the corresponding chain rule is indexed by rooted partitions and Faà di Bruno trees. A formal theorem will require a fixed differentiability category, base points, derivative conventions, symmetry factors, and remainder policy.

Outside the finite formal contract. Tree-level defect identities, higher chain rules, and nonlinear norm bounds are outside the finite Lean contract. Ordinary mathematical results in these directions appear in Part II under their stated hypotheses.

Boundary 11.8 (Analytic and geometric exclusions). The finite formal contract does not include convergence of an infinite tree series, existence of derivatives, a Banach-space Faà di Bruno theorem, a Baker–Campbell–Hausdorff expansion, a continuum limit, or an identification of algebraic holonomy with curvature of a smooth bundle. Part II supplies ordinary proofs for its explicit nonlinear and analytic statements. The theory does not derive a connection from data, optimization, physics, or probability.

12 Finite algebraic formalization ledger

Topic	Status	Declaration or roadmap target	Exact boundary
Packet matrix and edge operator	Lean-backed III	`PacketGraph.packetMatrix`; `EdgeSystem.edgeOp`	Finite scalar matrices over a semiring, with one scalar coordinate per packet.
Edge support and pair dichotomy	Lean-backed III	`edgeOp_eq_zero_off_support`; `edgeOp_mul_edgeOp_eq_zero`; `edgeOp_mul_edgeOp_of_composable`	Broken interfaces vanish. Matched pairs collapse to the endpoint block with coefficient in operator order.
Typed word evaluation	Lean-backed III	`Composable`; `wordOp`; `wordOp_append`; `wordOp_eq_zero_of_not_composable`	List order is execution order. Concatenation reverses operator-product order. Nonwalks vanish.

Topic	Status	Declaration or roadmap target	Exact boundary
Finite word and walk expansions	Lean-backed III	`explicitWordExpansion`; `walkExpansion`; `wordExpansion_eq_explicitWordExpansion`; `transferOp_pow_eq_walkExpansion`	Actual finite tuple sum and zero-filtered composable-walk sum over finite graph and packet types.
Endpoint coefficient walk sum	Lean-backed III	`reverseCoefficient`; `Connects`; `transferOp_pow_apply_eq_sum_walks`	Exact scalar endpoint entry, including the empty-walk case and noncommutative coefficient order.
Fixed reachability and orbit support	Lean-backed III, with an inherited hull bridge	`transferOp_pow_apply_eq_zero_of_no_walk`; `transferOp_pow_mulVec_apply_eq_zero_of_unreachable_support`	Finite powers and supported seeds. The orbit-hull span conclusion uses the stated Chapter I contract.
Exact frame transport	Lean-backed III	`exactTransport_cocycle`; `exactPathTransport_eq_endpoint`; `exactPathTransport_loop`	One frame family on a single module. Arbitrary finite paths telescope and closed paths are trivial.
Exact coordinate cocycle	Inherited Lean-backed II	`NestedRefinement.refineCoordinates_comp`; `NestedRefinement.coordinateRefinementEquiv_trans`	Complete finite projector coordinates, not reduction.
Typed coordinate naturality	Inherited Lean-backed II	`NestedRefinement.coordinateOperator_comp`; `NestedRefinement.coordinateOperator_naturality`	Linear maps over semiring modules.
Minimal connection API	Lean-backed III	`Transport.Connection`; `cocycleDefect`; `triangleHolonomy`; `triangleHolonomy_eq_refl_of_flat`	Only self-normalization is assumed. Reverse inversion and the cocycle are not structure fields.
Twisted three-point loop	Lean-backed III	`twistedThreePointConnection`; `twisted_triangleHolonomy_ne_refl`	Concrete rational connection. The selected loop sends 1 to 2.
Reversible additive defect	Lean-backed III	`ReversibleConnection`; `triangleHolonomy_sub_id`; `cocycleDefect_eq_zero_iff_triangleHolonomy_eq_refl`	Heterogeneous module fibers, reverse-edge inversion, and an additive defect over a commutative ring.

Topic	Status	Declaration or roadmap target	Exact boundary
Reversible finite paths	Lean-backed III	`pathTransport_eq_direct_of_flat`; `indexedPathTransport_eq_direct_of_flat`; `indexedLoopTransport_eq_refl_of_flat`	Finite pair-connection paths collapse to endpoints under algebraic flatness.
Gauge covariance	Lean-backed III	`gauge_cocycleDefect`; `gauge_triangleHolonomy`; `gauge_flat_iff`	Fiberwise algebraic conjugation, without smooth gauge theory.
Flat versus canonical transport	Lean-backed III	`flatGauge`; `flat_isGaugeOfCanonical`	A chosen base chart and ambient frames exhibit every flat pair connection as a gauge transform of canonical transport.
Operation-tree locality	Lean-backed III	`OperationTree`; `OperationTree.eval`; `OperationTree.eval_congr_on_inputs`	Arbitrary unary and binary semantics. Only dependence on named inputs is proved.
Generic obstruction packet	Lean-backed III	`ObstructionPacket.not_isSolution`; `not_isSolution_iff_nonempty_obstructionPacket`	Exact candidate-specific logical certificate, without global classification.
Holonomy block obstruction	Lean-backed III	`obstruction_sum_blocks`; `obstructionBlocks_zero_iff`; `obstructionDetection_equivalences`	Finite complete idempotent packet family on the base fiber. Orthogonality is not required by the compiled reconstruction.
Packet witness and block gauge	Lean-backed III	`exists_packetWitness_of_obstructionBlock_ne_zero`; `obstructionBlock_gauge_of_commutes`; `obstructionBlock_gauge_eq_zero_iff`	Witness extraction is classical. Blockwise covariance requires the gauge to commute with every packet projector.
Heterogeneous matrix paths	Lean-backed III	`heterogeneousPacketPathExpansion`; `heterogeneousProduct_apply_eq_zero_of_no_supportedPath`	Arbitrarily many different matrices over one common finite packet type. Fully typed changing-index chains compile only at lengths two and three.

Topic	Status	Declaration or roadmap target	Exact boundary
Arbitrary-function coordinates	Lean-backed III	`exactCoordinateMap_comp`; `exactCoordinateMap_naturality`	Exact set-level equivalences and arbitrary functions, without a linearity or differentiability assumption.
Colored and smooth trees	Roadmap only	roadmap `ColoredOperationTree.eval_eq_sum_packetLabellings`	Dependent colors, multilinear packet expansion, derivatives, and Faà di Bruno identities remain outside the contract.

12.1 Kernel-backed Chapter III surface

The source register identifies the authoritative declaration-level contract. It groups the compiled surface as follows.

- **EdgeOperators and EdgeExtensions:** scalar packet matrices, typed edge and word support, finite word/walk expansions, endpoint coefficient sums, fixed-length reachability, orbit support, and common-index heterogeneous products with declared supports.
- **Transport and ReversibleConnections:** exact frame transport, the minimal connection, heterogeneous reversible pair transport, additive defect and triangle holonomy, finite paths, canonical connections, and the fiberwise gauge action.
- **CoordinateNaturality and HolonomyBlocks:** composition and naturality for arbitrary functions between exact coordinate systems, finite two-sided block reconstruction, equivalent obstruction criteria, packet-supported witnesses, and packet-preserving block gauges.
- **NonlinearObstructions:** finite unary–binary operation trees, input locality, and candidate-specific obstruction certificates.

The formal companion records the checker-generated declaration and audit totals. The parity gate requires every fully qualified Chapter III target printed beside a statement to occur in the theorem map, rejects stale or duplicate targets, and checks it against the compiled environment. `KernelAudit.lean` reports dependencies for the mapped and supporting theorems, and its fail-closed gate scans every compiled `Komorebi.PaperIII` declaration. The four inherited statement contracts remain identified separately by their inherited declaration names.

Boundary 12.1 (No scope promotion by prose). The displayed endpoint coefficient formula, reachability results, reversible connection theorems, additive defect–holonomy identity, gauge covariance, holonomy-block reconstruction, packet witnesses, common-index heterogeneous path expansion, and arbitrary-function coordinate naturality are all part of the finite algebraic kernel-backed surface. What remains outside is the dependent fiber-valued edge-system generalization, a fully dependent arbitrary-length chain whose module and packet type change at every stage, dependent colored operation trees, packet-labeled multilinear tree expansions, nonlinear tree-defect and Faà di Bruno identities, and the analytic and geometric extensions listed above.

13 The finite contract and the nonlinear transition

Typed packet support turns the expansion of a transfer power into a walk calculus. Incompatible words vanish because their interfaces do not match. Canonical packet coordinate transport is the exact equivalence obtained from analysis and synthesis. It satisfies the cocycle law, so every finite canonical loop telescopes to the identity. Holonomy enters after a separate connection is supplied. The compiled minimal API proves that flatness makes both the relative defect and holonomy trivial, and it exhibits a nontrivial rational loop. Under the compiled reversible API, a nonzero additive triangle defect is equivalent to nonidentity holonomy, transforms covariantly under gauge, and is detected exactly by a finite family of packet blocks. Finite flat paths collapse to their endpoints. Every flat reversible pair connection is explicitly related to canonical transport by a gauge change through a chosen base chart.

These facts define the boundary of the finite formal contract. At that boundary, exact coordinates preserve composition and satisfy naturality for arbitrary functions in Chapter III, while the typed linear packet coordinate counterpart remains inherited from Chapter II. Nontrivial nonlinear defects must therefore be attached to additional modeling choices or to packet compatibility of the particular operation. Colored operation trees, multilinear packet labelings, and Faà di Bruno expansions remain outside this finite Lean contract. Part II develops the corresponding ordinary mathematics, including packet jets, rooted tree expansions, and explicit nonlinear obstruction theorems.

Part II Nonlinear packet calculus, obstruction complexes, and holonomy

This part moves from exact coordinates for arbitrary functions to differentiable interactions, specified correction problems, and finite or smooth transport. Each ordinary proof retains its stated hypotheses. These results are not asserted to belong to the finite Lean contract of Part I.

The notational change from $\mathcal{A}, \mathcal{S}$ to $\mathcal{A}, \mathcal{S}$ is typographical: both denote analysis and synthesis for the declared packet system. A connection remains additional data. Smooth canonical transport is constructed from a moving projector family, whereas the algebraic exact coordinate transport in Part I compares fixed exact descriptions of one ambient object.

14 Introduction

A finite family of pairwise annihilating idempotents gives exact coordinates. If

$$P_\alpha P_\beta = 0 \quad \text{for } \alpha \neq \beta, \qquad \sum_\alpha P_\alpha = I,$$

then every vector is the sum of its packet components. Linear operators become block matrices in these coordinates. A nonlinear map cannot be reconstructed from its diagonal restrictions, since mixed interactions between packet components are usually present. It can still be represented exactly if its input is the complete packet tuple.

This part develops nonlinear packet representation and the obstruction theory that follows from it. Exact coordinates preserve a nonlinear problem, but they do not solve it. Once the equation is written in packet coordinates, its derivatives, compositions, correction maps, refinement failures, and gluing defects can be separated without discarding mixed terms.

The first stage of Part II treats the local nonlinear calculus. Packet analysis and synthesis conjugate arbitrary maps. Fréchet derivatives split into multilinear packet jets. The higher chain rule then becomes a Faà di Bruno formula whose terms carry intermediate packet labels. Standard background on Fréchet calculus and the higher chain rule may be found in [1, 2, 4].

The next stage studies nonlinear iteration. Repeated substitution is indexed by rooted trees rather than operator words. A scalar majorant gives an absolute convergence theorem for polynomial fixed-point equations. The quadratic case recovers the Catalan series. Rooted tree combinatorics are discussed in [16, 11, 6].

A linear correction map

$$D : U \longrightarrow V$$

places the obstruction to solving $Du = -r$ in the canonical quotient coker D. This quotient has a universal property and behaves naturally under commuting squares. Mapping cones extend the same construction to cochain complexes. In a Hilbert space with closed range, the quotient is represented by the orthogonal projection onto Ker D^*. The Moore–Penrose inverse then gives the least norm correction. Relevant background appears in [18, 15].

A vanishing linear obstruction is only the first step. We give a contraction theorem for nonlinear correction, followed by a local Lyapunov–Schmidt reduction. In a complete filtered problem, every lifting step has its own cokernel class. Vanishing at all depths and compatible choices of corrections produce an exact inverse limit solution. A filtered correction complex carries a spectral sequence. Its first page records graded obstruction candidates, while later differentials record interactions that can cancel them. We use the standard spectral sequence of a filtered complex from [18, 12].

The final stage studies elimination and gluing. The implicit function theorem gives an exact Schur derivative after hidden variables are removed. Finite transport systems reduce, after a spanning tree gauge, to one holonomy element for each fundamental cycle. The same idea extends to smooth projector families through Kato transport. We use standard material from [4, 5, 7, 8, 10].

The chapter does not claim that every nonlinear problem has a finite obstruction space. The cokernel is canonical only after a correction map has been specified. It may be infinite dimensional. A first-order obstruction may vanish while a higher-order obstruction remains. The purpose of the calculus is to identify the exact object in which each failure lives and to show how those objects change under packets, refinement, filtration, and transport.

15 A map of the nonlinear calculus

Four questions organize the nonlinear calculus: representation, interaction, correction, and gluing.

The first question is representation. Given a nonlinear map F, can its packet form be written without approximation? The answer is yes. Analysis and synthesis are inverse coordinate maps, so conjugation preserves the full equation.

The second question is interaction. Which input packets influence a given output packet, and at what derivative order? Packet jets answer this question. They form a directed hypergraph rather than an ordinary block matrix because one nonlinear interaction can have several inputs.

The third question is correction. Suppose an approximate solution leaves a defect r. A declared linearized correction map D removes the part of r lying in $\operatorname{im} D$. The quotient class

$$[r] \in \operatorname{coker} D$$

is the part that no allowed first-order correction can remove. This quotient class is the obstruction. Its vanishing must be supplemented by a nonlinear theorem.

The fourth question is gluing. Local coordinate changes can solve every edge problem and still fail around a loop. The remaining cycle product is holonomy. It measures the failure of a global frame even when each local equation has been solved.

These four layers fit into the sequence

$$\begin{aligned}\text{exact coordinates} \longrightarrow \text{packet interactions} \longrightarrow \text{correction classes}\\ \longrightarrow \text{global gluing.}\end{aligned}$$

Each arrow needs hypotheses. Exact coordinates need a complete packet system. Differential interactions need regularity. A cokernel obstruction needs a specified correction map. Holonomy needs invertible local transports.

A second distinction concerns scale. A refinement defect compares a fine nonlinear model with a coarse one. It is a point in the coarse output space. An obstruction class is the image of such a defect, or

of another residual, in a quotient by allowed corrections. The correction map must be declared before the defect determines an obstruction class. A small defect can have a nonzero obstruction, and a large defect can have zero obstruction if it lies entirely in the correction range.

The chapter uses finite packet systems in the coordinate and graph sections. Banach space hypotheses enter only where norms, contractions, or Fréchet derivatives are used. Module and complex language is used for cokernels, filtered lifting, and cohomological obstructions. This separation keeps each result at the level of generality supported by its proof.

Standing conventions

All packet systems are finite unless a statement says otherwise. In a normed setting every packet projector and every coarsening operator is bounded. Differentiability of operator-valued maps is taken in operator norm. A Banach space isomorphism is a bounded linear bijection with bounded inverse. For a decreasing filtration $(F^m X)$, completeness means that the canonical map

$$X \longrightarrow \varprojlim_m X/F^m X$$

is an isomorphism and separatedness means $\bigcap_m F^m X = 0$. Statements about congruence classes in a filtered nonlinear problem also assume that the nonlinear map preserves filtration congruences at the stated depth. These assumptions are repeated where they are essential to a proof.

16 Exact nonlinear packet coordinates

Let X be a module over a unital ring. A finite packet system on X is a family

$$\mathcal{P} = (P_\alpha)_{\alpha \in I} \subseteq \mathrm{End}(X)$$

of nonzero idempotents such that

$$P_\alpha P_\beta = 0 \quad \text{when } \alpha \neq \beta, \qquad \sum_{\alpha \in I} P_\alpha = I_X.$$

Write

$$X_\alpha = P_\alpha X, \qquad X^{\mathcal{P}} = \bigoplus_{\alpha \in I} X_\alpha.$$

The analysis and synthesis maps are

$$\mathcal{A}_{\mathcal{P}} x = (P_\alpha x)_\alpha, \qquad \mathcal{S}_{\mathcal{P}} (x_\alpha)_\alpha = \sum_\alpha x_\alpha.$$

They are inverse isomorphisms.

Definition 16.1 (Nonlinear packet coordinate map)**.** Let $\mathcal{P}$ be a packet system on X and let $\mathcal{Q}$ be a packet system on Y. For any map $F : X \to Y$, define

$$F_{\mathcal{Q} \leftarrow \mathcal{P}} = \mathcal{A}_{\mathcal{Q}} F \mathcal{S}_{\mathcal{P}}.$$

Thus

$$F_{\mathcal{Q}\leftarrow\mathcal{P}}((x_\alpha)_\alpha) = \left(Q_\gamma F\left(\sum_\alpha x_\alpha\right)\right)_\gamma.$$

Theorem 16.2 (Exact nonlinear coordinate theorem)**.** *For every map $F : X \to Y$,*

$$\mathcal{S}_{\mathcal{Q}} F_{\mathcal{Q}\leftarrow\mathcal{P}} \mathcal{A}_{\mathcal{P}} = F.$$

If $G : Y \to Z$ and $\mathcal{R}$ is a packet system on Z, then

$$(G \circ F)_{\mathcal{R}\leftarrow\mathcal{P}} = G_{\mathcal{R}\leftarrow\mathcal{Q}} \circ F_{\mathcal{Q}\leftarrow\mathcal{P}}.$$

No linearity, continuity, or differentiability assumption is needed.

Proof. The identities $\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}} = I_X$ and $\mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}} = I_Y$ give

$$\mathcal{S}_{\mathcal{Q}} F_{\mathcal{Q}\leftarrow\mathcal{P}} \mathcal{A}_{\mathcal{P}} = \mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}} F \mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}} = F.$$

For composition,

$$G_{\mathcal{R}\leftarrow\mathcal{Q}} F_{\mathcal{Q}\leftarrow\mathcal{P}} = \mathcal{A}_{\mathcal{R}} G \mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}} F \mathcal{S}_{\mathcal{P}} = \mathcal{A}_{\mathcal{R}}(G \circ F)\mathcal{S}_{\mathcal{P}}.$$

□

Corollary 16.3 (Dynamical equivalence)**.** *Suppose $X = Y$ and the same packet system is used on both sides. Packet coordinates preserve fixed points, periodic points, injectivity, surjectivity, and invertibility. In particular,*

$$F(x) = x \quad \Longleftrightarrow \quad F_{\mathcal{P}\leftarrow\mathcal{P}}(\mathcal{A}_{\mathcal{P}} x) = \mathcal{A}_{\mathcal{P}} x.$$

Proof. The packet map is conjugate to F through the isomorphism $\mathcal{A}_{\mathcal{P}}$. Every listed property is invariant under conjugacy. □

Proposition 16.4 (Change of packet coordinates)**.** *Let $\mathcal{P}$ and $\mathcal{P}'$ be packet systems on X. Let $\mathcal{Q}$ and $\mathcal{Q}'$ be packet systems on Y. For any two packet systems $\mathcal{U}$ and $\mathcal{V}$ on the same space, write*

$$J_{\mathcal{U}\leftarrow\mathcal{V}} = \mathcal{A}_{\mathcal{U}}\mathcal{S}_{\mathcal{V}}.$$

Then

$$F_{\mathcal{Q}'\leftarrow\mathcal{P}'} = J_{\mathcal{Q}'\leftarrow\mathcal{Q}} F_{\mathcal{Q}\leftarrow\mathcal{P}} J_{\mathcal{P}\leftarrow\mathcal{P}'}.$$

Proof. Insert $\mathcal{S}_{\mathcal{Q}}\mathcal{A}_{\mathcal{Q}} = I_Y$ and $\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}} = I_X$ into the definition of $F_{\mathcal{Q}'\leftarrow\mathcal{P}'}$. □

Exactness by cancellation

Analysis and synthesis undo each other on the complete packet tuple. In a composition of packet descriptions, the intermediate synthesis and analysis maps cancel. This compares exact descriptions of the same ambient object. A connection adds data for transport along parameters or paths, with its own hypotheses.

Example 16.5 (A mixed quadratic map)**.** Let $X = Y = \Bbbk^2$ with coordinate packets. For

$$F(x_1, x_2) = (x_1 x_2, x_1^2 + x_2),$$

the first output packet depends on both input packets. The second output packet contains a quadratic contribution from the first input packet and a linear contribution from the second. Packet coordinates record these interactions exactly. Replacing F by the two diagonal restrictions would lose the product $x_1 x_2$.

Remark 16.6. Exact packet coordinates do not imply packet independence. They retain the complete input tuple. Every output packet may depend on every input packet.

17 Packet jets and higher composition

Let X and Y be Banach spaces over the same field $\mathbb{R}$ or $\mathbb{C}$ and let the packet projectors on both spaces be bounded. In the complex case, derivatives are complex Fréchet derivatives and the Taylor integral below has a real parameter. Assume that $F : X \to Y$ is m times continuously Fréchet differentiable. The same local statements hold on open domains containing the points and segments in question. For $1 \le r \le m$, the derivative

$$D^r F(x) : X^r \longrightarrow Y$$

is a continuous symmetric multilinear map.

The range X_α is closed because $X_\alpha = \ker(I - P_\alpha)$. It is therefore Banach with its inherited norm. The same holds for every Y_γ. Give the finite product of ranges the maximum norm. Packet analysis and synthesis are bounded, since they are formed from finitely many bounded projectors and a finite sum. Their algebraic inverse identities from section 16 make them bounded linear isomorphisms. For a nonempty input family, $\|\mathcal{A}_\mathcal{P}\| \le \max_\alpha \|P_\alpha\|$ and $\|\mathcal{S}_\mathcal{P}\| \le |I|$. An empty complete family can occur only on the zero space. Its coordinate product is the zero vector space with norm zero, and the coordinate identities hold directly.

Definition 17.1 (Packet jet)**.** For $1 \le r \le m$, define

$$J^r_{\gamma|\alpha_1,\dots,\alpha_r} F(x) = Q_\gamma D^r F(x)\big|_{X_{\alpha_1} \times \cdots \times X_{\alpha_r}}.$$

This is a continuous multilinear map

$$X_{\alpha_1} \times \cdots \times X_{\alpha_r} \longrightarrow Y_\gamma.$$

Theorem 17.2 (Exact reconstruction of derivatives)**.** *For $h_1, \dots, h_r \in X$,*

$$D^r F(x)[h_1, \dots, h_r] = \sum_\gamma \sum_{\alpha_1,\dots,\alpha_r} J^r_{\gamma|\alpha_1,\dots,\alpha_r} F(x)[P_{\alpha_1} h_1, \dots, P_{\alpha_r} h_r].$$

Proof. Insert $I_Y = \sum_\gamma Q_\gamma$ on the output and $I_X = \sum_\alpha P_\alpha$ in every input slot. Multilinearity expands the finite sums. □

An exact jet model with two packets

$F(x,y) = (x + xy,\ y + x^2)$ at $(0,0)$. Coordinate packets in both input and output.

$$DF(0) = I: \quad DF(0)e_x = (1,0), \qquad DF(0)e_y = (0,1).$$

Output 1

H_1

	x	y
x	0	**1**
y	**1**	0

$D^2F_1(0)[e_x, e_y] = D^2F_1(0)[e_y, e_x] = 1$

Output 2

H_2

	x	y
x	**2**	0
y	0	0

$D^2F_2(0)[e_x, e_x] = 2$

$$D^2F(0)[h,k] = (h_xk_y + h_yk_x,\ 2h_xk_x)$$

$$\tfrac{1}{2}D^2F(0)[h,h] = (h_xh_y,\ h_x^2)$$

$F(h) = h + \frac{1}{2}D^2F(0)[h,h]$ exactly. All higher jets vanish.

Cells are ordered Hessian responses: the two mixed slots and the Taylor factor 1/2 are both retained.

Figure 4. Second packet jets for $F(x,y) = (x + xy, y + x^2)$ at the origin. Coordinate axis projectors give $DF(0) = I$. The first output has mixed second derivatives equal to one, while the second has a repeated first input derivative equal to two. Each grid records the ordered pair of input packets. The mixed entries retain an interaction that diagonal restrictions would lose.

Proposition 17.3 (Jet norm bound)**.** *Give every packet range its inherited subspace norm. The restricted jet satisfies the sharper estimate*

$$\left\|J^r_{\gamma|\alpha_1,\dots,\alpha_r}F(x)\right\| \le \|Q_\gamma\|\,\|D^rF(x)\|.$$

Its ambient extension inserts P_{α_j} in the jth slot and has norm at most $\|Q_\gamma\|\,\|D^rF(x)\|\prod_j\|P_{\alpha_j}\|$. Consequently the operator norm of the restricted packet jet also satisfies

$$\left\|J^r_{\gamma|\alpha_1,\dots,\alpha_r}F(x)\right\| \le \|Q_\gamma\|\,\|D^rF(x)\|\prod_{j=1}^{r}\|P_{\alpha_j}\|.$$

When all packets are orthogonal projections on Hilbert spaces, every nonzero projector has norm one and the bound reduces to the norm of the full derivative.

Proof. For $h_j \in X_{\alpha_j}$, the inherited norm gives

$$\|Q_\gamma D^rF(x)[h_1,\dots,h_r]\| \le \|Q_\gamma\|\,\|D^rF(x)\|\prod_j\|h_j\|.$$

Taking the multilinear operator norm proves the sharper restricted estimate. For ambient inputs, replace h_j by $P_{\alpha_j}h_j$ and apply the operator norm bound to each projector. Every nonzero idempotent has norm at least one, since it fixes a nonzero vector in its range. The displayed product bound therefore also follows for the restricted jet. If a zero packet is retained as a redundant index, multilinearity makes any jet with that input or output packet zero, so both estimates remain valid. □

Corollary 17.4 (Packet Taylor formula)**.** *Assume F is $m+1$ times continuously Fréchet differentiable on an open set containing the segment $x+th$ for $0\le t\le 1$. Then*

$$\begin{aligned}Q_\gamma F(x+h) = Q_\gamma F(x) &+ \sum_{r=1}^{m}\frac{1}{r!}\sum_{\alpha_1,\dots,\alpha_r} J^r_{\gamma|\alpha_1,\dots,\alpha_r}F(x)[P_{\alpha_1}h,\dots,P_{\alpha_r}h]\\ &+ Q_\gamma R_{m+1}(x,h),\end{aligned}$$

where the Bochner integral remainder is

$$R_{m+1}(x,h) = \frac{1}{m!}\int_0^1 (1-t)^m D^{m+1}F(x+th)[h,\dots,h]\,dt.$$

Proof. Set $g(t) = F(x+th)$ on the open preimage of the domain under $t\mapsto x+th$. It contains $[0,1]$, and repeated differentiation gives $g^{(r)}(t) = D^rF(x+th)[h,\dots,h]$. The derivatives are continuous on the compact interval, so their Bochner integrals exist in the Banach codomain. Put

$$T_j = \frac{1}{j!}\int_0^1 (1-t)^j g^{(j+1)}(t)\,dt \qquad (0\le j\le m).$$

The fundamental theorem of calculus gives $T_0 = g(1)-g(0)$. For $j\ge 1$, integration by parts gives $T_j = T_{j-1} - g^{(j)}(0)/j!$. Iterating this relation proves the Taylor identity with remainder $T_m = R_{m+1}(x,h)$ and its exact factorial normalization.

Apply Q_γ to the identity and use theorem 17.2. Pairwise annihilation and idempotence retain exactly the output packet γ. Boundedness of Q_γ allows it to pass through the Bochner integral. In particular, if $\|D^{m+1}F(x+th)\| \le M$ along the segment, then

$$\|Q_\gamma R_{m+1}(x,h)\| \le \frac{\|Q_\gamma\| M \|h\|^{m+1}}{(m+1)!}.$$

For $m = 0$ the Taylor sum is empty. For $h = 0$, multilinearity makes every positive-order term and the remainder zero. □

The relation to derivatives of the complete coordinate representation is also literal. For an open domain $U \subseteq X$, put $\widehat{F} = \mathcal{A}_{\mathcal{Q}} \circ F \circ \mathcal{S}_{\mathcal{P}}$ on the open coordinate set $\mathcal{A}_{\mathcal{P}}(U)$. Boundedness and linearity of analysis and synthesis imply, for $1 \le r \le m$,

$$D^r\widehat{F}(u)[v_1, \dots, v_r] = \mathcal{A}_{\mathcal{Q}}(D^r F(\mathcal{S}_{\mathcal{P}}u)[\mathcal{S}_{\mathcal{P}}v_1, \dots, \mathcal{S}_{\mathcal{P}}v_r]).$$

Indeed, the first derivative follows from the chain rule. Repeating it adds no higher derivatives of the fixed linear coordinate maps. If each v_j is supported in one coordinate slot α_j, synthesis includes that slot into X. Its γ output component is exactly the range jet defined above, including when a chosen direction is zero.

At a fixed base point, the nonzero packet jets form a directed hypergraph. An order r interaction has r input packet labels and one output packet label. The support therefore records interactions relative to the chosen packet system.

For a block $B = \{i_1 < \cdots < i_s\}$ and an intermediate packet γ, write

$$G_{\gamma,B}(x \mid h) = J^s_{\gamma|\alpha_{i_1},\dots,\alpha_{i_s}} G(x)[h_{i_1}, \dots, h_{i_s}].$$

Arity of packet jets

A packet jet has one output slot and as many input slots as its derivative order. In the composition formula, each partition block collects inputs for one derivative of the inner map. The number of blocks determines the arity of the derivative of the outer map. Intermediate packet labels record the outputs passed between them.

Theorem 17.5 (Packet Faà di Bruno formula)**.** *Let $n \ge 1$, let X, Y, Z be Banach spaces over the same real or complex field, and let $G : X \to Y$ and $F : Y \to Z$ be n times continuously Fréchet differentiable. Let $\mathcal{P}$, $\mathcal{Q}$, and $\mathcal{R}$ be packet systems on X, Y, and Z. Fix input packets $\alpha_1, \dots, \alpha_n$, an output packet δ, and directions $h_i \in X_{\alpha_i}$. Then*

$$\begin{aligned} &J^n_{\delta|\alpha_1,\dots,\alpha_n}(F \circ G)(x)[h_1, \dots, h_n] \\ &= \sum_{\pi=\{B_1,\dots,B_k\}} \sum_{\gamma_1,\dots,\gamma_k} J^k_{\delta|\gamma_1,\dots,\gamma_k} F(Gx)[G_{\gamma_1,B_1}(x \mid h), \dots, G_{\gamma_k,B_k}(x \mid h)]. \end{aligned}$$

The first sum runs over all set partitions of $\{1, \dots, n\}$.

Proof. First derive the unprojected partition formula. At order one it is the ordinary chain rule. Suppose it holds at order n and the maps are C^{n+1}. Differentiating a summand in direction h_{n+1} has two kinds

of contribution. A derivative of the outer map creates the new singleton block $\{n+1\}$. A derivative of an inner block jet adjoins $n+1$ to that block. Every partition of $\{1,\dots,n+1\}$ arises exactly once: if $\{n+1\}$ is a block, remove that block. Otherwise remove $n+1$ from the unique block that contains it. The chain and product rules for bounded multilinear evaluation justify the differentiation. This proves the unprojected formula by induction.

Insert $I_Y = \sum_\gamma Q_\gamma$ in each argument of the outer derivative and expand the finite sums by multilinearity. Apply R_δ to the output. The directions already lie in the declared input ranges, and each intermediate projection lands in its literal output range. The resulting summands are exactly the displayed packet jets. List directions within a block in increasing index order and blocks in increasing least-element order. Symmetry of the higher derivative makes the final value independent of the block ordering. □

Proposition 17.6 (Number of labeled composition terms)**.** *For $n \geq 1$, if Y has M packets, then the number of packet labeled terms at order n before zero jets are removed is*

$$N_{n,M} = \sum_{k=1}^{n} S(n,k) M^k,$$

where $S(n,k)$ is a Stirling number of the second kind. Thus $N_{n,M}$ is the nth Touchard polynomial evaluated at M.

Proof. A set partition with k blocks receives one independent intermediate packet label on each block. It therefore gives M^k labeled terms. There are $S(n,k)$ such partitions. □

Corollary 17.7 (Structural pruning)**.** *For a map H with fixed input and output packet systems, let $\operatorname{supp}_r H(x)$ be the set of external profiles $(\delta;\alpha_1,\dots,\alpha_r)$ for which the restricted jet $J^r_{\delta|\alpha_1,\dots,\alpha_r} H(x)$ is nonzero. A profile belongs to the admissible composition set if it admits a partition $\pi = \{B_1,\dots,B_k\}$ and intermediate labels $\gamma_1,\dots,\gamma_k$ such that the outer jet of F and every inner block jet of G in theorem 17.5 are nonzero. Then $\operatorname{supp}_n(F \circ G)(x)$ is contained in this admissible set. In particular, a summand vanishes whenever one of its constituent packet jets vanishes.*

Proof. If a profile has no admissible decorated partition, every summand in theorem 17.5 has a zero constituent and therefore vanishes. The composed jet is then the zero multilinear map. This proves the support inclusion by contraposition. The inclusion can be strict. Nonzero constituent maps may compose to zero, and nonzero summands may cancel. Thus the admissible set is a structural upper bound rather than a claim of equality. □

Example 17.8 (The second-order composition law)**.** At order two, the partition formula has two shapes. For packet directions h_1 and h_2,

$$\begin{aligned} R_\delta D^2(F\circ G)(x)[h_1,h_2] = &\sum_{\gamma_1,\gamma_2} J^2_{\delta|\gamma_1,\gamma_2} F(Gx)[J^1_{\gamma_1|\alpha_1} G(x)h_1, J^1_{\gamma_2|\alpha_2} G(x)h_2] \\ &+ \sum_{\gamma} J^1_{\delta|\gamma} F(Gx)[J^2_{\gamma|\alpha_1,\alpha_2} G(x)[h_1,h_2]]. \end{aligned}$$

The first line records two first-order changes entering a quadratic interaction of F. The second records a genuine second-order interaction created inside G before F is applied.

Remark 17.9. Jet sparsity is not invariant under an arbitrary change of coordinates. A useful packet system normally comes from symmetry, scale, support, grading, valuation, or another structure that is already present in the problem. Every sparsity claim should therefore name the packet system with respect to which it is made.

18 Rooted tree expansions

Repeated nonlinear substitution is indexed by rooted trees. We begin with a polynomial fixed point equation on a Banach space.

Let X be a Banach space. Fix $s \in X$ and continuous multilinear maps

$$B_r : X^r \longrightarrow X, \qquad 2 \le r \le d.$$

Set

$$a = \|s\|, \qquad b_r = \|B_r\|, \qquad \phi(t) = a + \sum_{r=2}^{d} b_r t^r.$$

An ordered rooted tree has leaves labeled by s and every internal vertex of arity r labeled by B_r. Its value is obtained by evaluating from the leaves toward the root.

Theorem 18.1 (Polynomial tree expansion). *Suppose there is $R > 0$ such that*

$$\phi(R) \le R$$

and

$$q = \sum_{r=2}^{d} r b_r R^{r-1} < 1.$$

Then the map

$$\Phi(x) = s + \sum_{r=2}^{d} B_r(x, \dots, x)$$

has a unique fixed point in the closed ball $\overline{B}_R(0)$. The sum of the values of all finite ordered rooted trees converges absolutely to that fixed point.

Proof. For $x, y \in \overline{B}_R(0)$, multilinearity and telescoping in the r input positions give

$$\|B_r(x, \dots, x) - B_r(y, \dots, y)\| \le r b_r R^{r-1} \|x - y\|.$$

Hence Φ is q-Lipschitz on the ball. The inequality $\phi(R) \le R$ shows that Φ preserves the ball. The contraction mapping theorem gives a unique fixed point u in that ball.

Let $\mathfrak{T}_m$ be the finite set of ordered rooted trees of height less than m. A leaf has value s. If the root of τ has arity r and ordered subtrees $\tau_1, \dots, \tau_r$, define

$$B_\tau(s) = B_r(B_{\tau_1}(s), \dots, B_{\tau_r}(s)).$$

Induction on m shows that the Picard iterate $u_0 = 0$ and $u_{m+1} = \Phi(u_m)$ satisfies

$$u_m = \sum_{\tau \in \mathfrak{T}_m} B_\tau(s).$$

Define a nonnegative scalar weight by assigning weight a to a leaf and applying the scalar map $(t_1, \dots, t_r) \mapsto b_r t_1 \cdots t_r$ at a vertex of arity r. A second induction gives

$$\sum_{\tau \in \mathfrak{T}_m} \|B_\tau(s)\| \le \sum_{\tau \in \mathfrak{T}_m} w(\tau) = t_m,$$

where $t_0 = 0$ and $t_{m+1} = \phi(t_m)$. The sequence (t_m) is increasing because ϕ has nonnegative coefficients. It is bounded by R because $t_0 \le R$ and $\phi(R) \le R$. The sum of the norms of all tree values is therefore finite. The tree series converges absolutely. Its partial sums are the Picard iterates, so its sum is u. □

Corollary 18.2 (Quadratic Catalan expansion)**.** *Let $B : X \times X \to X$ be bounded and consider*

$$u = s + B(u, u).$$

Put $a = \|s\|$ and $b = \|B\|$. If $4ab < 1$, then

$$u = \sum_{n \ge 1} \sum_{\substack{\tau \text{ full ordered binary tree} \\ \text{with } n \text{ leaves}}} B_\tau(s)$$

converges absolutely. It also satisfies

$$\|u\| \le \frac{1 - \sqrt{1 - 4ab}}{2b}$$

when $b > 0$.

Proof. If $b = 0$, the equation is $u = s$ and the tree series contains only its one leaf. If $a = 0$, every tree value is zero. Choose any R with $0 < R < 1/(2b)$ and apply theorem 18.1 to obtain uniqueness of the zero fixed point in that ball.

Assume now that $a > 0$ and $b > 0$. Take

$$R = \frac{1 - \sqrt{1 - 4ab}}{2b}.$$

Then $a + bR^2 = R$ and $2bR < 1$. Apply theorem 18.1. The number of full ordered binary trees with n leaves is the Catalan number C_{n-1}, which gives the displayed majorant. □

Theorem 18.3 (Packet labeled tree reconstruction)**.** *Let X carry a packet system $\mathcal{P}$. At each internal vertex of a tree, insert the output identity and one input identity for every child. Summing over all internal packet labels reconstructs the original tree value exactly.*

Proof. At a vertex labeled by an r multilinear map B_r, insert

$$I_X = \sum_{\beta} P_\beta$$

on the output and in every input slot. Multilinearity gives an exact finite sum of packet blocks at that vertex. Apply this identity successively from the leaves toward the root. Since the tree and the packet set are finite, all sums are finite and their total reconstructs the original tree value. □

For an infinite tree expansion, the finite sum of packet decorations for each underlying tree is kept together. The unlabeled tree majorant does not imply absolute convergence when all decorations are summed separately for arbitrary oblique projectors. Finite tree reconstruction and the grouped interpretation remain exact.

> **Arity in a tree**
>
> At each internal vertex, the number of children is the number of input slots of its multilinear map. Their order is retained because symmetry is not assumed. Packet labels resolve each finite tree into a finite sum. In an infinite expansion these sums stay grouped by tree, as required by the convergence statement above.

Corollary 18.4 (Tree pruning)**.** *A packet labeled tree vanishes if one internal vertex carries a zero packet block of the corresponding multilinear map. Removing all such zero terms leaves every finite tree sum unchanged and therefore leaves the grouped infinite series unchanged.*

Proof. A zero vertex map makes the value of the full tree zero. □

The tree theorem separates combinatorial growth from analytic convergence. The number of trees may grow rapidly, while multilinear bounds control their values. The scalar map ϕ controls the total weight of the expansion. Packet pruning changes the combinatorics but not the proof. It removes trees whose values are already zero before any norm estimate is used.

Example 18.5 (Catalan parity packets)**.** Over a field of characteristic zero, the formal equation

$$u = z + u^2$$

has the branch

$$u(z) = \frac{1 - \sqrt{1 - 4z}}{2}.$$

Write $u = u_0 + u_1$, where u_0 contains the even powers of z and u_1 contains the odd powers. Exact packet projection gives

$$u_0 = u_0^2 + u_1^2, \qquad u_1 = z + 2u_0u_1.$$

The two equations remain coupled. Their sum is the original fixed point equation.

19 Graded nonlinear operations

Let G be a finite abelian group and let

$$A = \bigoplus_{g \in G} A_g$$

be a G graded module.

Definition 19.1 (Grade respecting operation)**.** An r multilinear map $\mu : A^r \to A$ respects the grading when

$$\mu(A_{g_1}, \dots, A_{g_r}) \subseteq A_{g_1+\cdots+g_r}.$$

Theorem 19.2 (Graded packet convolution)**.** *If $a_j = \sum_{g\in G} a_{j,g}$ and μ respects the grading, then*

$$P_k\mu(a_1, \dots, a_r) = \sum_{g_1+\cdots+g_r=k} \mu(a_{1,g_1}, \dots, a_{r,g_r}).$$

Proof. Expand every input into its homogeneous components. Each term lands in the component whose label is the sum of its input labels. Projection onto A_k retains exactly the displayed terms. □

Corollary 19.3 (Cyclic product formula)**.** *For a cyclically graded algebra*

$$A = \bigoplus_{j\in\mathbb{Z}/N\mathbb{Z}} A_j, \qquad A_iA_j \subseteq A_{i+j},$$

one has

$$P_k(ab) = \sum_{i+j=k} a_ib_j.$$

Proof. Apply theorem 19.2 to multiplication. □

Theorem 19.4 (Packet Maurer Cartan equations)**.** *Let*

$$\mathcal{L} = \bigoplus_{g\in G} \mathcal{L}_g$$

be a differential graded Lie algebra over a ring in which two is invertible. Assume

$$d\mathcal{L}_g \subseteq \mathcal{L}_g, \qquad [\mathcal{L}_g, \mathcal{L}_h] \subseteq \mathcal{L}_{g+h}.$$

For a degree one element $\eta = \sum_g \eta_g$, the Maurer Cartan equation

$$d\eta + \frac{1}{2}[\eta, \eta] = 0$$

is equivalent to

$$d\eta_k + \frac{1}{2}\sum_{g+h=k} [\eta_g, \eta_h] = 0$$

for every $k \in G$.

Proof. The differential preserves the group label and the bracket adds labels. Apply the projector onto $\mathcal{L}_k$ and use exact reconstruction. □

The same argument applies to higher brackets.

Proposition 19.5 (Packet equations for L_∞ operations)**.** *Let $\mathcal{L}$ be complete and carry operations ℓ_r that respect a finite abelian group grading. Assume the packet projectors are continuous for the topology in which the series below converges. Assume the Maurer Cartan series*

$$\sum_{r\geq 1}\frac{1}{r!}\ell_r(\eta,\dots,\eta)$$

converges and the required factorials are invertible. Then its packet of label k is

$$\sum_{r\geq 1}\frac{1}{r!}\sum_{g_1+\cdots+g_r=k}\ell_r(\eta_{g_1},\dots,\eta_{g_r}).$$

The full Maurer Cartan equation holds if and only if every packet equation vanishes.

Proof. Apply theorem 19.2 to each operation ℓ_r. Continuity of the packet projectors permits the convergent sums to be projected term by term. □

Definition 19.6 (Divided square)**.** A divided square on degree one elements is a map q satisfying

$$q(x+y)=q(x)+q(y)+[x,y],\qquad q(ax)=a^2q(x),$$

whenever the expressions are defined.

Proposition 19.7 (Divided square packet equations)**.** *Assume $q(\mathcal{L}_g)\subseteq\mathcal{L}_{2g}$. Choose an ordering of the finite label set. The equation*

$$d\eta+q(\eta)=0$$

is equivalent to

$$d\eta_k+\sum_{2g=k}q(\eta_g)+\sum_{\substack{g<h\\ g+h=k}}[\eta_g,\eta_h]=0$$

for every k.

Proof. Repeated use of the polarization identity for q gives

$$q\left(\sum_g\eta_g\right)=\sum_g q(\eta_g)+\sum_{g<h}[\eta_g,\eta_h].$$

Project onto the component of label k. □

Example 19.8 (Matrix difference grading)**.** Let $A=M_N(\Bbbk)$ and assign the matrix unit E_{rs} the label $r-s$ modulo N. Since

$$E_{rs}E_{uv}=\delta_{su}E_{rv},$$

the output label is

$$(r-s)+(u-v)=r-v$$

whenever the product is nonzero. Matrix multiplication therefore obeys the cyclic convolution law exactly. The same grading resolves commutators and polynomial matrix equations.

Remark 19.9. These results begin with a graded differential or higher algebra. They do not assert that every deformation problem has such a controlling object. Differential graded and infinity algebra methods are developed in [11].

20 Nonlinear refinement defects

Let

$$F_f : X_f \longrightarrow Y_f, \qquad F_c : X_c \longrightarrow Y_c$$

be fine and coarse maps. Let

$$C_X : X_f \longrightarrow X_c, \qquad C_Y : Y_f \longrightarrow Y_c$$

be linear coarsening maps. Whenever a norm, a Lipschitz constant, or a Fréchet derivative is used, the spaces are Banach spaces and the coarsening maps are bounded.

Definition 20.1 (Nonlinear refinement defect)**.** The pointwise defect of F is

$$\Delta_F(x) = C_Y F_f(x) - F_c(C_X x).$$

The two models are exactly compatible when Δ_F vanishes everywhere.

The defect is a vector in Y_c. It determines an obstruction class after a correction map into Y_c has been chosen and the defect has been passed to the corresponding cokernel. Norm estimates measure the size of the defect. The quotient determines whether an allowed linear correction can remove it.

Theorem 20.2 (Exact defect under composition)**.** *Let $G_f : Y_f \to Z_f$ and $G_c : Y_c \to Z_c$, with coarsening $C_Z : Z_f \to Z_c$. Then*

$$\Delta_{G\circ F}(x) = \Delta_G(F_f(x)) + G_c(F_c(C_X x) + \Delta_F(x)) - G_c(F_c(C_X x)).$$

If G_c is L-Lipschitz on the relevant set, then

$$\|\Delta_{G\circ F}(x)\| \le \|\Delta_G(F_f(x))\| + L\|\Delta_F(x)\|.$$

Proof. Add and subtract $G_c(C_Y F_f(x))$. Use

$$C_Y F_f(x) = F_c(C_X x) + \Delta_F(x).$$

The norm estimate follows from the Lipschitz bound. □

Corollary 20.3 (Linear product rule)**.** *If all maps in theorem 20.2 are linear, then*

$$\Delta_{GF} = \Delta_G F_f + G_c \Delta_F.$$

Proof. Linearity turns the last difference in theorem 20.2 into $G_c\Delta_F(x)$. □

Theorem 20.4 (Iterated orbit defect). *Let $F_f : X_f \to X_f$ and $F_c : X_c \to X_c$, with coarsening $C : X_f \to X_c$. Suppose F_c is q-Lipschitz. For a fine orbit starting at x, assume*

$$\|\Delta_F(F_f^j x)\| \le \varepsilon_j.$$

Then

$$\left\|CF_f^n(x) - F_c^n(Cx)\right\| \le \sum_{j=0}^{n-1} q^{n-1-j}\varepsilon_j.$$

If $0 \le q < 1$ and every $\varepsilon_j \le \varepsilon$, then

$$\left\|CF_f^n(x) - F_c^n(Cx)\right\| \le \varepsilon\frac{1-q^n}{1-q}.$$

Proof. Let

$$e_n = \left\|CF_f^n(x) - F_c^n(Cx)\right\|.$$

The definition of the defect and the Lipschitz property give

$$e_{n+1} \le \varepsilon_n + qe_n.$$

Iterating this recurrence proves the first estimate. The second is the geometric sum. □

Theorem 20.5 (Fixed point stability). *Assume F_c is a contraction with constant $q < 1$. Let x_f and x_c be fixed points of F_f and F_c. If*

$$\|\Delta_F(x_f)\| \le \varepsilon,$$

then

$$\|Cx_f - x_c\| \le \frac{\varepsilon}{1-q}.$$

When the defect at x_f is zero, the fixed points are compatible.

Proof. Using the fixed-point equations,

$$\begin{aligned}\|Cx_f - x_c\| &\le \|CF_f(x_f) - F_c(Cx_f)\| + \|F_c(Cx_f) - F_c(x_c)\| \\ &\le \varepsilon + q\|Cx_f - x_c\|.\end{aligned}$$

Rearrange. □

Corollary 20.6 (Several refinement levels). *Let $C_\ell : X_{\ell+1} \to X_\ell$ for $0 \le \ell < m$. Suppose x_ℓ is a fixed point at level ℓ, the coarse map at level ℓ has contraction constant $q_\ell < 1$, and the adjacent defect at $x_{\ell+1}$ is at most ε_ℓ. Write*

$$C_{a,b} = C_a C_{a+1} \cdots C_{b-1} \quad \text{for } a < b, \qquad C_{a,a} = I.$$

Then

$$\|C_{0,m}x_m - x_0\| \le \sum_{\ell=0}^{m-1} \|C_{0,\ell}\|\frac{\varepsilon_\ell}{1-q_\ell}.$$

Proof. Insert the intermediate vectors $C_{0,\ell}x_\ell$ and telescope. Apply theorem 20.5 to every adjacent pair. □

Proposition 20.7 (Derivative defects). *Assume F_f and F_c are r times Fréchet differentiable and the coarsening maps are bounded and linear. Then*

$$D\Delta_F(x) = C_Y DF_f(x) - DF_c(C_X x)C_X.$$

For $r \geq 2$,

$$D^r\Delta_F(x)[h_1, \dots, h_r] = C_Y D^r F_f(x)[h_1, \dots, h_r] - D^r F_c(C_X x)[C_X h_1, \dots, C_X h_r].$$

Proof. Differentiate the defining identity for Δ_F. The coarsening maps are linear, so their higher derivatives vanish. □

Example 20.8 (Sharp affine bound). Let $F_c(y) = qy + b$ with $0 < q < 1$. Choose a fine fixed point whose coarsening has constant defect ε in the direction of the scalar state. The fixed point mismatch is exactly $\varepsilon/(1-q)$. Thus the constant in theorem 20.5 cannot be improved without more information.

21 Canonical obstruction objects

We begin by isolating the part of a defect that cannot be removed by an allowed linear correction.

Definition 21.1 (Linear correction datum). A linear correction datum consists of a homomorphism

$$D : U \longrightarrow V$$

and a defect $r \in V$. A correction is an element $u \in U$ satisfying

$$Du = -r.$$

The obstruction class is

$$\mathrm{Ob}_D(r) = [r] \in \operatorname{coker} D = V / \operatorname{im} D.$$

Theorem 21.2 (Cokernel obstruction criterion). *A linear correction exists if and only if*

$$\mathrm{Ob}_D(r) = 0.$$

The quotient map

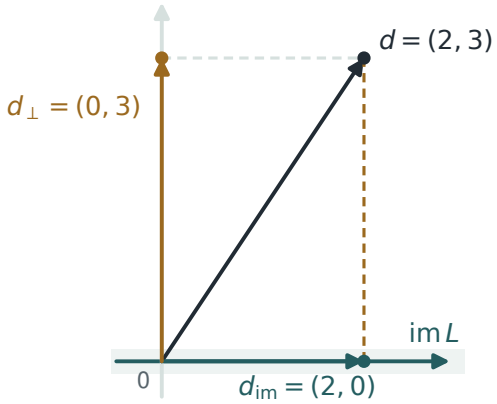
$$q_D : V \longrightarrow \operatorname{coker} D$$

has the following universal property. If $\varphi : V \to W$ is linear and $\varphi D = 0$, then there is a unique linear map

$$\overline{\varphi} : \operatorname{coker} D \longrightarrow W$$

with $\varphi = \overline{\varphi} q_D$.

Proof. The class of r is zero exactly when $r \in \operatorname{im} D$, which is equivalent to solvability of $Du = -r$. If $\varphi D = 0$, then φ vanishes on $\operatorname{im} D$. It therefore descends uniquely to the quotient. □



The universal property explains why the cokernel is the canonical obstruction object relative to D. Any linear obstruction test that vanishes on correctable defects factors through it.

Canonical obstruction data

The residual, the correction map, and the obstruction class are distinct data. The residual is a vector. The correction map specifies which changes are allowed, and its cokernel records the remaining class. Canonicality is relative to that declared correction map. A scalar or orthogonal representative of the class may require further choices or hypotheses.

Correctable defect and cokernel residual

$L : \mathbb{R}^2 \to \mathbb{R}^2$, $L(a, b) = (a, 0)$. Defect $d = (2, 3)$.

A chosen scalar detector

$$\ell(x, y) = y$$

$$\ell L = 0$$

$$\ell(d) = 3 \neq 0$$

$$u = (-2, 0): \quad d + Lu = (0, 3) \neq 0.$$

The class $[d] \in \mathbb{R}^2/\mathrm{im}\, L$ is represented by $(0, 3)$.

Standard Euclidean splitting is used. The scalar 3 depends on the displayed quotient identification.

Figure 5. A specified correction range in $\mathbb{R}^2$. For $L(a, b) = (a, 0)$, the image is the horizontal axis. The defect $(2, 3)$ splits into $(2, 0)$ in that image and the remaining representative $(0, 3)$. Subtracting the image component leaves the same cokernel class. The functional $(x, y) \mapsto y$ vanishes on the correction range and detects the value three. The correction equation $Lu = -(2, 3)$ therefore has no solution.

Theorem 21.3 (Naturality of obstruction classes)**.** *Suppose*

$$\begin{array}{ccc} U & \xrightarrow{D} & V \\ a\downarrow & & \downarrow b \\ U' & \xrightarrow{D'} & V' \end{array}$$

is a commuting square. Then there is a unique induced map

$$\overline{b} : \operatorname{coker} D \longrightarrow \operatorname{coker} D'$$

satisfying

$$\overline{b}\,\operatorname{Ob}_D(r) = \operatorname{Ob}_{D'}(br).$$

Proof. The relation $bD = D'a$ shows that the quotient map $q_{D'}b$ vanishes on $\operatorname{im} D$. Apply the universal property in theorem 21.2. □

Theorem 21.4 (Packet decomposition of an obstruction)**.** *Suppose*

$$U = \bigoplus_{\alpha\in I} U_\alpha, \qquad V = \bigoplus_{\alpha\in I} V_\alpha,$$

and $D(U_\alpha) \subseteq V_\alpha$ for every α. Let

$$D_\alpha : U_\alpha \longrightarrow V_\alpha$$

be the restriction. Then

$$\operatorname{coker} D \cong \bigoplus_{\alpha\in I} \operatorname{coker} D_\alpha.$$

Under this isomorphism, the obstruction class of $r = \sum_\alpha r_\alpha$ is the tuple

$$\big([r_\alpha]\big)_\alpha.$$

Hence r is correctable if and only if every packet obstruction vanishes.

Proof. The grading assumption gives

$$\operatorname{im} D = \bigoplus_{\alpha} \operatorname{im} D_\alpha.$$

Taking the quotient of the direct sum by this direct sum of images gives the displayed isomorphism. □

Remark 21.5. The conclusion of theorem 21.4 requires the correction map to preserve the packets. Off-diagonal correction blocks can couple packet defects. In that case the full cokernel remains canonical, but it need not split into the separate packet cokernels.

Proposition 21.6 (Projectors on the obstruction quotient)**.** *Let $(Q_\alpha)_{\alpha\in I}$ be a complete family of pairwise annihilating idempotents on V. Assume*

$$Q_\alpha(\operatorname{im} D) \subseteq \operatorname{im} D$$

for every α. Then each Q_α induces an idempotent $\overline{Q}_\alpha$ on coker D*, and*

$$\operatorname{coker} D = \bigoplus_{\alpha\in I} \overline{Q}_\alpha(\operatorname{coker} D).$$

For every defect $r \in V$,

$$\overline{Q}_\alpha \operatorname{Ob}_D(r) = [Q_\alpha r].$$

No packet decomposition of the correction space U is required.

Proof. If $v - v' \in \operatorname{im} D$, then

$$Q_\alpha(v - v') \in \operatorname{im} D.$$

Hence $[v] \mapsto [Q_\alpha v]$ is well defined on the quotient. The idempotent, annihilation, and reconstruction identities descend from V to $V/\operatorname{im} D$. The formula for an obstruction class follows from the definition. □

21.1 Relative obstruction under coarsening

Coarsening can erase an obstruction that remains present in the fine problem. The next exact sequence identifies the part removed by coarsening.

Theorem 21.7 (Relative obstruction exact sequence)**.** *Suppose the following diagram of modules commutes and has exact rows:*

$$\begin{array}{ccccccccc} 0 & \longrightarrow & U_0 & \xrightarrow{i_U} & U_f & \xrightarrow{p_U} & U_c & \longrightarrow & 0 \\ & & D_0 \downarrow & & D_f \downarrow & & D_c \downarrow & & \\ 0 & \longrightarrow & V_0 & \xrightarrow{i_V} & V_f & \xrightarrow{p_V} & V_c & \longrightarrow & 0. \end{array}$$

There is a natural exact sequence

$$\begin{aligned} 0 \longrightarrow \operatorname{Ker} D_0 \longrightarrow \operatorname{Ker} D_f \longrightarrow \operatorname{Ker} D_c \xrightarrow{\delta} \operatorname{coker} D_0 \\ \longrightarrow \operatorname{coker} D_f \longrightarrow \operatorname{coker} D_c \longrightarrow 0. \end{aligned}$$

For $u_c \in \operatorname{Ker} D_c$, choose $u_f \in U_f$ with $p_U u_f = u_c$. There is a unique $v_0 \in V_0$ such that

$$D_f u_f = i_V v_0,$$

and the connecting map is

$$\delta(u_c) = [v_0].$$

Proof. Since $D_c u_c = 0$, commutativity gives

$$p_V D_f u_f = D_c p_U u_f = 0.$$

Exactness of the lower row gives a unique v_0 with $D_f u_f = i_V v_0$. A different lift has the form $u_f + i_U u_0$. The corresponding element of V_0 changes by $D_0 u_0$, so $[v_0]$ is independent of the lift.

The map $\operatorname{Ker} D_0 \to \operatorname{Ker} D_f$ is injective because i_U is injective. If $u_f \in \operatorname{Ker} D_f$ maps to zero in U_c, then $u_f = i_U u_0$ for a unique u_0. The identity

$$i_V D_0 u_0 = D_f i_U u_0 = 0$$

and injectivity of i_V show that $u_0 \in \operatorname{Ker} D_0$. This proves exactness at $\operatorname{Ker} D_f$.

If u_c comes from an element of $\operatorname{Ker} D_f$, one may choose that element as its lift and obtain $\delta(u_c) = 0$. Conversely, if $\delta(u_c) = 0$, then $v_0 = D_0 u_0$ for some u_0. Replacing u_f by $u_f - i_U u_0$ gives an element of $\operatorname{Ker} D_f$ that maps to u_c. This proves exactness at $\operatorname{Ker} D_c$.

The class $[v_0] \in \operatorname{coker} D_0$ maps to zero in $\operatorname{coker} D_f$ whenever it equals $\delta(u_c)$, since the chosen lift satisfies $i_V v_0 = D_f u_f$. Conversely, if $i_V v_0 = D_f u_f$, then $u_c = p_U u_f$ lies in $\operatorname{Ker} D_c$ and $\delta(u_c) = [v_0]$. This proves exactness at $\operatorname{coker} D_0$.

If a class in $\operatorname{coker} D_f$ comes from $\operatorname{coker} D_0$, its image in $\operatorname{coker} D_c$ is zero. Conversely, suppose $[v_f]$ maps to zero in $\operatorname{coker} D_c$. Choose u_c with $D_c u_c = p_V v_f$ and lift it to $u_f \in U_f$. Then

$$p_V(v_f - D_f u_f) = 0,$$

so $v_f - D_f u_f = i_V v_0$ for some $v_0 \in V_0$. Thus $[v_f]$ comes from $[v_0]$. Surjectivity at the last term follows from surjectivity of p_V. □

Corollary 21.8 (Coarse vanishing and fine vanishing)**.** *Let $[r_f] \in \operatorname{coker} D_f$. If its image in $\operatorname{coker} D_c$ is zero, then $[r_f]$ comes from $\operatorname{coker} D_0$. Coarse vanishing therefore means that the fine obstruction is supported in information removed by coarsening. It does not imply $[r_f] = 0$.*

Proof. This is exactness of the sequence in theorem 21.7 at $\operatorname{coker} D_f$. □

Example 21.9 (A fine obstruction erased by coarsening)**.** Take all three correction spaces to be zero. Let

$$V_f = \Bbbk^2, \qquad V_c = \Bbbk, \qquad p_V(x, y) = x + y,$$

and let

$$V_0 = \operatorname{Ker} p_V = \operatorname{span}\{(1, -1)\}.$$

The fine defect $(1, -1)$ is a nonzero class in $\operatorname{coker} D_f = V_f$, while its coarse image is zero. The class comes from $\operatorname{coker} D_0 = V_0$, exactly as corollary 21.8 predicts.

The same construction has a cohomological form.

Definition 21.10 (Mapping cone)**.** Let $D : C^\bullet \to E^\bullet$ be a cochain map. Its mapping cone is

$$\operatorname{Cone}(D)^n = E^n \oplus C^{n+1}$$

with differential

$$d_{\operatorname{Cone}}(e, c) = (d_E e + Dc, -d_C c).$$

Theorem 21.11 (Cohomological obstruction through the cone)**.** *Let $e \in E^n$ satisfy $d_E e = 0$. The class of $(e, 0)$ in*

$$H^n(\operatorname{Cone}(D))$$

vanishes if and only if the class $[e] \in H^n(E)$ lies in the image of

$$H^n(D) : H^n(C) \longrightarrow H^n(E).$$

When C and E are concentrated in degree zero,

$$H^0(\mathrm{Cone}(D)) \cong \operatorname{coker} D.$$

Proof. The class of $(e, 0)$ vanishes exactly when there are $e' \in E^{n-1}$ and $c \in C^n$ with

$$(e, 0) = d_{\mathrm{Cone}}(e', c).$$

This means

$$e = d_E e' + Dc, \qquad d_C c = 0.$$

Equivalently, $[e] = H^n(D)[c]$. The degree zero statement follows directly from the definition of the cone differential. □

Corollary 21.12 (Packet obstruction complexes)**.** *If $C^\bullet$ and $E^\bullet$ split into finite packet subcomplexes and D preserves those packets, then* $\mathrm{Cone}(D)$ *splits into packet subcomplexes and*

$$H^n(\mathrm{Cone}(D)) \cong \bigoplus_\alpha H^n(\mathrm{Cone}(D_\alpha)).$$

Proof. Both the cone and its cohomology commute with finite direct sums. □

Example 21.13 (A two component obstruction)**.** Let

$$D : \Bbbk \longrightarrow \Bbbk^2, \qquad D(t) = (t, t).$$

The cokernel is one dimensional. The defect (a, b) is correctable exactly when $a = b$. The obstruction can be represented by $a - b$, but this scalar representative depends on a choice of isomorphism from the cokernel to $\Bbbk$. The quotient class itself is canonical.

22 Split Hilbert obstructions and nonlinear correction

The quotient obstruction has a concrete orthogonal representative when the correction map acts between Hilbert spaces and has closed range. The Hilbert and Banach space results below are analytic extensions of the finite calculus. They use the stated analytic hypotheses and lie outside the finite formal contract.

Theorem 22.1 (Orthogonal obstruction projector)**.** *Let $D : H_1 \to H_2$ be a bounded operator between Hilbert spaces with closed range. Let $D^\dagger$ be its Moore–Penrose inverse. Then*

$$P_{\mathrm{ob}} = I_{H_2} - DD^\dagger$$

is the orthogonal projector onto

$$(\operatorname{im} D)^\perp = \operatorname{Ker} D^*.$$

For $r \in H_2$, the following are equivalent:

1. *$Du = -r$ is solvable*
2. *$[r] = 0$ in* $\operatorname{coker} D$

3. $P_{\mathrm{ob}} r = 0$.

When these conditions hold, $-D^{\dagger} r$ is the least norm correction. For every r,

$$\operatorname{dist}(r, \operatorname{im} D) = \|P_{\mathrm{ob}} r\|.$$

Proof. Closed range gives the orthogonal decomposition

$$H_2 = \operatorname{im} D \oplus \operatorname{Ker} D^{*}.$$

The Moore–Penrose identities show that $DD^{\dagger}$ is the orthogonal projector onto $\operatorname{im} D$. The stated equivalences and distance formula follow from this decomposition. The least norm property is the standard characterization of $D^{\dagger} r$. □

Once the defect lies in the range, nonlinear correction still requires control of the nonlinear term. The next theorem gives that control through a bounded right inverse and a contraction estimate.

Theorem 22.2 (Right inverse correction theorem)**.** *Let $D : X \to Y$ be a bounded linear map between Banach spaces. Assume $Z = \operatorname{im} D$ is closed and there is a bounded linear right inverse*

$$R : Z \longrightarrow X, \qquad DR = I_Z.$$

Put $X_R = R(Z)$. Let

$$N : \overline{B}_{\rho}(0) \cap X_R \longrightarrow Z$$

be L-Lipschitz. Let $y \in Z$ and put

$$q = \|R\| L.$$

Assume $q < 1$ and

$$\|R(y - N(0))\| \leq (1 - q)\rho.$$

Then the equation

$$Dx + N(x) = y$$

has a unique solution in $\overline{B}_{\rho}(0) \cap X_R$.

Proof. The space X_R is closed. Indeed, if $Rz_n \to x$, then $z_n = DRz_n \to Dx$, so $x = R(Dx)$. Define

$$\Psi(x) = R(y - N(x)).$$

This map takes X_R to itself. For $x \in \overline{B}_{\rho}(0) \cap X_R$,

$$\begin{aligned} \|\Psi(x)\| &\leq \|R(y - N(0))\| + \|R\| \, \|N(x) - N(0)\| \\ &\leq (1 - q)\rho + q\rho = \rho. \end{aligned}$$

Also,

$$\|\Psi(x) - \Psi(x')\| \leq q \|x - x'\|.$$

The contraction mapping theorem gives a unique fixed point in the stated set. Applying D to the fixed point identity gives the equation. Conversely, a solution in X_R equals $R(Dx)$ and is therefore a fixed point of Ψ. □

The hypotheses behind correction

Closed range gives the obstruction an orthogonal representative in the Hilbert setting. A bounded right inverse chooses a correction slice. In the nonlinear theorem, the target and the nonlinear term both lie in the range, and the Lipschitz bound makes the correction map a contraction on the chosen ball. The uniqueness statement concerns the chosen ball within that correction slice.

Corollary 22.3 (Stability with respect to the target)**.** *Under the hypotheses of theorem 22.2, let x and x' be the fixed points associated with targets y and y'. If both fixed point maps preserve the same ball, then*

$$\|x - x'\| \le \frac{\|R\|}{1-q}\|y - y'\|.$$

Proof. Subtract the two fixed-point equations and use the Lipschitz bound for N:

$$\|x - x'\| \le \|R\|\|y - y'\| + q\|x - x'\|.$$

□

Lyapunov–Schmidt reduction separates the equation into two parts. The implicit function theorem solves the range component, leaving an equation in the obstruction space. Standard accounts of this reduction appear in [9, 19].

Theorem 22.4 (Local Lyapunov–Schmidt reduction)**.** *Let $\mathcal{U} \subseteq X$ be an open neighborhood of zero and let $F : \mathcal{U} \to Y$ be a C^r map between Banach spaces with $r \ge 1$, $F(0) = 0$, and $L = DF(0)$. Assume there are closed decompositions*

$$X = K \oplus X_1, \qquad Y = R \oplus O,$$

where $K = \operatorname{Ker} L$, $R = \operatorname{im} L$, and

$$L_1 = L|_{X_1} : X_1 \longrightarrow R$$

is a Banach space isomorphism. Let π_R and π_O be the two projections on Y. Then there are neighborhoods $U_K \subseteq K$ and $U_1 \subseteq X_1$ of zero and a unique C^r map

$$\psi : U_K \longrightarrow U_1$$

with $\psi(0) = 0$ such that

$$\pi_R F(k + \psi(k)) = 0$$

for every $k \in U_K$. After the neighborhoods are made smaller if needed, the solutions of $F(x) = 0$ near zero are exactly the points

$$x = k + \psi(k)$$

for which the reduced obstruction map

$$\kappa(k) = \pi_O F(k + \psi(k))$$

vanishes. At the base point,

$$D\psi(0) = 0, \qquad D\kappa(0) = 0.$$

Proof. Define

$$G(k, x_1) = \pi_R F(k + x_1).$$

The derivative of G in the X_1 variable at $(0, 0)$ is L_1, which is invertible. The implicit function theorem gives the unique map ψ. Every nearby x has a unique decomposition $x = k + x_1$. The range equation forces $x_1 = \psi(k)$, and the remaining equation is precisely $\kappa(k) = 0$.

Differentiate $G(k, \psi(k)) = 0$ at zero. Since L vanishes on K, one obtains $L_1 D\psi(0) = 0$, hence $D\psi(0) = 0$. Finally,

$$D\kappa(0) = \pi_O L|_K = 0.$$

□

Corollary 22.5 (Quadratic reduced obstruction)**.** *Assume the hypotheses of theorem 22.4 with $r \geq 2$. For $k_1, k_2 \in K$,*

$$D^2\kappa(0)[k_1, k_2] = \pi_O D^2 F(0)[k_1, k_2].$$

Proof. Differentiate $\kappa(k) = \pi_O F(k+\psi(k))$ twice. The terms containing $D\psi(0)$ vanish. The term containing $D^2\psi(0)$ is multiplied by $\pi_O L$, which is zero because $L(X) = R$. □

Example 22.6 (A purely quadratic obstruction)**.** Let

$$F(x, y) = (y, x^2)$$

on $\mathbb{R}^2$. At the origin,

$$L(h, k) = (k, 0).$$

The kernel is the x axis, the range is the first output axis, and the cokernel is the second output axis. The range equation forces $y = 0$. The reduced obstruction map is

$$\kappa(x) = x^2.$$

The linear obstruction vanishes for every kernel direction, but the nonlinear equation still has only the solution $x = 0$ near the origin.

Remark 22.7. The reduced map κ begins at quadratic order. This is why vanishing of the first-order cokernel class need not settle a nonlinear problem. Higher terms can produce a genuine obstruction on the kernel directions.

23 Filtered lifting

Let X and Y be modules with decreasing filtrations

$$X = F^0X \supseteq F^1X \supseteq \cdots, \qquad Y = F^0Y \supseteq F^1Y \supseteq \cdots.$$

Assume both are separated and complete for their filtration topologies. Let $\Phi : X \to Y$ be continuous and filtration congruence preserving in the sense that

$$h \in F^mX \quad \Longrightarrow \quad \Phi(x + h) - \Phi(x) \in F^mY$$

for every $x \in X$ and every m. This condition makes the statement $\Phi(x) \in F^m Y$ depend only on the class of x modulo $F^m X$.

Suppose x_m satisfies

$$\Phi(x_m) \in F^m Y.$$

Assume that corrections $h \in F^m X$ obey a first-order congruence

$$\Phi(x_m + h) \equiv \Phi(x_m) + L_m h \pmod{F^{m+1} Y},$$

where $L_m : F^m X \to F^m Y$ is a module homomorphism satisfying

$$L_m(F^{m+1} X) \subseteq F^{m+1} Y$$

and therefore induces

$$\overline{L}_m : F^m X / F^{m+1} X \longrightarrow F^m Y / F^{m+1} Y.$$

At depth m, only the associated graded correction is visible. The cokernel below has finite length whenever the target graded piece has finite length, even if the completed problem is infinite. Vanishing of the depth obstruction decides whether the current approximation can be improved by one level. When the graded pieces are finite, the branching count below applies. Finite length alone does not imply finite cardinality.

Definition 23.1 (Depth obstruction)**.** The depth m obstruction of x_m is

$$\mathrm{Ob}_m(x_m) = [\Phi(x_m)] \in \operatorname{coker} \overline{L}_m,$$

where $\Phi(x_m)$ is first viewed in $F^m Y / F^{m+1} Y$.

Theorem 23.2 (One-step lifting criterion)**.** *The approximation x_m has a correction $h_m \in F^m X$ such that*

$$\Phi(x_m + h_m) \in F^{m+1} Y$$

if and only if

$$\mathrm{Ob}_m(x_m) = 0.$$

When a correction exists, the set of its classes in

$$F^m X / F^{m+1} X$$

is a coset of $\operatorname{Ker} \overline{L}_m$*. If the graded pieces are vector spaces, this coset is an affine space.*

Proof. The next depth condition is equivalent to

$$\overline{L}_m[h_m] = -[\Phi(x_m)]$$

in $F^m Y / F^{m+1} Y$. This is solvable exactly when the displayed defect has zero cokernel class. If h_m and h'_m are two solutions, their difference lies in $\operatorname{Ker} \overline{L}_m$. Adding an element of the kernel to one solution gives another, so the solution set is a coset of the kernel. □

Corollary 23.3 (Finite branching count)**.** *Suppose the graded pieces are finite vector spaces over a finite field. If the depth obstruction vanishes, then the number of correction classes at depth m is*

$$|\operatorname{Ker}\overline{L}_m|.$$

If the obstruction does not vanish, the number is zero.

Proof. A nonempty affine space over a finite vector space has the same number of elements as that vector space. □

Lemma 23.4 (Well-defined lift classes)**.** *Under the filtration congruence assumption, the condition*

$$\Phi(x) \in F^m Y$$

depends only on the class of x in $X/F^m X$. Fix a representative x_m of a depth m class. The map

$$[h] \longmapsto [x_m + h]_{m+1}$$

identifies correction classes $[h] \in F^m X/F^{m+1}X$ with the classes at depth $m+1$ that reduce to $[x_m]_m$. Under this identification, the solutions of the associated graded correction equation in theorem 23.2 are exactly the children whose defect lies in $F^{m+1}Y$. A different representative of the same parent gives a translated parametrization of the same set of children.

Proof. If $x' - x \in F^m X$, then filtration congruence preservation gives

$$\Phi(x') - \Phi(x) \in F^m Y.$$

Thus one defect lies in $F^m Y$ exactly when the other does. If $h - h' \in F^{m+1}X$, then $x_m + h$ and $x_m + h'$ define the same depth $m+1$ class. Conversely, two depth $m+1$ classes reducing to $[x_m]_m$ differ from x_m by elements of $F^m X$, and they are equal precisely when those elements agree modulo $F^{m+1}X$. The first-order congruence shows that such a child has defect in $F^{m+1}Y$ exactly when its correction class solves the associated graded equation. Replacing x_m by another representative translates the correction coordinate by an element of $F^m X/F^{m+1}X$ and leaves the child classes themselves unchanged. □

Definition 23.5 (Lift tree)**.** Fix an initial approximation. A vertex at depth m is a class $[x]_m \in X/F^m X$ with $\Phi(x) \in F^m Y$ that reduces to the fixed initial class. A depth $m+1$ vertex is joined to its reduction in $X/F^m X$. By lemma 23.4, this rooted graph is independent of the chosen representatives. It is called the lift tree.

Theorem 23.6 (Finitely branching lift tree)**.** *Assume every level of the lift tree is nonempty and every vertex has only finitely many children. Then the tree contains an infinite branch. If X and Y are separated and complete and Φ is continuous, that branch determines an exact solution of $\Phi(x) = 0$.*

Proof. The first assertion is König's infinity argument. The root has finitely many children. Since vertices occur at arbitrarily large depths, at least one child has descendants at arbitrarily large depths. Choose such a child and repeat the argument at every chosen vertex. This gives one compatible vertex at each depth.

Choose representatives recursively. Once x_m represents the selected depth m vertex, choose a representative x_{m+1} of its selected child with

$$x_{m+1} - x_m \in F^m X.$$

The resulting sequence is Cauchy for the filtration topology. Each representative satisfies $\Phi(x_m) \in F^m Y$. The conclusion now follows from theorem 23.8. □

Corollary 23.7 (Unique lift branch)**.** *Suppose an initial approximation is fixed, every depth obstruction vanishes along its descendants, and every map $\overline{L}_m$ has zero kernel. Then at most one compatible lift branch extends the initial approximation.*

Proof. By theorem 23.2, the correction classes at each depth form a coset of $\operatorname{Ker} \overline{L}_m$. A zero kernel leaves at most one correction class, so induction gives at most one branch. □

Theorem 23.8 (Complete filtered lifting)**.** *Assume there is a compatible sequence*

$$x_{m+1} \equiv x_m \pmod{F^m X}$$

with

$$\Phi(x_m) \in F^m Y$$

for every m. Then x_m converges to an element $x_\infty \in X$ and

$$\Phi(x_\infty) = 0.$$

In particular, if the obstruction vanishes at every depth and compatible corrections are chosen, an exact solution exists.

Proof. For every fixed r, the congruences imply

$$x_n - x_m \in F^r X$$

whenever $n \geq m \geq r$. Thus (x_m) is Cauchy for the filtration topology. Completeness gives a limit x_∞.

Fix r. For every $m \geq r$, one has $\Phi(x_m) \in F^m Y \subseteq F^r Y$. The submodule $F^r Y$ is open and therefore closed in the filtration topology. Continuity of Φ gives $\Phi(x_m) \to \Phi(x_\infty)$, so $\Phi(x_\infty) \in F^r Y$. Since this holds for every r and Y is separated,

$$\Phi(x_\infty) \in \bigcap_r F^r Y = 0.$$

□

Theorem 23.9 (Naturality of filtered obstructions)**.** *Suppose a morphism of filtered lifting problems sends x_m to x'_m, intertwines L_m with L'_m, and sends $\Phi(x_m)$ to $\Phi'(x'_m)$ on the associated graded pieces. Then the induced cokernel map sends*

$$\mathrm{Ob}_m(x_m) \quad \text{to} \quad \mathrm{Ob}'_m(x'_m).$$

Proof. Apply theorem 21.3 to the induced commuting square on the depth m graded pieces. □

Example 23.10 (Three lifting outcomes)**.** The scalar equation $x^2-2=0$ at $x=3$ modulo 7 has invertible derivative. It has one correction modulo 49 and gives $x=10$ modulo 49.

For $x^2-3=0$ at $x=0$ modulo 3, the derivative is zero and the defect class is nonzero. No correction exists.

For $x^2=0$ at $x=0$ modulo 3, the derivative and defect both vanish. Every correction digit lies in the kernel, so the lift branches.

Proposition 23.11 (Maurer Cartan lifting obstruction)**.** *Let $\mathcal{L}$ be a complete filtered differential graded Lie algebra over a ring in which two is invertible. Assume*

$$dF^i\mathcal{L} \subseteq F^i\mathcal{L}, \qquad [F^i\mathcal{L}, F^j\mathcal{L}] \subseteq F^{i+j}\mathcal{L}.$$

For a degree one element η, put

$$\Omega(\eta) = d\eta + \frac{1}{2}[\eta,\eta].$$

Suppose $\Omega(\eta) \in F^m\mathcal{L}^2$ with $m \geq 1$. For every $h \in F^m\mathcal{L}^1$,

$$\Omega(\eta+h) \equiv \Omega(\eta) + d_\eta h \pmod{F^{m+1}\mathcal{L}^2}, \qquad d_\eta = d + [\eta,\cdot].$$

The obstruction to improving η by one depth is therefore the class of $\Omega(\eta)$ in the cokernel of

$$\mathrm{gr}^m(d_\eta) : \mathrm{gr}^m\,\mathcal{L}^1 \longrightarrow \mathrm{gr}^m\,\mathcal{L}^2.$$

Proof. Direct expansion gives

$$\Omega(\eta+h) = \Omega(\eta) + dh + [\eta,h] + \frac{1}{2}[h,h].$$

The filtration rule places $[h,h]$ in $F^{2m}\mathcal{L}^2$, which is contained in $F^{m+1}\mathcal{L}^2$ because $m \geq 1$. The congruence follows. The last statement is theorem 23.2 applied to the induced graded correction map. □

24 Filtered obstruction complexes

A direct packet decomposition splits a complex into independent pieces, so cohomology splits packet by packet. A filtration retains relations between depths. Its associated graded cohomology can contain classes that disappear on later pages of a spectral sequence.

There are therefore two ways for fine obstruction data to give zero total obstruction. Each fine class may already vanish, or later differentials may remove nonzero classes through compatibility between depths. Only the first mechanism occurs in a direct sum of subcomplexes. A filtration can exhibit both.

Standard Fact 24.1 (Spectral sequence of a finite filtered complex)**.** Let $C^\bullet$ be a cochain complex with a finite decreasing filtration by subcomplexes

$$C^\bullet = F^0C^\bullet \supseteq F^1C^\bullet \supseteq \cdots \supseteq F^{N+1}C^\bullet = 0.$$

There is a natural spectral sequence with

$$E_0^{p,q} = \mathrm{gr}^p\,C^{p+q}, \qquad E_1^{p,q} = H^{p+q}(\mathrm{gr}^p\,C^\bullet),$$

which converges to the associated graded object of $H^{p+q}(C^\bullet)$ with its induced filtration. A filtered cochain map induces a morphism of spectral sequences.

This is the standard construction for a filtered complex, in the form given in [18, 12]. When $C^\bullet$ is a correction or deformation complex, the groups on its pages can be read as graded obstruction candidates. For an arbitrary filtered complex, they are cohomology classes of the associated graded problem.

> **Lifting and survival answer different questions**
>
> A depth obstruction tests whether a chosen approximation admits one further correction. A spectral sequence follows cohomology classes of a filtered complex through later differentials. Turning successive corrections into an exact solution also uses compatible choices, completeness, continuity, and separatedness.

Proposition 24.2 (Fine obstruction survival)**.** *A class on the first page contributes to the total obstruction only if it is represented by a permanent cycle, so it is neither killed nor identified as a boundary on any later page. If the spectral sequence degenerates at the first page, then $H^n(C^\bullet) = 0$ exactly when $E_1^{p,n-p} = 0$ for every p.*

Proof. Convergence identifies the last page with the associated graded object of the total cohomology. A first page class contributes to that object exactly when it determines a nonzero class on the last page. If the sequence degenerates at the first page, the associated graded pieces of $H^n(C^\bullet)$ are the groups $E_1^{p,n-p}$. A finite filtered module is zero exactly when all its associated graded pieces are zero. □

Corollary 24.3 (Direct packet complexes)**.** *Suppose*

$$C^\bullet = \bigoplus_{\alpha \in I} C^\bullet_\alpha$$

is a finite direct sum of subcomplexes. Then

$$H^n(C^\bullet) \cong \bigoplus_{\alpha \in I} H^n(C^\bullet_\alpha).$$

A total cohomology class vanishes if and only if every packet class vanishes.

Proof. The differential acts independently on the summands. Kernels and images therefore split as finite direct sums, and so does their quotient. □

Example 24.4 (A fine class killed at the next page)**.** Let $C^0 = \Bbbk x$ and $C^1 = \Bbbk y$, with differential $d(x) = y$. Give C^0 the filtration

$$F^0C^0 = \Bbbk x, \qquad F^1C^0 = 0,$$

and give C^1 the filtration

$$F^0C^1 = F^1C^1 = \Bbbk y, \qquad F^2C^1 = 0.$$

The associated graded differential is zero in the relevant positions, so both x and y give nonzero classes on the next page. The next differential sends the class of x to the class of y. The total complex is acyclic. Thus nonzero fine obstruction classes can cancel through a later refinement differential.

Remark 24.5. The spectral sequence does not guarantee that a total obstruction vanishes. It records which fine classes survive and which are removed by compatibility across depths.

25 Nonlinear elimination

Let U, V, Y_P, Y_Q be Banach spaces. On an open neighborhood of $(u_0, v_0) \in U \times V$, split the variables and equations as

$$x = (u, v), \qquad F(u, v) = \begin{pmatrix} F_P(u, v) \\ F_Q(u, v) \end{pmatrix}.$$

Assume F takes values in $Y_P \times Y_Q$, is twice continuously Fréchet differentiable near (u_0, v_0), satisfies $F_Q(u_0, v_0) = 0$, and

$$A = D_v F_Q(u_0, v_0)$$

is a Banach space isomorphism from V to Y_Q. The implicit function theorem gives a local map $v = \varphi(u)$, with $\varphi(u_0) = v_0$, satisfying

$$F_Q(u, \varphi(u)) = 0.$$

Define the reduced equation

$$R(u) = F_P(u, \varphi(u)).$$

Theorem 25.1 (Exact local elimination). *After the neighborhoods are chosen small enough, the equation*

$$F(u, v) = 0$$

is equivalent to

$$v = \varphi(u) \qquad \textit{and} \qquad R(u) = 0.$$

Thus eliminating the hidden variable loses no local solutions.

Proof. The hidden equation $F_Q(u, v) = 0$ has the unique local solution $v = \varphi(u)$ by the implicit function theorem. After this identity is imposed, the remaining component of F is exactly $R(u)$. □

Theorem 25.2 (Nonlinear Schur derivative). *At (u_0, v_0),*

$$DR = D_u F_P - D_v F_P A^{-1} D_u F_Q.$$

Proof. Differentiate $F_Q(u, \varphi(u)) = 0$:

$$D_u F_Q + A D\varphi = 0.$$

Thus

$$D\varphi = -A^{-1} D_u F_Q.$$

Substitute this into

$$DR = D_u F_P + D_v F_P D\varphi.$$

□

The hidden variable still contributes

The reduced derivative includes the response of the hidden variable to a retained variation. That response travels through the inverse hidden derivative and then back into the retained equation.

The Schur term records this contribution. Its use depends on the hidden derivative being invertible, as required in the local elimination setup.

The second derivative records how this response enters the first nonlinear feedback from the hidden variables.

Theorem 25.3 (Second Schur derivative)**.** *For retained directions h, k, set*

$$\hat{h} = (h, D\varphi h), \qquad \hat{k} = (k, D\varphi k).$$

Then

$$D^2\varphi[h,k] = -A^{-1}D^2F_Q[\hat{h},\hat{k}]$$

and

$$D^2R[h,k] = D^2F_P[\hat{h},\hat{k}] - D_vF_PA^{-1}D^2F_Q[\hat{h},\hat{k}].$$

All derivatives on the right are evaluated at (u_0, v_0).

Proof. Differentiate the identity $F_Q(u, \varphi(u)) = 0$ twice. The chain rule gives

$$D^2F_Q[\hat{h},\hat{k}] + AD^2\varphi[h,k] = 0.$$

This proves the first formula. Differentiate $R(u) = F_P(u, \varphi(u))$ twice and substitute the first formula. □

Corollary 25.4 (Packet jets of the reduced equation)**.** *If the retained and hidden spaces carry packet systems, then the first and second packet jets of R are obtained by projecting the formulas in theorems 25.2 and 25.3. Hidden packet feedback is carried by the factors involving A^{-1}.*

Proof. Apply the packet projectors to the input and output slots of the two derivative formulas. □

Example 25.5 (Two retained variables and one hidden variable)**.** Suppose the derivative of F at a solution has block form

$$DF = \begin{pmatrix} A & B \\ C & D \end{pmatrix},$$

where D is invertible. Eliminating the hidden variable replaces the retained derivative A by

$$A - BD^{-1}C.$$

The feedback term is exact. Keeping only A would ignore the path from retained variables into the hidden variable and back.

Remark 25.6. Elimination and obstruction reduction address different situations. The Schur formula assumes that the hidden derivative is invertible. Lyapunov–Schmidt reduction allows a nontrivial kernel and cokernel, then leaves a reduced obstruction equation on the kernel directions.

26 Finite transport and holonomy

Let $\Gamma = (V, E)$ be a finite connected graph and fix a vector space X. At every vertex take one labeled copy of X. Every oriented edge $u \to v$ carries an invertible transport

$$T_{vu} \in \mathrm{GL}(X), \qquad T_{uv} = T_{vu}^{-1}.$$

Equivalently, one may begin with separate but isomorphic vertex fibers and choose one frame in each fiber. The matrices below are then the transports in those frames. For a path $\gamma = (v_0, \dots, v_r)$, set

$$T_\gamma = T_{v_r v_{r-1}} \cdots T_{v_1 v_0}.$$

For a loop, this product is its holonomy. In the based loop group, $\gamma_2\gamma_1$ means first traverse γ_1 and then γ_2, so $T_{\gamma_2\gamma_1} = T_{\gamma_2} T_{\gamma_1}$. Standard graph terminology may be found in [5].

An invertible map on each edge supplies the local transport data. A global frame must make these maps agree around every cycle. A spanning tree has no cycles, so a gauge can make every tree transport the identity. Each remaining edge closes a loop and retains that loop's holonomy.

Definition 26.1 (Gauge change)**.** A gauge is a family $G_v \in \mathrm{GL}(X)$. It changes the edge transports to

$$T'_{vu} = G_v T_{vu} G_u^{-1}.$$

Proposition 26.2 (Gauge covariance)**.** *For a loop γ based at v_0,*

$$\mathrm{Hol}'(\gamma) = G_{v_0} \mathrm{Hol}(\gamma) G_{v_0}^{-1}.$$

Thus the conjugacy class of each loop holonomy is gauge invariant.

Proof. Every intermediate gauge factor cancels with its inverse. The initial and terminal factors remain at the base vertex. □

Theorem 26.3 (Spanning tree normalization)**.** *Choose a root and a spanning tree $\mathcal{T}$ of Γ. There is a gauge in which every tree edge transport is the identity. In that gauge, the transport on each edge outside the tree is the holonomy of its fundamental cycle, with the orientation used to define that cycle.*

Proof. Set the gauge at the root to the identity. Propagate gauges along the unique tree paths so that every tree edge becomes the identity. An edge outside the tree closes one fundamental cycle. Since every tree factor is now the identity, the remaining edge transport is the cycle product. □

Theorem 26.4 (Cycle gluing criterion)**.** *There are vertex coordinates in which every edge transport is the identity if and only if every fundamental cycle holonomy is the identity.*

Proof. If all edge transports are identity maps, every loop product is the identity. Conversely, use theorem 26.3. Identity fundamental holonomy forces every edge outside the tree to become the identity as well. □

Corollary 26.5 (Number of independent cycle tests)**.** *For a connected graph with $|V|$ vertices and $|E|$ unoriented edges, a spanning tree leaves*

$$|E| - |V| + 1$$

fundamental cycle holonomies.

Proof. A spanning tree has $|V| - 1$ edges. Every remaining edge creates one fundamental cycle. □

26.1 Intertwining two transport systems

Let A be a transport system on copies of a fixed vector space V_0, and let B be a transport system on copies of a fixed vector space W_0. Fix a root r and an isomorphism

$$U_r : V_0 \longrightarrow W_0.$$

Theorem 26.6 (Fundamental holonomy intertwining criterion)**.** *The following conditions are equivalent.*

1. *There is a family of isomorphisms $U_v : V_0 \to W_0$ with the prescribed root value U_r and satisfying*

$$U_v A_{vu} = B_{vu} U_u$$

   for every oriented edge $u \to v$.

2. *For every fundamental loop γ based at r,*

$$U_r \operatorname{Hol}_A(\gamma) = \operatorname{Hol}_B(\gamma) U_r.$$

3. *The same identity holds for every loop based at r.*

When these conditions hold, the family (U_v) is uniquely determined by U_r.

Proof. If the edge intertwiners exist, multiply their equations around a loop. Every intermediate vertex map cancels. This proves that the first condition implies the third, and the third implies the second.

Conversely, choose a spanning tree. Starting from U_r, propagate U_v along the unique tree path by the rule

$$U_v = B_{vu} U_u A_{vu}^{-1}$$

on every tree edge. This is the only possible extension satisfying the tree edge equations. An edge outside the tree closes one fundamental loop. Its intertwining equation holds exactly when U_r intertwines the two corresponding fundamental holonomies. The second condition therefore supplies every remaining edge equation. Uniqueness follows from propagation along the tree. □

Corollary 26.7 (Scalar holonomy bridge)**.** *Suppose every vertex space is one dimensional. Two transport systems are gauge equivalent if and only if their holonomies agree on a fundamental cycle basis.*

Proof. Choose a nonzero root isomorphism. Scalar loop maps commute with it, so theorem 26.6 reduces to equality of the cycle scalars. □

Theorem 26.8 (Gauge classification of transports)**.** *Let $G \subseteq \mathrm{GL}(X)$ be the chosen structure group and fix a root r. Restrict both edge transports and gauge values to G. Gauge equivalence classes of G valued transport systems are naturally identified with*

$$\mathrm{Hom}(\pi_1(\Gamma, r), G)/G,$$

where G acts by conjugation. After a spanning tree and orientations of the remaining edges are chosen, this set is identified with simultaneous conjugacy classes of

$$b_1 = |E| - |V| + 1$$

tuples in G.

Proof. A transport system assigns a group element to every oriented edge, with inversion under reversal. The product along a based loop gives a homomorphism from the free group $\pi_1(\Gamma, r)$ to G. A gauge change conjugates this homomorphism by the gauge value at the root. Conversely, normalize a transport system on a spanning tree. The remaining edge values prescribe the images of a free basis of $\pi_1(\Gamma, r)$, and every homomorphism arises in this way. A further gauge preserving the tree normalization is constant at all vertices and acts by simultaneous conjugation. The number of non-tree edges is b_1. □

Corollary 26.9 (Abelian cohomology class)**.** *When the structure group A is abelian, gauge classes of transports are naturally*

$$H^1(\Gamma, A) \cong \mathrm{Hom}(H_1(\Gamma, \mathbb{Z}), A).$$

After a basis of $H_1(\Gamma, \mathbb{Z})$ is chosen, this group is identified with A^{b_1}.

Proof. An edge assignment is an A valued one cochain. A gauge change multiplies it by a coboundary. A graph has no two cells, so every one cochain is a cocycle. The usual computation of the first cohomology of a connected graph gives A^{b_1}. □

Corollary 26.10 (Projective transport)**.** *The same normalization and gluing statements hold for transports valued in a projective linear group. A projective transport is globally trivial exactly when all fundamental holonomies are identity elements in that projective group.*

Proof. Apply theorems 26.3 and 26.4 with the projective linear group as the structure group. □

Example 26.11 (A square loop)**.** A square graph has four vertices and four edges, so it has one fundamental cycle. After a tree gauge, three edges are identities and the fourth is the full loop holonomy. The system glues to one global frame exactly when that remaining matrix is the identity.

27 Smooth projector transport

Finite graph transport has a continuous counterpart. Let H be a Hilbert space and let

$$\mathcal{P}(t) = (P_\alpha(t))_{\alpha \in I}$$

be a complete orthogonal packet system with finitely many labels. Assume that it is continuously differentiable in operator norm for $t \in [0,T]$, where $T \geq 0$. Here every $P_\alpha(t)$ is a bounded self-adjoint projection, so $P_\alpha(t)^* = P_\alpha(t) = P_\alpha(t)^2$.

Zero projections are permitted in this section and contribute zero to all generator sums. When $T = 0$, every partition product is the empty product I. Completeness and orthogonality give

$$P_\alpha(t)P_\beta(t) = 0 \quad \text{for } \alpha \neq \beta, \qquad \sum_\alpha P_\alpha(t) = I.$$

Define the canonical generator

$$K(t) = \sum_\alpha \dot{P}_\alpha(t)P_\alpha(t).$$

Lemma 27.1 (Complete packet commutator identity)**.** *For every packet label β,*

$$\dot{P}_\beta(t) = [K(t), P_\beta(t)].$$

The generator is also skew-adjoint:

$$K(t)^* = -K(t).$$

Proof. Differentiating $P_\alpha^2 = P_\alpha$ gives

$$P_\alpha \dot{P}_\alpha P_\alpha = 0.$$

Differentiating $P_\beta P_\alpha = 0$ for $\alpha \neq \beta$ gives

$$P_\beta \dot{P}_\alpha = -\dot{P}_\beta P_\alpha.$$

Hence

$$KP_\beta = \dot{P}_\beta P_\beta$$

and

$$P_\beta K = -\dot{P}_\beta (I - P_\beta).$$

Their difference is $\dot{P}_\beta$. Also,

$$K + K^* = \sum_\alpha (\dot{P}_\alpha P_\alpha + P_\alpha \dot{P}_\alpha) = \sum_\alpha \dot{P}_\alpha = 0.$$

□

Theorem 27.2 (Canonical packet transport)**.** *Let $U(t)$ solve*

$$\dot{U}(t) = K(t)U(t), \qquad U(0) = I.$$

Then $U(t)$ is unitary and transports every packet exactly:

$$P_\alpha(t)U(t) = U(t)P_\alpha(0)$$

for all α.

Proof. The continuous bounded generator has an evolution inverse. Indeed, solve $\dot{V} = -VK$ with $V(0) = I$. Differentiation gives $(VU)' = 0$, hence $VU = I$. The product $W = UV$ satisfies $\dot{W} = KW - WK$ and $W(0) = I$. Uniqueness of this bounded linear equation gives $UV = I$. Thus U is invertible.

Skew-adjointness of $K(t)$ gives

$$\frac{d}{dt}(U(t)^*U(t)) = 0,$$

so $U(t)$ is unitary. By lemma 27.1,

$$\frac{d}{dt}(U(t)^{-1}P_\alpha(t)U(t)) = U(t)^{-1}(\dot{P}_\alpha - [K, P_\alpha])U(t) = 0.$$

The expression equals $P_\alpha(0)$ at time zero. □

Corollary 27.3 (One moving subspace)**.** *For one orthogonal projection $P(t)$ and its complement, the canonical generator is*

$$K(t) = [\dot{P}(t), P(t)].$$

The transport in theorem 27.2 maps $\operatorname{im} P(0)$ *unitarily onto* $\operatorname{im} P(t)$*.*

Proof. Apply the complete packet formula to $P(t)$ and $I - P(t)$, then simplify the sum. □

Definition 27.4 (Direct rotation of nearby packet systems)**.** Let $(P_\alpha)_{\alpha\in I}$ and $(Q_\alpha)_{\alpha\in I}$ be complete orthogonal packet systems on the same Hilbert space. Put

$$S(\mathcal{Q}, \mathcal{P}) = \sum_{\alpha\in I} Q_\alpha P_\alpha.$$

When $S(\mathcal{Q}, \mathcal{P})$ is invertible, define

$$\mathcal{U}(\mathcal{Q}, \mathcal{P}) = S(\mathcal{Q}, \mathcal{P})(S(\mathcal{Q}, \mathcal{P})^*S(\mathcal{Q}, \mathcal{P}))^{-1/2}.$$

Proposition 27.5 (Exact direct packet rotation)**.** *If*

$$\max(\{0\} \cup \{\|P_\alpha - Q_\alpha\| : \alpha \in I\}) < 1,$$

then $S(\mathcal{Q}, \mathcal{P})$ is invertible. The operator $\mathcal{U}(\mathcal{Q}, \mathcal{P})$ is unitary and satisfies

$$Q_\alpha\mathcal{U}(\mathcal{Q}, \mathcal{P}) = \mathcal{U}(\mathcal{Q}, \mathcal{P})P_\alpha$$

for every α.

Proof. The identities

$$Q_\alpha S(\mathcal{Q}, \mathcal{P}) = S(\mathcal{Q}, \mathcal{P})P_\alpha = Q_\alpha P_\alpha$$

follow from pairwise orthogonality. Also

$$S^*S = \sum_\alpha P_\alpha Q_\alpha P_\alpha, \qquad SS^* = \sum_\alpha Q_\alpha P_\alpha Q_\alpha.$$

Put $\delta = \max(\{0\} \cup \{\|P_\alpha - Q_\alpha\| : \alpha \in I\})$. On $P_\alpha H$,

$$P_\alpha Q_\alpha P_\alpha = P_\alpha - P_\alpha(P_\alpha - Q_\alpha)P_\alpha,$$

so this block is bounded below by $1-\delta > 0$. The same argument on $Q_\alpha H$ applies to $Q_\alpha P_\alpha Q_\alpha$. Thus both S^*S and SS^* are invertible. It follows that S is injective and surjective. The polar factor $\mathcal{U} = S(S^*S)^{-1/2}$ is unitary. Since S^*S commutes with every P_α, the intertwining identity for S passes to $\mathcal{U}$. □

Lemma 27.6 (One-step direct rotation estimate)**.** *Assume $\mathcal{P}(t)$ is twice continuously differentiable in operator norm on $[0,T]$. There are constants $h_0 > 0$ and $C > 0$ such that, whenever $t, t+h \in [0,T]$ and $|h| \le h_0$,*

$$\|\mathcal{U}(\mathcal{P}(t+h), \mathcal{P}(t)) - I - hK(t)\| \le Ch^2.$$

The constants can be chosen uniformly in t.

Proof. Taylor's theorem in the Banach space of bounded operators gives

$$P_\alpha(t+h) = P_\alpha(t) + h\dot{P}_\alpha(t) + E_\alpha(t,h), \qquad \|E_\alpha(t,h)\| \le C_1 h^2,$$

uniformly in t and α. Hence

$$S(\mathcal{P}(t+h), \mathcal{P}(t)) = I + hK(t) + E(t,h), \qquad \|E(t,h)\| \le C_2 h^2.$$

Since $K(t)^* = -K(t)$,

$$S^*S = I + E_2(t,h), \qquad \|E_2(t,h)\| \le C_3 h^2.$$

For small h, the spectrum of S^*S lies in a fixed compact subinterval of $(0,\infty)$. The functional calculus for $z^{-1/2}$ gives

$$(S^*S)^{-1/2} = I + E_3(t,h), \qquad \|E_3(t,h)\| \le C_4 h^2.$$

Multiplying the last two expansions proves the estimate. □

Theorem 27.7 (Direct rotations converge to packet transport)**.** *Assume the complete packet family $\mathcal{P}(t)$ is twice continuously differentiable in operator norm on $[0,T]$. For a partition*

$$0 = t_0 < t_1 < \cdots < t_N = T$$

with sufficiently small mesh, define

$$V_\pi = \mathcal{U}(\mathcal{P}(t_N), \mathcal{P}(t_{N-1})) \cdots \mathcal{U}(\mathcal{P}(t_1), \mathcal{P}(t_0)).$$

Then

$$V_\pi \longrightarrow U(T)$$

in operator norm, where U is the canonical transport from theorem 27.2. On a fixed compact interval the error is bounded by a constant times the mesh.

Proof. Let $U(t,s)$ be the exact propagator generated by K. Since K is continuously differentiable, the integral equation for $U(t+h,t)$ gives a uniform estimate

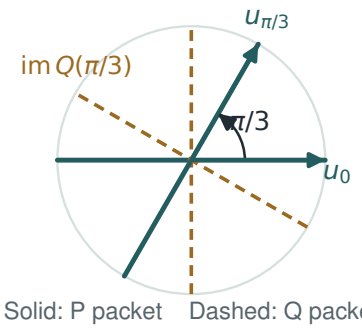
$$\|U(t+h,t) - I - hK(t)\| \le C_1 h^2.$$

By lemma 27.6, the direct rotation V_j from t_j to t_{j+1} therefore satisfies

$$\|V_j - U(t_{j+1}, t_j)\| \le C_2 h_j^2, \qquad h_j = t_{j+1} - t_j.$$

Both V_j and the exact propagator are unitary. A telescoping product comparison gives

$$\|V_\pi - U(T,0)\| \le \sum_j \|V_j - U(t_{j+1},t_j)\| \le C_2 \sum_j h_j^2 \le C_2 T|\pi|.$$



This proves norm convergence and the stated first-order global bound. □

Exact packet matching at each sample

Each direct rotation maps a sampled packet exactly to the corresponding packet at the next sample. The product therefore preserves packet labels throughout the partition. Convergence compares this discrete product with the canonical continuous transport. The uniform estimate uses twice continuous differentiability in operator norm, as stated in the theorem.

A rotating line and its complementary packet

$u_\theta = (\cos\theta, \sin\theta)$, $P(\theta) = u_\theta u_\theta^\mathsf{T}$, $Q(\theta) = I - P(\theta)$.

Canonical continuous transport

$$K = [P', P] = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$$

$$U'(\theta) = KU(\theta), \quad U(0) = I$$

$$U(\theta) = R(\theta)$$

$$S = \cos\delta\, R(\delta), \qquad S^\mathsf{T}S = \cos^2\delta\, I$$

For $|\delta| < \pi/2$: polar$(S) = R(\delta)$ exactly.

Steps N	Each increment	Ordered product
2	$\pi/6$	$R(\pi/3)$
4	$\pi/12$	$R(\pi/3)$
8	$\pi/24$	$R(\pi/3)$

Every mesh product is exact in this finite model.
The general theorem concerns convergence for broader projector paths.

Figure 6. A rotating rank-one packet and its orthogonal complement. With $u(\theta) = (\cos\theta, \sin\theta)$ and $P(\theta) = u(\theta)u(\theta)^\mathsf{T}$, the canonical generator is $[P', P] = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$. For a positive step $\delta < \pi/2$, the polar unitary is the usual rotation $R(\delta)$. On each displayed mesh, the direct rotation product equals $R(\pi/3)$ exactly. This special planar example illustrates the construction. The general theorem supplies convergence for families whose step products need not already equal the continuous transport.

Theorem 27.8 (Convergence of sampled transports)**.** *Assume K is Lipschitz on $[0,T]$. For a partition*

$$0 = t_0 < t_1 < \cdots < t_N = T,$$

define

$$U_\pi = \exp\big((t_N - t_{N-1})K(t_{N-1})\big)\cdots\exp\big((t_1 - t_0)K(t_0)\big).$$

As the mesh $|\pi|$ tends to zero,

$$U_\pi \longrightarrow U(T)$$

in operator norm. There is a constant C, depending only on T, the supremum norm of K, and its Lipschitz constant, such that

$$\|U_\pi - U(T)\| \le C|\pi|.$$

Proof. On each interval, compare the exact propagator with the frozen exponential. Variation of constants and the Lipschitz bound give a local error bounded by a constant times the square of the interval length. Every factor is unitary, so multiplication does not amplify norms. Summing the local errors gives a bound by a constant times

$$\sum_j (t_{j+1} - t_j)^2 \le T|\pi|.$$

□

Corollary 27.9 (Continuous holonomy from graph products)**.** *Assume the complete packet family is twice continuously differentiable in operator norm on $[0,T]$. If $P_\alpha(0) = P_\alpha(T)$ for every α, then $U(T)$ preserves every initial packet. Its restriction to each packet is the holonomy of the closed packet path. The products in theorems 27.7 and 27.8 converge to these holonomies. The direct rotation product has the added property that every factor maps each sampled packet exactly to its successor.*

Proof. The transport identity in theorem 27.2 gives packet preservation at the endpoint. The two convergence statements follow from theorems 27.7 and 27.8. □

Example 27.10 (A rotating line)**.** In $\mathbb{R}^2$, let

$$v(t) = (\cos t, \sin t)$$

and let $P(t)$ be the orthogonal projection onto the line spanned by $v(t)$. The canonical transport is the ordinary rotation matrix

$$U(t) = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}.$$

It carries the initial line and its orthogonal complement to the two moving packets. Products of short rotations converge to the same transport.

Standard Fact 27.11 (Curvature of a projected connection)**.** Let P be a smooth orthogonal projector-valued map on a parameter manifold. The connection

$$\nabla = P\,d$$

on the range bundle has curvature

$$\mathcal{F} = P(dP \wedge dP)P.$$

Proof. For a section s satisfying $Ps = s$,

$$\nabla^2 s = P\, d(P\, ds) = P(dP) \wedge ds.$$

Since $ds = (dP)s + Pds$ and $P(dP)P = 0$, the surviving term is

$$P(dP \wedge dP)Ps.$$ □

28 Realization data and limits of the calculus

The smooth transport theorem starts with a declared projector family. Applying it to a physical model requires a construction of that family and, where relevant, a separate continuum limit. Triviality of holonomy is a further geometric question. The curvature formula in standard fact 27.11 is classical. Relating it to global holonomy requires geometric information as in [7, 8, 10].

An application begins by specifying the following objects:

1. an ambient nonlinear equation or continuation problem
2. the allowed correction space
3. a linear correction map or a correction complex
4. the defect whose class is to be tested
5. a packet decomposition or filtration compatible with the correction data
6. transition maps between refinement levels
7. transport maps when local solutions must be glued.

Once these objects are fixed, the cokernel and cone constructions are functorial by theorems 21.3 and 21.11. Packet splitting and descent follow from theorem 21.4, proposition 21.6, and corollary 21.12. Relative loss under coarsening is measured by theorem 21.7.

Filtered lifting follows from theorems 23.2, 23.6 and 23.8. Gluing and comparison of transport systems follow from theorems 26.4 and 26.6. Smooth packet transport follows from theorems 27.2 and 27.7.

Exact packet coordinates give a representation of the data. Solving the associated problem still requires the correction and lifting hypotheses. The correction map belongs to the problem data, and its cokernel is canonical relative to that choice. The cokernel may be infinite dimensional. In the Hilbert setting, the orthogonal obstruction projector requires closed range.

Coarse vanishing can erase a nonzero fine obstruction, and higher nonlinear terms can obstruct a problem whose linear class vanishes. A spectral sequence records which classes survive the later differentials. An application of finite graph holonomy or smooth projector transport to a continuum field theory requires the additional realization data just described.

Whenever a nonlinear continuation problem supplies a correction map, its residual can be recorded in an exact quotient or cohomology object. Under the stated hypotheses, these objects admit packet decomposition, filtered refinement, natural transport, and holonomy tests. They identify the obstruction that a correction or gluing step must address.

REALIZATION CALCULUS

Projector Resolved Seed Calculus III

Analytic Packet Jets and Exact Composition

Mathematical and verification supplement

Komorebi P.

This supplement gives full ordinary mathematical arguments for the analytic packet claims of Section 17, identifies a stronger norm bound, and records how the calculation relates to the actual projector ranges. The accompanying formal development verifies multilinear reconstruction, continuous jets on the actual projector ranges, their norm bound, and the decorated composition and structural support laws. The ordinary Taylor and counting arguments retain their proof status as stated here. The companion Lean guide identifies the exact declarations and replay evidence.

1 Two distinct contracts

Let $\mathsf{X}, \mathsf{Y}, \mathsf{Z}$ be real Banach spaces. The same statements hold for complex Banach spaces with complex Fréchet derivatives. The integral below uses a real parameter. A *bounded packet system* on X is a finite family $P_i \in \mathcal{L}(\mathsf{X}, \mathsf{X})$ such that

$$\sum_{i \in I} P_i = \mathrm{id}_{\mathsf{X}}, \qquad P_i^2 = P_i, \qquad P_i P_j = 0 \quad (i \neq j). \tag{1}$$

Write $\mathsf{X}_i = \operatorname{ran} P_i$ with the subspace norm. Analogously, let $(Q_\gamma)_{\gamma \in J}$ and $(R_\delta)_{\delta \in K}$ be bounded packet systems on Y and Z. Zero projectors are allowed in this supplement. An empty family can satisfy (1) only on the zero space. Its coordinate product is the zero vector space with norm zero. For a continuous r-linear map, the operator norm is the supremum over tuples whose individual norms are at most one. Derivative orders are nonnegative integers, and a packet jet has positive order unless a nullary convention is explicitly invoked.

A weaker family of operators that only satisfies $\sum_i P_i = \mathrm{id}$ yields a useful algebraic expansion, but it need not produce independent coordinates. We keep these statements separate.

Lemma 1.1 (Closed ranges and bounded coordinates)**.** *Each X_i is closed. The maps*

$$A_{\mathsf{X}}(x) = (P_i x)_{i \in I} : \mathsf{X} \longrightarrow \prod_{i \in I} \mathsf{X}_i, \qquad S_{\mathsf{X}}((z_i)_{i \in I}) = \sum_{i \in I} z_i$$

are inverse bounded linear maps when the finite product carries the maximum norm.

Proof. The identity $\operatorname{ran} P_i = \ker(\mathrm{id} - P_i)$ follows from idempotence. The kernel of a continuous linear map is closed, so each range is itself Banach. Both coordinate maps are bounded because the family is finite. The identity $\sum_i P_i = \mathrm{id}_{\mathsf{X}}$ gives $S_{\mathsf{X}} A_{\mathsf{X}} = \mathrm{id}$. If $z_i \in \operatorname{ran} P_i$, then $P_i z_i = z_i$ and $P_j z_i = 0$ for $j \neq i$. Thus $A_{\mathsf{X}} S_{\mathsf{X}} = \mathrm{id}$. Moreover, $\|A_{\mathsf{X}}\| \leq \max_i \|P_i\|$ and $\|S_{\mathsf{X}}\| \leq |I|$ whenever I is nonempty. The case of the zero space follows from the identities directly. □

2 Multilinear reconstruction and packet jets

Theorem 2.1 (Completeness is enough for multilinear expansion)**.** *Let I, J be finite and $r \geq 0$. Suppose $\sum_i P_i = \mathrm{id}_{\mathsf{X}}$ and $\sum_\gamma Q_\gamma = \mathrm{id}_{\mathsf{Y}}$, without assuming idempotence or annihilation. Let $B : \mathsf{X}^r \to \mathsf{Y}$ be multilinear. Then, for all $h_1, \ldots, h_r \in \mathsf{X}$,*

$$B(h_1, \ldots, h_r) = \sum_{\gamma \in J} \sum_{\alpha \in I^r} Q_\gamma B(P_{\alpha_1} h_1, \ldots, P_{\alpha_r} h_r). \tag{2}$$

The statement includes $r = 0$ under the usual empty-product convention.

Proof. For every input, $h_a = \sum_{i \in I} P_i h_a$. Additivity in each slot expands B into the sum over all choices $\alpha \in I^r$. The finite output identity expresses each resulting value as its sum of Q_γ components. All exchanges of sums are finite. No property beyond completeness and multilinearity enters the calculation. For $r = 0$, the sum over input indices has exactly one term, and output completeness still gives the identity. □

Proposition 2.2 (Literal continuous range jet)**.** *Under (1) for the input and output families, let $B : \mathsf{X}^r \to \mathsf{Y}$ be a continuous multilinear map, $r \geq 1$. The formula*

$$J_{\gamma|\alpha} B(z_1, \ldots, z_r) = Q_\gamma B(z_1, \ldots, z_r), \qquad z_a \in \mathsf{X}_{\alpha_a},$$

defines a continuous multilinear map $\prod_a \mathsf{X}_{\alpha_a} \to \mathsf{Y}_\gamma$ with the actual range as codomain. For $z_a = P_{\alpha_a} h_a$, its image in Y is the corresponding summand in (2).

Proof. The output lies in $\operatorname{ran} Q_\gamma$ by construction. The subspace inclusions are continuous and isometric. The output projector Q_γ and B are continuous. Their composition therefore gives a continuous multilinear map into Y. Since Y_γ carries the induced norm and is closed, viewing this value in Y_γ does not change its norm or continuity. On the projected arguments $P_{\alpha_a} h_a$, the defining expression is precisely the summand in (2). □

Proposition 2.3 (A stronger range norm bound)**.** *The literal range jet satisfies*

$$\left\| J_{\gamma|\alpha} B \right\| \leq \|Q_\gamma\| \, \|B\| \, . \tag{3}$$

Its ambient extension $\widetilde{J} = Q_\gamma \circ B \circ (P_{\alpha_1}, \ldots, P_{\alpha_r})$ satisfies

$$\left\| \widetilde{J} \right\| \leq \|Q_\gamma\| \, \|B\| \prod_{a=1}^{r} \|P_{\alpha_a}\| \, . \tag{4}$$

In particular, the published bound for the range jet with the projector norm product on the right follows from (3).

Proof. For inputs $z_a \in \mathsf{X}_{\alpha_a}$, the induced norms yield $\|Q_\gamma B(z_1, \ldots, z_r)\| \leq \|Q_\gamma\| \, \|B\| \prod_a \|z_a\|$, proving (3). Apply additionally $\|P_{\alpha_a} h_a\| \leq \|P_{\alpha_a}\| \, \|h_a\|$ to obtain (4). If every selected input projector is nonzero, idempotence implies $\|P_{\alpha_a}\| \geq 1$ by evaluating at a unit vector in its range. Then (3) implies the weaker published inequality. If any selected input projector is zero, the corresponding input range is the zero space and the positive-order jet is zero. Both sides of the published inequality then vanish. This completes the comparison, including the degenerate case. □

3 Derivatives, coordinates, and Taylor remainder

Let $U \subset \mathsf{X}$ be open and $F : U \to \mathsf{Y}$ be C^m. For $1 \le r \le m$, the Fréchet derivative $\mathrm{D}^r F(x)$ is a continuous multilinear map. Apply Theorem 2.1 to $B = \mathrm{D}^r F(x)$. Thus the actual packet jets recover the entire derivative, without presupposing a separate packet derivative object.

Corollary 3.1 (Conjugated derivatives in packet coordinates)**.** *Let $\widehat{F} = A_{\mathsf{Y}} \circ F \circ S_{\mathsf{X}}$ on the open set $A_{\mathsf{X}}(U)$. Then $\widehat{F}$ is C^m and, for $1 \le r \le m$,*

$$\mathrm{D}^r \widehat{F}(u)[v_1, \dots, v_r] = A_{\mathsf{Y}}\big(\mathrm{D}^r F(S_{\mathsf{X}} u)[S_{\mathsf{X}} v_1, \dots, S_{\mathsf{X}} v_r]\big).$$

If v_a is supported only in packet slot α_a, let $z_a \in \mathsf{X}_{\alpha_a}$ denote its possibly zero coordinate in that slot. Then the output component γ is

$$J_{\gamma|\alpha}(\mathrm{D}^r F(S_{\mathsf{X}} u))[z_1, \dots, z_r].$$

Proof. Lemma 1.1 makes A_{X} a homeomorphism, so $A_{\mathsf{X}}(U)$ is open in the Banach coordinate product. The operators A_{Y} and S_{X} are bounded and linear. Their derivatives of order at least two vanish. Repeated application of the ordinary Fréchet chain rule therefore gives the stated formula. The last assertion follows because S_{X} includes a single supported slot into X and A_{Y} applies Q_γ in the chosen output slot. □

Theorem 3.2 (Packet Taylor identity with integral remainder)**.** *Let $F : U \to \mathsf{Y}$ be C^{m+1} on an open set containing the closed segment $[x, x+h]$. For $m \ge 0$,*

$$Q_\gamma F(x+h) = Q_\gamma F(x) + \sum_{r=1}^{m} \frac{1}{r!} \sum_{\alpha \in I^r} J_{\gamma|\alpha}(\mathrm{D}^r F(x))[P_{\alpha_1} h, \dots, P_{\alpha_r} h] + Q_\gamma R_{m+1},$$

where

$$R_{m+1} = \frac{1}{m!} \int_0^1 (1-t)^m \mathrm{D}^{m+1} F(x+th)[h^{m+1}]\, dt.$$

If $\|\mathrm{D}^{m+1} F(x+th)\| \le M$ on the segment, where $M \ge 0$, then

$$\|Q_\gamma R_{m+1}\| \le \frac{\|Q_\gamma\|\ M\, \|h\|^{m+1}}{(m+1)!}.$$

Proof. The preimage of U under $t \mapsto x + th$ is an open neighborhood of $[0,1]$, and $g(t) = F(x+th)$ is C^{m+1} there. Repeated chain differentiation gives $g^{(r)}(t) = \mathrm{D}^r F(x+th)[h^r]$. These derivatives are continuous on the compact interval, so the displayed Bochner integrals exist in the Banach codomain. To see the exact normalization, put

$$T_j = \frac{1}{j!} \int_0^1 (1-t)^j g^{(j+1)}(t)\, dt \qquad (0 \le j \le m).$$

The Banach-valued fundamental theorem of calculus gives $T_0 = g(1) - g(0)$. Integration by parts gives $T_j = T_{j-1} - g^{(j)}(0)/j!$ for $1 \le j \le m$. Iterating yields the Taylor identity with remainder $T_m = R_{m+1}$. Each Q_γ is bounded, so it commutes with the Bochner integral. Expand each derivative by Theorem 2.1 and use $Q_\gamma Q_\eta = 0$ for $\eta \ne \gamma$ and $Q_\gamma^2 = Q_\gamma$ to take its γ component. The norm bound follows from the derivative norm and $\int_0^1 (1-t)^m\, dt = 1/(m+1)$. When $m = 0$ the derivative sum is empty, and when $h = 0$ every positive-order term and the remainder vanish. □

4 The partition chain rule and packet decorations

Let $U \subseteq \mathsf{X}$ and $V \subseteq \mathsf{Y}$ be open, let $G : U \to \mathsf{Y}$ and $F : V \to \mathsf{Z}$ be C^n, and assume $G(U) \subseteq V$. Fix $x \in U$. Write Π_n for set partitions of $\{1, \dots, n\}$. Within each block the directions are listed by increasing index. Blocks may be listed by increasing least element to make every displayed tuple unambiguous.

Theorem 4.1 (Faà di Bruno in Banach spaces)**.** *For $n \geq 1$ and $h_1, \dots, h_n \in \mathsf{X}$,*

$$\mathrm{D}^n(F \circ G)(x)[h_1, \dots, h_n] = \sum_{\pi \in \Pi_n} \mathrm{D}^{|\pi|}F(Gx)\left[\mathrm{D}^{|B|}G(x)[h_i : i \in B] : B \in \pi\right].$$

The order of blocks is immaterial because Fréchet higher derivatives are symmetric.

Proof. For $n = 1$ this is the chain rule. Suppose the identity holds at order n and the maps are C^{n+1}. Differentiate a summand in direction h_{n+1}. Differentiating the outer $\mathrm{D}^{|\pi|}F(Gx)$ produces the same partition with the new singleton block $\{n+1\}$. Differentiating the argument $\mathrm{D}^{|B|}G(x)[h_i : i \in B]$ produces the partition obtained by adjoining $n+1$ to the existing block B. Every partition of $\{1, \dots, n+1\}$ arises in exactly one of these ways, depending on whether $\{n+1\}$ is a singleton. The product and chain rules apply to the bounded multilinear evaluations, and all sums are finite. Induction completes the proof. □

Corollary 4.2 (Decorated packet chain rule)**.** *Fix input labels α_i, directions $h_i \in \mathsf{X}_{\alpha_i}$, and an output label δ. For each partition π and intermediate label function $\gamma : \pi \to J$, replace the Bth argument of the outer derivative by $Q_{\gamma(B)}\mathrm{D}^{|B|}G(x)[h_i : i \in B]$. The sum over all such decorations, followed by R_δ, equals the δ output packet of $\mathrm{D}^n(F \circ G)(x)[h_1, \dots, h_n]$.*

Proof. In every outer argument of Theorem 4.1, insert the identity on Y as $\sum_{\gamma \in J} Q_\gamma$. Expand by multilinearity. The output projection R_δ distributes over the finite sum. Because the directions are already in their actual packet ranges, this is precisely the literal packet-jet expression. No statement assumes that mixed input labels disappear. □

Proposition 4.3 (Decorated term count and pruning)**.** *For $n \geq 1$, if the intermediate family contains $M \geq 0$ packet labels, the number of formal decorated terms before pruning is*

$$N_{n,M} = \sum_{k=1}^{n} S(n,k)M^k,$$

where $S(n,k)$ is a Stirling number of the second kind. A decorated summand vanishes if any of its constituent packet jets is the zero multilinear map.

More precisely, define the order-n support at x by

$$\mathcal{S}_n(F \circ G; x) = \{(\delta, \alpha) \in K \times I^n : J_{\delta|\alpha}(\mathrm{D}^n(F \circ G)(x)) \neq 0\}.$$

Let $\mathcal{A}_n(F, G; x) \subseteq K \times I^n$ consist of the profiles (δ, α) for which there exist $\pi \in \Pi_n$ and $\gamma : \pi \to J$ such that all the following restricted multilinear maps are nonzero:

$$J_{\delta|(\gamma(B))_{B\in\pi}}(\mathrm{D}^{|\pi|}F(Gx)),$$
$$J_{\gamma(B)|(\alpha_i)_{i\in B}}(\mathrm{D}^{|B|}G(x)) \qquad (B \in \pi).$$

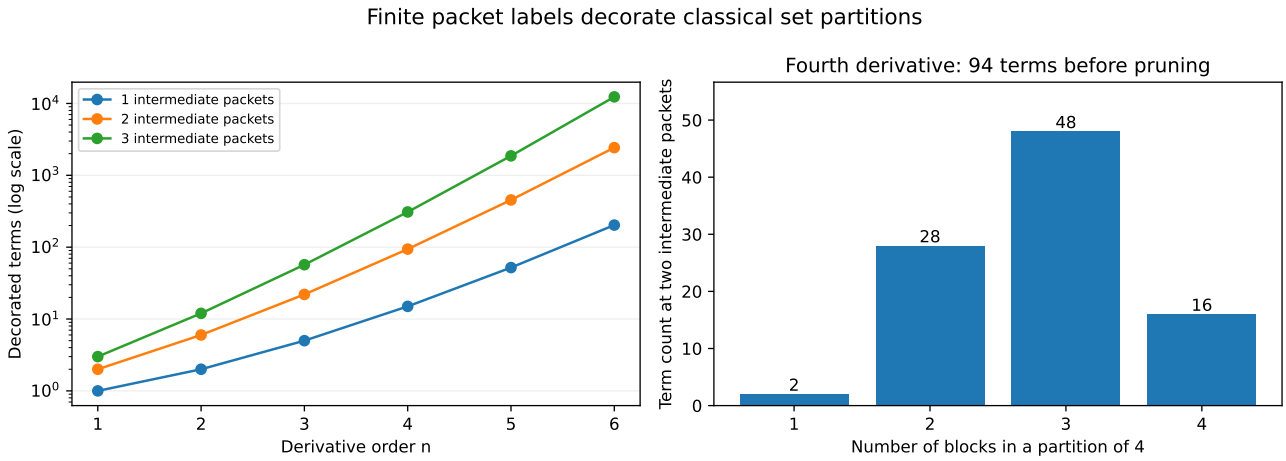


Figure 1. The growth of labeled partition terms. At fourth order with two intermediate packet labels, the contributions for the four block counts are 2, 28, 48, and 16, totaling 94. These are exact combinatorial counts, before structural pruning or cancellations.

Here the jet notation uses the relevant input and output packet families. Then

$$\mathcal{S}_n(F \circ G; x) \subseteq \mathcal{A}_n(F, G; x).$$

Thus the set of admissible decorated witnesses is projected to the same external packet profiles as the composed support. Equality need not hold.

Proof. There are $S(n,k)$ partitions with k blocks and M^k functions assigning labels to those blocks. If a profile is outside $\mathcal{A}_n(F, G; x)$, every decorated summand has a zero constituent jet. A zero inner jet supplies a zero argument to a positive-order multilinear outer jet. A zero outer jet gives zero directly. Every summand therefore vanishes for every tuple of directions, so the composed restricted jet is zero. This proves the support inclusion. Nonzero constituent maps can still compose to zero, and distinct nonzero summands can cancel. For example, take $\mathsf{X} = \mathsf{Z} = \mathbb{R}$ with one packet, $\mathsf{Y} = \mathbb{R}^2$ with its two coordinate packets, $G(t) = (t, t)$, and $F(y_1, y_2) = y_1 - y_2$. At order one both decorated terms are nonzero and their sum is zero. If $M = 0$, then $\mathsf{Y} = 0$. In that case, for $n \geq 1$ the term count and every derivative of $F \circ G$ are zero. These counts concern formal summands before structural pruning. □

5 Verification and reproduction

Layer	Verified scope
Algebraic reconstruction	The finite core and Section 16 source were compiled in the pinned Lean environment. Multilinear reconstruction retains every input label and the actual output packet.
Continuous packet jets	The accepted source uses literal projector ranges with inherited norms. Its reconstruction theorem specializes to mathlib's total `iteratedFDeriv`. Differentiability is asserted only when a theorem supplies the required hypotheses.

Layer	Verified scope
Composition and support	The accepted source expands the composite derivative over finite ordered partitions and all intermediate labels. A nonzero composite jet has a witness with nonzero constituent jets. This is a one-way support inclusion.
Taylor and counting	The integral remainder, its exact factorial normalization and bound, and the Stirling term count are proved mathematically in this supplement. They are not included in the accompanying Lean formalization.
Exact computation	Three suites passed 18,630 assertions on specified integer, rational, and polynomial examples. Repeated assertions and sampled norm inequalities are identified in the computation audit. These are finite checks.
Later monograph	The ordinary review covers all 59 later results and both classical standard facts under their stated hypotheses. Matching expanded Lean proofs were not recovered for those sections.

The source package contains the exact toolchain and dependency pins, compiler transcripts, ownership and axiom audit, kernel replay, adverse controls, mathematical reviews, and statement register. Run `python VERIFY_RELEASE.py` to check the extracted bytes. The separate Lean guide and `formal/README.md` give the formal replay commands.

Reading rule. An ordinary proof, an exact computation, a Lean theorem under explicit hypotheses, and an open research construction are separate kinds of evidence. The statement register records the scope of each claim.

How to use this volume

Twenty-four worked plates and twenty-two exact model figures accompany the monograph and its Lean guide. Integer, rational, and symbolic calculations determine the figures. The source package includes the model generators and their explicit finite verification ranges.

A route through the examples

The labels Plate III.1 through Plate III.24 identify worked pages independently of PDF pagination. Each page names its corresponding statement in the main text. The Lean guide provides the separate formal contract.

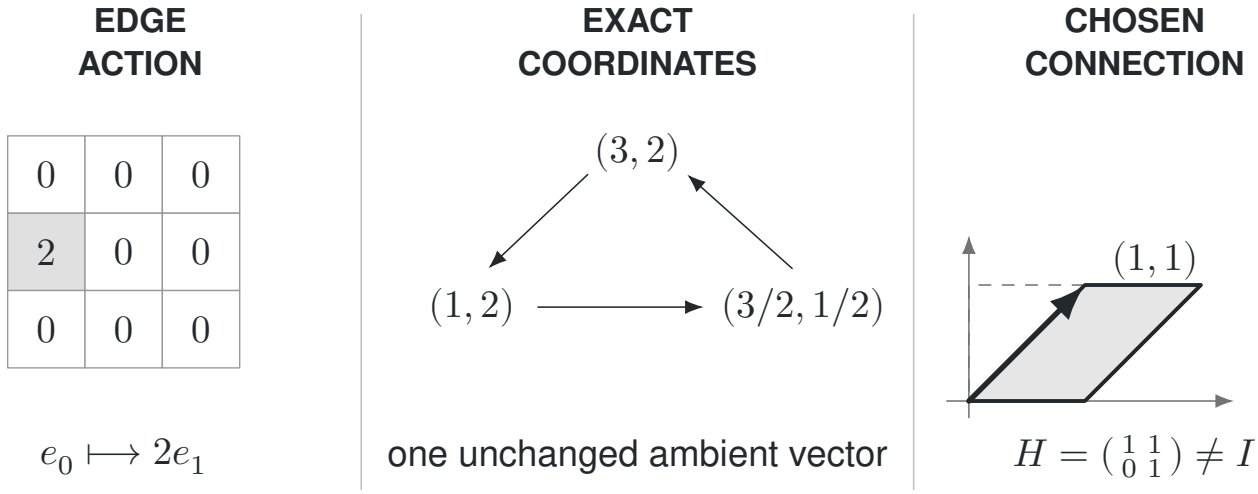
Three reading routes

Typed transfer: Plate III.3 to Plate III.8. **Coordinates, connection, and gauge:** Plate III.9 to Plate III.18, then Plate III.23. **Candidate witnesses and trees:** Plate III.19 to Plate III.22, then Plate III.24.

From the finite models to the broader chapter

The monograph continues with rooted tree expansions, nonlinear refinement defects, obstruction objects, filtered lifting, elimination, and smooth projector transport. Read the finite examples as concrete preparation. The broader ordinary proofs keep their own hypotheses and are distinct from the finite Lean contract. Chapter III: rooted trees: Section 18. Nonlinear defects: Section 20. Obstruction objects: Section 21. Filtered lifting: Section 23. Smooth transport: Section 27.

Read products in traversal order



A path $e_1, e_2, \dots, e_n$ acts as $L_{e_n} \cdots L_{e_2} L_{e_1}$: the first traversed edge is the rightmost operator. Row indices are targets and column indices are sources throughout the guide.

Plate III.1 / CHAPTER III / A WORKED VISUAL COMPANION

Three objects, three different questions

Chapter III, mathematical text: Section 1, Section 4, Section 5

An edge operator moves data between named packets. An exact coordinate change describes the same data in another complete chart. A connection supplies an additional choice of transport. The three can use similar arrows while making different mathematical assertions.

Three actual models used below: a single supported matrix entry, one ambient vector in three coordinate systems, and a shear obtained as chosen loop transport. The coordinates in the middle are not three different ambient vectors.

One chapter, three tests

For an edge word, ask whether the target of each step matches the source of the next. For exact coordinates, ask whether analysis and synthesis are inverses. For a connection, ask whether its transports through two steps agree with its declared direct transports. None of these tests can replace another.

This guide follows explicit integer and rational matrices through these tests. Each example has an inspectable input, calculation, and conclusion. Vector drawings display those calculations rather than replace them. A graph with two paths can have zero net transfer. A loop with trace two and determinant one can still differ from the identity.

Scope of the worked models

The worked models illustrate the finite algebraic core. The main text also develops rooted tree expansions, nonlinear defects, obstruction objects, filtered lifting, and analytic transport under their stated hypotheses. Those ordinary mathematical developments have a wider scope than the finite Lean contract. The present models explain the finite mechanisms and provide a route into the broader chapter.

> **Read this as:** Follow the object, not the arrow shape. A typed transfer can vanish, a complete coordinate loop must telescope, and an independently chosen connection can have genuine algebraic holonomy.

Plate III.2 / ORIENTATION / KEEP THE TYPES VISIBLE

An atlas of the objects

Chapter III, mathematical text: Definition 2.1, Definition 5.5, Definition 7.4

Rows are targets and columns are sources throughout. If E_{ji} is a matrix unit, then $E_{ji}e_i = e_j$. The notation e_i means a basis vector. A named graph edge is written a, b, c, d or e, f when its role is explicit.

Object	What it records	First worked page
$\mathrm{src}, \mathrm{tgt} : E \to V$	The ordered endpoints of each distinct edge, including parallel edges.	Plate III.3 to Plate III.4
$L_e = c(e)E_{\mathrm{tgt}(e),\mathrm{src}(e)}$	One operator supported on a packet.	Plate III.3
$L_w = L_{e_n} \cdots L_{e_1}$	Execute the written word from left to right.	Plate III.4 to Plate III.5
$T = \sum_e L_e$	Add all edge operators before taking powers.	Plate III.4 to Plate III.7
F_a	A synthesis frame from chart a into the ambient space.	Plate III.9
$\mathcal{A}_a, \mathcal{S}_a$	Inverse analysis and synthesis maps, which may be maps of sets.	Plate III.10
$J_{b\leftarrow a}$	Canonical coordinate transport, forced by the exact charts.	Plate III.9 to Plate III.10
$\Gamma_{b\leftarrow a}$	Additional connection data, with reversibility stated explicitly.	Plate III.11 to Plate III.12
$\Delta_{c,b,a}$	The difference between transport through two steps and direct transport, a map from C_a to C_c.	Plate III.12
$H_{c,b,a}$	Loop transport based at a, an automorphism of C_a.	Plate III.13
G_a	An invertible gauge change at each chart.	Plate III.14 to Plate III.15
$\Pi_\mu \,\mathrm{Ob}\, \Pi_\nu$	Block from input to output of $\mathrm{Ob} = H - I$.	Plate III.16 to Plate III.18
$r(x, p)$	A residual at packet p for the named candidate x.	Plate III.19
$t, \mathrm{inputs}(t)$	A finite operation tree and its syntactically used input labels.	Plate III.20

Reading routes

For transfer, read Plate III.3 to Plate III.8. For the finite geometry models, read Plate III.9 to Plate III.18. For candidate certificates and nonlinear scope, read Plate III.19 to Plate III.22. Plate III.23 puts the matrix mechanisms together. Plate III.24 gives the formal boundary and replay guide.

> **Read this as:** A $C_a \to C_c$ defect and a $C_a \to C_a$ holonomy are not the same typed map. Returning the defect to the base fiber requires a specified inverse transport.

Plate III.3 / MODEL A / ONE EDGE IS ONE MATRIX ENTRY

Read the product in execution order

Chapter III, mathematical text: Lemma 2.2, Theorem 2.3, Theorem 2.4

Work over $\mathbb{Z}$ with packets $0, 1, 2$. Let $e : 0 \to 1$ have coefficient 2, and let $f : 1 \to 2$ have coefficient 3. The elementary operators are

$$L_e = 2E_{10}, \qquad L_f = 3E_{21}.$$

The location of the nonzero entry records the type of the transfer, not an arbitrary matrix convention.

L_e

	0	1	2
0	0	0	0
1	2	0	0
2	0	0	0

L_f

	0	1	2
0	0	0	0
1	0	0	0
2	0	3	0

$L_f L_e$

	0	1	2
0	0	0	0
1	0	0	0
2	6	0	0

Each grid is an actual 3×3 matrix. The rightmost matrix factor acts first. In $L_f L_e$, packet 1 is the shared intermediate index. In $L_e L_f$ the interface is broken.

On a vector $(x_0, x_1, x_2)^{\mathsf{T}}$, the first step produces $(0, 2x_0, 0)^{\mathsf{T}}$, and the second produces $(0, 0, 6x_0)^{\mathsf{T}}$. Thus

$$L_f L_e = 6E_{20}, \qquad L_e L_f = 0.$$

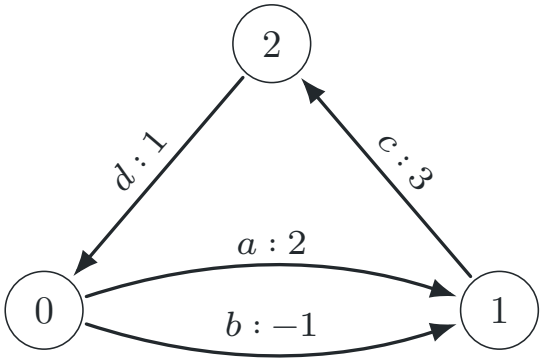
For general edges, a summand in the entrywise product can survive only when the same intermediate packet is both $\mathrm{tgt}(e)$ and $\mathrm{src}(f)$:

$$(L_f L_e)_{yx} = \sum_z (L_f)_{yz} (L_e)_{zx}.$$

This is why a broken interface annihilates the entire product, even if both edge coefficients are nonzero.

What the zero says

It says that this ordered composition does not pass data through the declared packet types. It does not say that either edge is individually zero. For a longer word, finding one broken adjacent interface is sufficient to prove that the whole word vanishes.



> **Read this as:** Write the traversed edges first. Then reverse their order when writing the operator product: e followed by f is $L_f L_e$.

Plate III.4 / MODEL A / PARALLEL EDGES REMAIN DISTINCT

All sixteen words, only five walks

Chapter III, mathematical text: Theorem 3.8, Corollary 3.9

Add four edges on three packets: $a : 0 \to 1$ with coefficient 2, $b : 0 \to 1$ with coefficient -1, $c : 1 \to 2$ with coefficient 3, and $d : 2 \to 0$ with coefficient 1. The parallel edges a and b are separate labels even though their source and target agree.

$$(T^2)_{20} = 6 - 3 = 3$$

first executed edge = column

	a	b	c	d
a	×	×	×	2
b	×	×	×	−1
c	6	−3	×	×
d	×	×	3	×

second executed edge = row

×: broken packet interface

The board tests all ordered pairs. Columns are the first executed edge and rows are the second. A shaded cell gives the ordered coefficient of a valid walk. A cross means the product is zero by type mismatch.

The surviving words are ac, bc, cd, da, db. Their coefficients are $6, -3, 3, 2, -1$, respectively. Their endpoints determine where these numbers enter the matrix:

$$T = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 3 & 0 \end{pmatrix}, \qquad T^2 = \begin{pmatrix} 0 & 3 & 0 \\ 0 & 0 & 1 \\ 3 & 0 & 0 \end{pmatrix}.$$

At row 2, column 0, the two parallel choices give $6 - 3 = 3$. Deduplicating the edge labels before summing would alter the operator. On the other hand, adding the parallel coefficients in the already assembled matrix is legitimate: both act in the same supported matrix position.

The same calculation extends from pairs to all finite words by distributivity. The included check enumerates every word through length six and independently accumulates the endpoint coefficients. The empty word is treated separately as the identity.

> **Read this as:** The matrix power is a signed, ordered walk sum. It is not simply the number of paths, and a graph edge is not identified solely by its endpoints.

Plate III.5 / MODEL A / A MATRIX RING AS THE COEFFICIENT SEMIRING

Coefficients need not commute

Chapter III, mathematical text: Lemma 3.7, Section 9

The edge theorem allows a noncommutative coefficient semiring. Use $R = M_2(\mathbb{Q})$ and let the two coefficients themselves be matrices:

$$A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad B = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}.$$

Attach A to $0 \to 1$ and B to $1 \to 2$. The single surviving endpoint coefficient is BA, not AB.

A

1	1
0	1

B

1	0
1	1

BA

1	1
1	2

AB

2	1
1	1

$$e : 0 \to 1 \text{ carries } A; \quad f : 1 \to 2 \text{ carries } B$$

$$BA(1,0)^{\mathsf{T}} = (1,1)^{\mathsf{T}}, \qquad AB(1,0)^{\mathsf{T}} = (2,1)^{\mathsf{T}}$$

All entries are exact integers. The two products differ on the diagonal and act differently on the same input vector. This example is within the scalar model with semiring coefficients by taking the scalar ring to be $M_2(\mathbb{Q})$.

The distinction is visible before any abstraction:

$$BA \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \qquad AB \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 2 \\ 1 \end{pmatrix}.$$

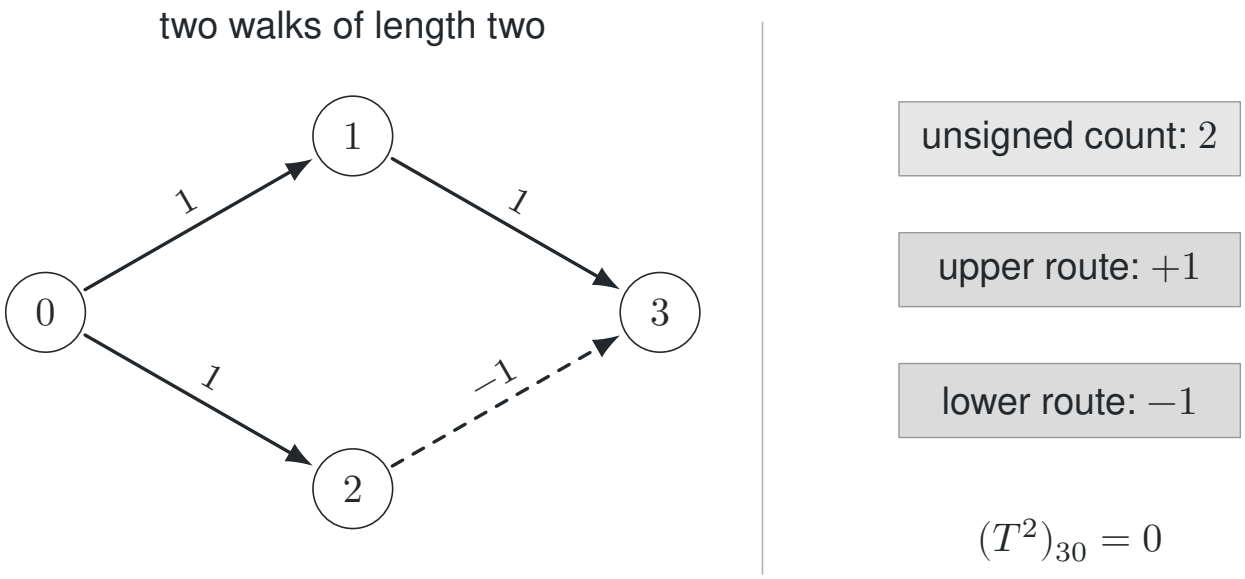
For a written walk $(e_1, \dots, e_n)$, its coefficient must therefore be

$$c^{\leftarrow}(w) = c(e_n)c(e_{n-1}) \cdots c(e_1).$$

A commutative example can hide an orientation mistake because reversing the coefficients changes nothing. This one cannot.

One ring is not a dependent family of fibers

The 3×3 matrix over $M_2(\mathbb{Q})$ can be displayed as an ordinary 6×6 matrix with 2×2 blocks. This is a concrete representation of the example over one ring. It does not establish an arbitrary family of differently typed edge fibers, which is outside the finite formal contract's scalar interface for edge systems.



> **Read this as:** The order rule carries mathematical information. It survives exact tests over a noncommutative ring and must not be inferred from pictures drawn over scalar real numbers alone.

Plate III.6 / MODEL A / CANCELLATION IS NOT A BROKEN INTERFACE

A reachable packet can receive zero

Chapter III, mathematical text: Corollary 3.9, Corollary 3.10

Consider a diamond: two routes of length two from packet 0 to packet 3. Three edge coefficients are 1 and the lower final coefficient is -1. Both routes are correctly typed. Neither is annihilated by an interface mismatch.

The dashed edge carries the coefficient -1. It is an actual edge, not an uncertain or missing one. Both paths exist. The unsigned count is two, while their exact operator contributions sum to zero.

The endpoint identity gives

$$(T^2)_{30} = (1)(1) + (-1)(1) = 0.$$

Thus the chapter's reachability implication has a definite direction:

$$\text{no compatible walk} \implies (T^n)_{ji} = 0.$$

Its converse is false. A zero entry may come from absent paths, zero coefficients, zero divisors in the coefficient ring, or cancellation among nonzero terms. The diamond exhibits the last possibility over $\mathbb{Z}$, where no zero divisor is needed.

Three different support records

The declared graph records permitted routes. The support of an individual word records the endpoints of that word when its coefficient is nonzero. The support of the sum records what remains after all contributions have been added. Passing from either of the first two records to the last requires the coefficients, not just adjacency.

A deliberately false test in the companion script asserts that reachability forces nonzero transfer. This diamond makes the test fail. That is a check against overreading the theorem, not a defect in the theorem.

> **Read this as:** Do not interpret a visible route as an occupied output. Graph support is a useful upper bound. Signed operator support can be strictly smaller.

Plate III.7 / MODEL A / AN ORBIT THAT STAYS IN TWO DIMENSIONS

Reachability is only an upper bound

Chapter III, mathematical text: Corollary 3.11

Keep the diamond and add an isolated packet 4. Start with the single seed $e_0 \in \mathbb{Q}^5$. Direct multiplication gives

$$Te_0 = e_1 + e_2, \qquad T^2 e_0 = 0.$$

Every later orbit vector is zero. The orbit hull generated by T is therefore exactly the span of the first two displayed columns.

$[e_0 \;\; Te_0 \;\; T^2 e_0]$

0	1	0	0
1	0	1	0
2	0	1	0
3	0	0	0
4	0	0	0

rank $= 2$

a basis of the orbit hull

1	0
0	1
0	1
0	0
0	0

$\mathrm{Reach}(0) = \{0, 1, 2, 3\}$

$\mathrm{Hull}_T(e_0) = \{(a, b, b, 0, 0)\}$

e_3 : reachable but absent

e_4 : unreachable and absent

The first matrix contains the actual orbit columns. The second supplies a basis of their span. The orbit hull lies inside the reachable subspace on four coordinates, but it has dimension two, not four.

A vector belongs to this hull precisely when it has the form

$$(a, b, b, 0, 0)^{\mathsf{T}}, \qquad a, b \in \mathbb{Q}.$$

Packet 4 is excluded because it is unreachable. Packet 3 is also absent, but for a different reason: the two contributions cancel. Even the reachable packets 1 and 2 remain linked. Powers of the single total operator do not separate them.

The admissible operator grammar matters

Allowing each individual edge operator is a different generation problem. For instance, applying the edge $0 \to 1$ and then $1 \to 3$ individually produces e_3. It does not follow that e_3 belongs to the orbit of the summed operator T. The chapter's theorem on orbit support concerns the explicitly stated operator action.

> **Read this as:** Unreachable means impossible under the declared action. Reachable means only that graph geometry has not ruled it out. Linear dependence and cancellation still have to be checked.

Plate III.8 / MODEL B / RECTANGULAR PRODUCTS WITH TWO OR THREE STEPS

Paths through changing packet lists

Chapter III, mathematical text: Proposition 8.1

Here the packet lists have sizes $2, 3, 2, 1$ in succession. Let the actual maps be

$$\mathbb{Q}^2 \xrightarrow{A} \mathbb{Q}^3 \xrightarrow{B} \mathbb{Q}^2 \xrightarrow{C} \mathbb{Q}.$$

Unlike a power of one matrix, each step has its own entries and its own source and target list.

$A : \mathbb{Q}^2 \to \mathbb{Q}^3$

1	0
2	1
0	3

$B : \mathbb{Q}^3 \to \mathbb{Q}^2$

1	−1	2
0	1	1

$C : \mathbb{Q}^2 \to \mathbb{Q}$

2	−1

CBA

−4	6

	$(j,k)=(0,0)$	$(0,1)$	$(0,2)$	$(1,0)$	$(1,1)$	$(1,2)$	
$i=0$	2	−4	0	0	−2	0	$=-4$
$i=1$	0	−2	12	0	−1	−3	$=6$

The lower board expands one final row into all six choices of intermediate indices for each input packet. The entries are $C_{0j}B_{jk}A_{ki}$, with $k \in \{0,1,2\}$ and $j \in \{0,1\}$. Zero terms remain visible.

The intermediate and total products are

$$BA = \begin{pmatrix} -1 & 5 \\ 2 & 4 \end{pmatrix}, \qquad CBA = \begin{pmatrix} -4 & 6 \end{pmatrix}.$$

For input packet 0, the six contributions sum to $2 - 4 + 0 + 0 - 2 + 0 = -4$. For input packet 1, they sum to $0 - 2 + 12 + 0 - 1 - 3 = 6$. These are literal matrix entries, not probabilities or path counts.

The formal scope is deliberately precise

The finite formal contract's forms with two and three steps allow changing packet types. Its heterogeneous product theorem for arbitrary lengths allows changing *factors* over one common finite packet index. That formal statement does not assert a fully dependent chain of changing index types at arbitrary lengths. The finite rectangular illustration here uses exactly three factors.

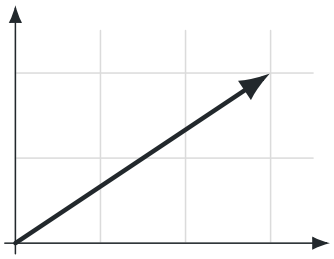
For a single factor, the list of intermediate indices is empty and contributes that matrix entry once. For zero factors, the result is the identity on the common space. These conventions must not be replaced by an empty sum equal to zero.

> **Read this as:** Heterogeneous can mean different matrices or different spaces. State which one is allowed before using a path formula.

Plate III.9 / MODEL C / CANONICAL TRANSPORT HAS NO HOLONOMY

One vector, three exact frames

Chapter III, mathematical text: Theorem 4.1, Theorem 4.2

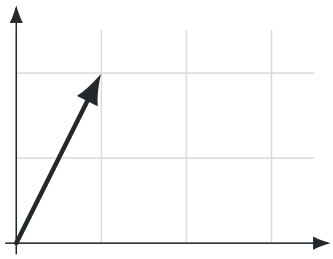


Let F_a synthesize chart coordinates into one ambient $\mathbb{Q}^2$. Choose

$$F_0 = I, \qquad F_1 = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad F_2 = \begin{pmatrix} 2 & 0 \\ 1 & 1 \end{pmatrix}.$$

The same ambient vector $x = (3,2)^{\mathsf{T}}$ has chart coordinates $u_a = F_a^{-1}x$.

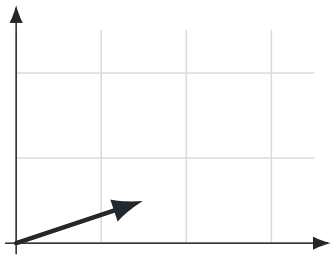
chart 0



$(3,2)$

$F_0 u_0 = (3,2)^{\mathsf{T}}$

chart 1



$(1,2)$

$F_1 u_1 = (3,2)^{\mathsf{T}}$

chart 2

$(\frac{3}{2}, \frac{1}{2})$

$F_2 u_2 = (3,2)^{\mathsf{T}}$

Each panel is a coordinate plane, not a different physical location. The numerical arrows differ because the frames differ. Multiplying each coordinate vector by its corresponding F_a recovers the same x.

Transport from chart a to chart b is forced:

$$J_{b \leftarrow a} = F_b^{-1} F_a.$$

The route $0 \to 1 \to 2$ agrees with the direct route because the middle frame cancels:

$$(F_2^{-1}F_1)(F_1^{-1}F_0) = F_2^{-1}F_0.$$

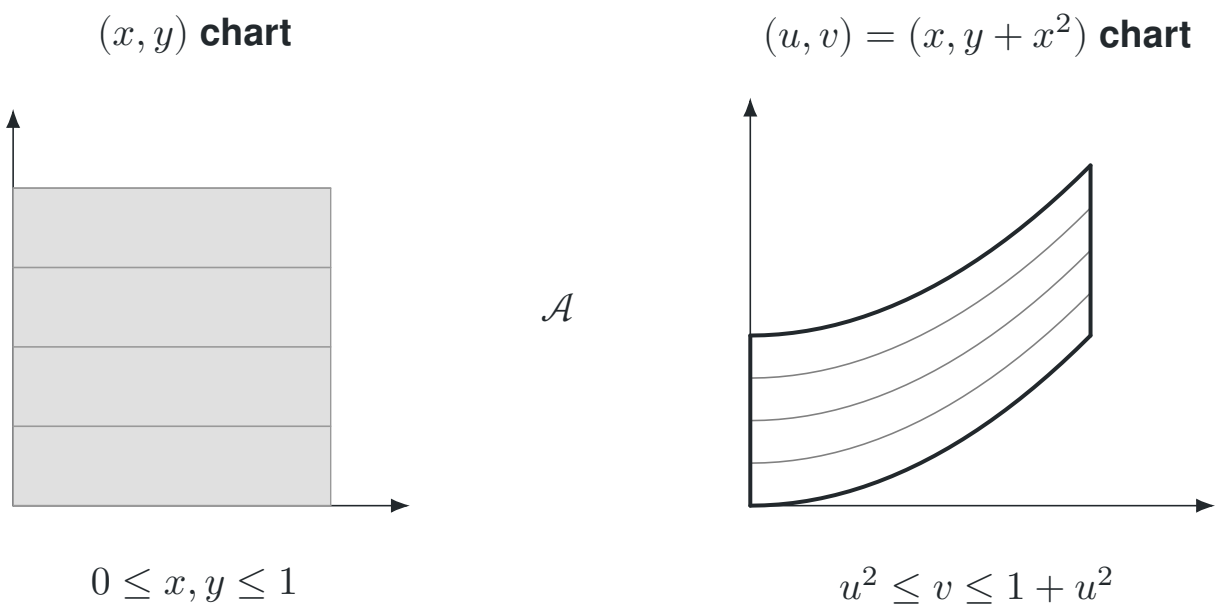
Returning to chart 0 cancels every remaining frame. The final coordinate vector is $(3,2)^{\mathsf{T}}$, not a sheared or rotated variant.

No metric is required

The frames need not be orthogonal. The second one is a shear, and the third has determinant two. Exact invertibility, rather than preservation of angles or lengths, gives the cocycle and loop identities. The same telescoping argument works for every finite chart path.

> **Read this as:** A canonical coordinate loop is a sequence of changes in description of one object. Nonidentity holonomy requires additional transport data, not merely nonorthogonal charts.

Plate III.10 / MODEL C / NATURALITY DOES NOT REQUIRE DERIVATIVES



Nonlinear charts still cancel exactly

Chapter III, mathematical text: Proposition 10.1

Exact coordinate equivalences can be nonlinear. On $\mathbb{Q}^2$, use

$$\mathcal{A}(x,y) = (x, y + x^2), \qquad \mathcal{S}(u,v) = (u, v - u^2).$$

Both composites are the identity by direct substitution. The real drawing below is a geometric view of these same polynomial formulas.

Horizontal segments become parabolas, but no information is discarded. The drawing samples the displayed polynomial boundaries for rendering. Inverse identities and route equality are checked symbolically, not inferred from the curves.

Now represent the nonlinear operation $F(x,y) = (x + y, xy)$ in the new chart. Set $w = u + v - u^2$. Its correct coordinate formula is

$$\widehat{F}_b(u,v) = \mathcal{A}F\mathcal{S}(u,v) = (w,\ u(v - u^2) + w^2).$$

For $(x,y) = (1,2)$, applying F first gives $(3,2)$ and then $(3,11)$ in the new chart. Changing the input first gives $(u,v) = (1,3)$, and $\widehat{F}_b(1,3) = (3,11)$ as well.

The equality holds as a polynomial identity for all inputs. It is the naturality theorem for maps of sets: only the inverse laws for the coordinate maps are needed. No Taylor expansion, derivative, or higher chain rule is involved.

> **Read this as:** Nonlinearity alone does not create a coordinate defect. Reusing the old formula after changing coordinates would be an extra modeling choice, not exact conjugation.

Plate III.11 / MODEL D / THE MINIMAL AND REVERSIBLE INTERFACES

Reversibility is a real hypothesis

Chapter III, mathematical text: Definition 5.1, Definition 5.5

Choose the forward scalar transports $\Gamma_{1\leftarrow 0} = 2$, $\Gamma_{2\leftarrow 1} = 3$, and $\Gamma_{2\leftarrow 0} = 5$. Their multiplicative comparison between transport through two steps and direct transport is $D^{\times} = 6/5$. A loop also needs a declared return map $\Gamma_{0\leftarrow 2}$.

connection data	$\Gamma_{0\leftarrow 2}$	H	$D^{\times}$	$\Gamma_{0\leftarrow 2}\Gamma_{2\leftarrow 0}$
self normalization only	$\frac{1}{6}$	1	$6/5$	$\frac{5}{6}$
reversible	$\frac{1}{5}$	$\frac{6}{5}$	$6/5$	1

$$\Gamma_{1\leftarrow 0} = 2, \quad \Gamma_{2\leftarrow 1} = 3, \quad \Gamma_{2\leftarrow 0} = 5$$

The first row has H = identity at this triangle, but fails its cocycle.

All transports are invertible rational scalars and transport from each chart to itself is one. The first row is permitted by the minimal interface. The second uses the inverse of the direct forward edge and therefore satisfies that part of reversibility.

In the first row, choose the return scalar $1/6$. Then

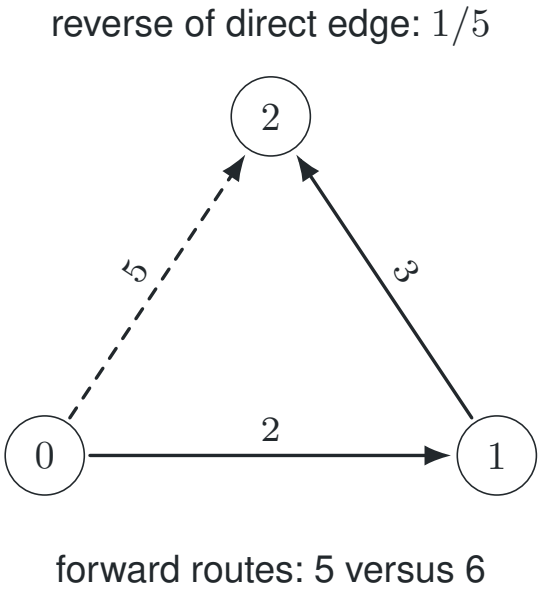
$$H = (1/6) \cdot 3 \cdot 2 = 1, \qquad \Gamma_{2\leftarrow 1}\Gamma_{1\leftarrow 0} - \Gamma_{2\leftarrow 0} = 1.$$

This triangle loop is the identity even though its cocycle equation fails. The return is not the inverse of the direct transport: $(1/6)5 \neq 1$. Thus one cannot transfer the reversible equivalence between defect and holonomy to the minimal interface.

In the reversible row, the return is $1/5$. Now the loop is $6/5$, and the additive defect of one is converted into the loop obstruction $1/5$ by that inverse return map.

Two safeguards

Global flatness in the minimal interface implies trivial loops by using its cocycle on the whole route, including the return. Separately, in the reversible interface, triviality of each triangle loop is equivalent to that triangle's cocycle. Neither assertion says that one isolated loop certifies all triangles.



> **Read this as:** Self normalization means $\Gamma_{a\leftarrow a} = I$. Reversible additionally means $\Gamma_{a\leftarrow b} = \Gamma_{b\leftarrow a}^{-1}$. These are different assumptions.

Plate III.12 / MODEL D / AN EXACT REVERSIBLE TRIANGLE

Measure the mismatch at its base

Chapter III, mathematical text: Theorem 5.10, Section 9

Retain the reversible scalar model with forward values $2, 3, 5$ and all reverse values given by inverses. Two routes from chart 0 to chart 2 multiply the input by 6 and 5, respectively. The additive discrepancy equals the original input.

loop input 1 returns $6/5$

loops	returned value
0	1
1	$\frac{6}{5}$
2	$\frac{36}{25}$
3	$\frac{216}{125}$
4	$\frac{1296}{625}$

The dashed direct edge is a specified comparison map, not a missing edge. The table shows the exact effect of traversing the same loop repeatedly. These are rational values of this example, not an analytic convergence claim.

The defect lives at the target of the forward routes:

$$\Delta_{2,1,0} = 3 \cdot 2 - 5 = 1.$$

The holonomy lives back at chart 0:

$$H_{2,1,0} = 5^{-1} \cdot 3 \cdot 2 = \frac{6}{5}, \qquad H - I = \frac{1}{5} = \Gamma_{0 \leftarrow 2}\Delta.$$

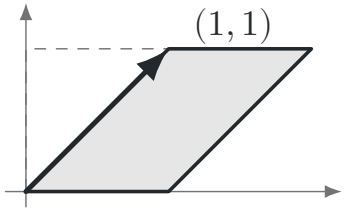
For input 5, the direct output and the output after two steps are 25 and 30. Returning by $1/5$ gives 5 and 6. The target discrepancy of 5 has become a base discrepancy of 1. The types and locations of these differences matter even in an example in one dimension.

Because the return map is invertible, it cannot turn a nonzero defect into zero. This is the mechanism behind $\Delta = 0 \iff H = I$ in the reversible interface.

> **Read this as:** Holonomy compares paths after both have been returned to the same base fiber. It is the transported mismatch, not an untyped difference between outputs in different charts.

Plate III.13 / MODEL E / A SHEAR WITH NONTRIVIAL HOLONOMY

The identity can hide in the spectrum



Chapter III, mathematical text: Definition 5.9, Definition 7.4

Put $\Gamma_{1\leftarrow 0} = H$, $\Gamma_{2\leftarrow 1} = I$, and $\Gamma_{2\leftarrow 0} = I$, with reverse maps given by inverses, where

$$H = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

The loop $0 \to 1 \to 2 \to 0$ then has exactly this shear as its holonomy.

The unit square under H

H

1	1
0	1

$H - I$

0	1
0	0

$$\operatorname{tr} H = 2, \quad \det H = 1, \quad (H - I)e_1 = e_0$$

The dashed square is the original set. The solid parallelogram is its exact image. The second coordinate basis vector moves to $(1, 1)^{\mathsf{T}}$. Its nonzero displacement is the first basis vector.

The usual scalar invariants can be misleading:

$$\operatorname{tr} H = 2, \qquad \det H = 1, \qquad \chi_H(t) = (t-1)^2.$$

These are also the invariants of the 2×2 identity matrix. Nevertheless,

$$\mathrm{Ob} = H - I = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \neq 0, \qquad \mathrm{Ob}\, e_1 = e_0.$$

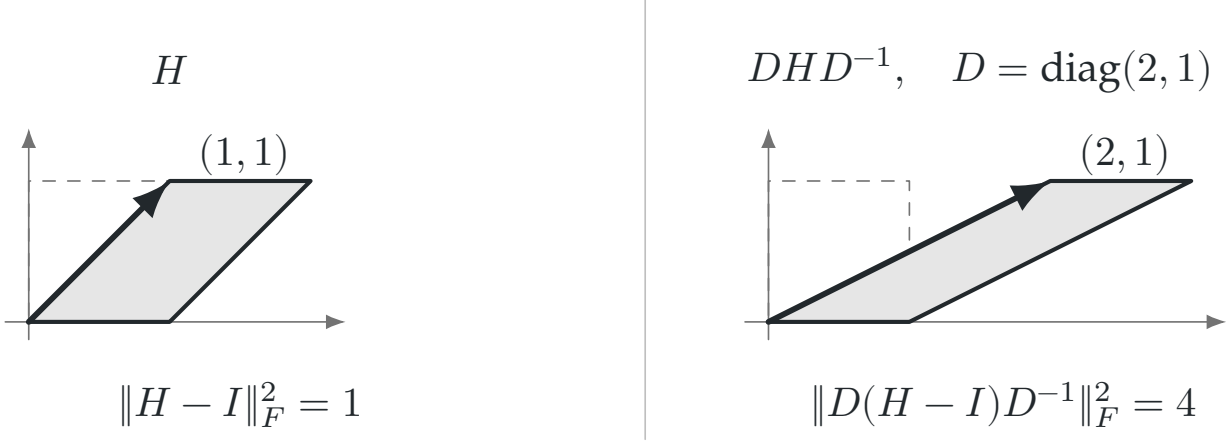
A complete obstruction test must therefore retain the operator or a certificate strong enough to detect its nonzero action. Trace, determinant, and eigenvalue lists alone do not distinguish this loop from the identity.

What the picture certifies, and what it does not

The plotted corners are the images of the four corners of the unit square under the displayed matrix. The equation $\mathrm{Ob}\, e_1 = e_0$ is the exact witness. No smooth connection, curvature tensor, or continuum limit is used in this model. Its holonomy is the finite algebraic loop product. The mathematical text treats smooth transport separately under additional hypotheses.

> **Read this as:** Flatness is the equality $H = I$, not agreement of a short list of spectral summaries. A single explicit moved vector can disprove that equality.

Plate III.14 / MODEL E / CONJUGATION AND ITS LIMITS



Gauge changes the picture, not flatness

Chapter III, mathematical text: Theorem 6.2

At the base chart, change coordinates by $D = \mathrm{diag}(2, 1)$. Transform every connection edge by the prescribed endpoint gauges. The loop transforms by conjugation, giving

$$H^D = DHD^{-1} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}.$$

The shear looks stronger in these fixed numerical axes, but the verdict on flatness is unchanged by gauge.

Both figures are exact images of a unit square under their displayed matrices. The Frobenius norms are computed in the indicated fixed coordinate bases. A nonorthogonal gauge need not preserve such a norm.

The rank of the obstruction is one on both sides. Trace, determinant, and characteristic polynomial are preserved under this conjugation. Conjugation also gives

$$D(H - I)D^{-1} = 0 \quad \Longleftrightarrow \quad H - I = 0.$$

An invertible coordinate change cannot turn a nonidentity loop into the identity. The fact that a particular residual norm changes does not contradict the invariance of exact vanishing.

The base chart determines the outer gauge

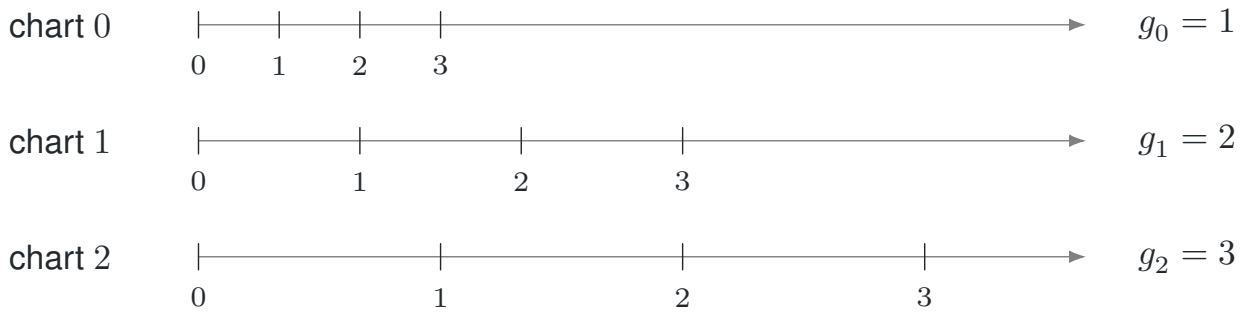
In a triangle product, adjacent intermediate gauges cancel:

$$(G_a \Gamma_{a \leftarrow c} G_c^{-1})(G_c \Gamma_{c \leftarrow b} G_b^{-1})(G_b \Gamma_{b \leftarrow a} G_a^{-1}) = G_a H G_a^{-1}.$$

Only the base gauge survives around the loop. For the additive defect, the surviving outer gauges instead belong to its different source and target fibers.

> **Read this as:** Exact nonvanishing is gauge invariant. The numerical size of a matrix entry or a chosen norm generally is not.

Plate III.15 / MODEL D / A FLAT CONNECTION WITH NONIDENTITY EDGES



Flat is not the same as calibrated

Chapter III, mathematical text: Theorem 6.3

Make all three canonical charts literally identical, so $J_{b\leftarrow a} = 1$ over $\mathbb{Q}$. Choose scalar gauges $g_0 = 1$, $g_1 = 2$, and $g_2 = 3$, and define

$$\Gamma_{b\leftarrow a} = g_b g_a^{-1}.$$

The edge $0 \to 1$ is multiplication by two, although its canonical counterpart is the identity.

$$\Gamma_{1\leftarrow 0} = 2, \quad \Gamma_{2\leftarrow 1} = 3/2, \quad \Gamma_{2\leftarrow 0} = 3$$

The rulers display the chosen gauge scales: the marks are $g_a n$ for integer n. They visualize the supplied scalar factors, not an intrinsic metric. Relative transport is the ratio of the target and source scales.

The route through two steps $0 \to 1 \to 2$ has multiplier $(3/2)2 = 3$, equal to the direct route $0 \to 2$. More generally,

$$(g_c g_b^{-1})(g_b g_a^{-1}) = g_c g_a^{-1}$$

for every triple. Thus this connection is flat and reversible, but it is not calibrated to the original J, whose values are identities.

Recovering the gauge from one root

Choose a base chart o. The theorem constructs

$$G_a = \Gamma_{a\leftarrow o} J_{o\leftarrow a}, \qquad \Gamma_{b\leftarrow a} = G_b J_{b\leftarrow a} G_a^{-1}.$$

With $o = 0$ and $J = 1$, the recovered G_a are exactly $1, 2, 3$. The statement concerns the complete pairwise interface and its cocycle. It is not a topological claim about an arbitrary graph with missing direct comparisons.

> **Read this as:** Flatness makes the chosen transports independent of path. Calibration identifies them with one particular canonical transport before any gauge change.

Plate III.16 / MODEL F / PACKET BLOCKS FROM INPUT TO OUTPUT

Resolve the entire obstruction

Chapter III, mathematical text: Theorem 7.5, Corollary 7.6

Use three coordinate packets with projectors P_0, P_1, P_2, and set

$$H = I + 2E_{01} + 3E_{12}, \qquad \mathrm{Ob} = H - I.$$

Here H is invertible, so it can be the loop product of a reversible connection on three charts. Its entries outside the diagonal encode two effects that mix packets.

H

1	2	0
0	1	3
0	0	1

$\mathrm{Ob} = H - I$

0	2	0
0	0	3
0	0	0

	$\nu = 0$	$\nu = 1$	$\nu = 2$
$\mu = 0$	0	$2E_{01}$	0
$\mu = 1$	0	0	$3E_{12}$
$\mu = 2$	0	0	0

$$\mathrm{Ob}(4,5,6)^{\mathsf{T}} = (10,18,0)^{\mathsf{T}}$$

sum all nine blocks

The board on the right contains all nine actual embedded blocks $P_\mu \,\mathrm{Ob}\, P_\nu$. Row labels are output packets and column labels are input packets. Only the addresses $(0,1)$ and $(1,2)$ carry nonzero maps.

Completeness on both sides supplies the reconstruction:

$$\mathrm{Ob} = (P_0 + P_1 + P_2)\,\mathrm{Ob}\,(P_0 + P_1 + P_2) = \sum_{\mu,\nu} P_\mu \,\mathrm{Ob}\, P_\nu.$$

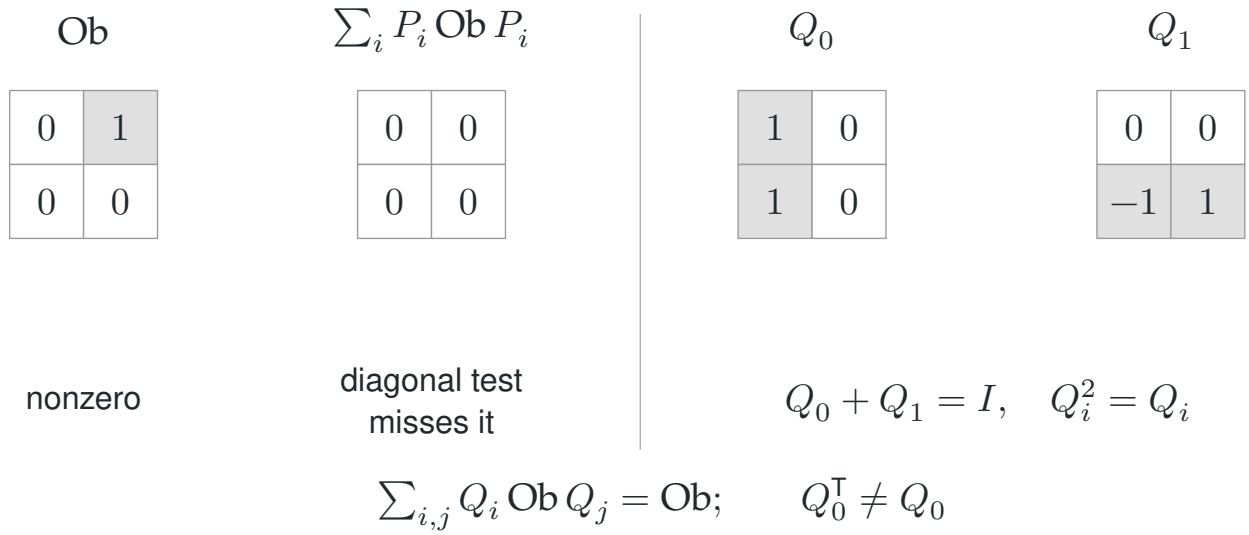
For $x = (4,5,6)^{\mathsf{T}}$, the input in packet 1 contributes $10e_0$ and the input in packet 2 contributes $18e_1$. Their sum is the full displacement $\mathrm{Ob}\, x$.

A block becomes a witness when it acts

The nonzero block $2E_{01}$ has the explicit source vector e_1, supported entirely in packet 1, and $P_0 \,\mathrm{Ob}\, e_1 = 2e_0 \neq 0$. Similarly, $P_1 \,\mathrm{Ob}\, e_2 = 3e_1 \neq 0$. The general theorem supplies such a witness classically when a nonzero block is known. The example displays it concretely.

> **Read this as:** An obstruction packet is not just a colored matrix cell. It consists of a specific label for a pair of packets and an exact nonvanishing statement about the corresponding map.

Plate III.17 / MODEL E / COMPLETENESS, TWO SIDES, AND OBLIQUE PACKETS



Why diagonal checks are insufficient

Chapter III, mathematical text: Theorem 7.5

Return to $\mathrm{Ob} = E_{01}$. With the two standard coordinate projectors, both diagonal blocks vanish:

$$P_0 \,\mathrm{Ob}\, P_0 = P_1 \,\mathrm{Ob}\, P_1 = 0.$$

The obstruction nevertheless survives in the block outside the diagonal $P_0 \,\mathrm{Ob}\, P_1 = E_{01}$.

The test of diagonal blocks alone on the left misses the whole obstruction. On the right, the displayed oblique projectors still form a complete exact resolution. They need not be orthogonal projections for the Euclidean inner product.

There is a second failure mode. Supplying only P_0 gives a family of idempotents but not a complete one. The single tested block is zero, while the omitted packet carries the missing input. The implication "all tested blocks vanish, therefore the operator vanishes" requires the completeness hypothesis.

Exact reconstruction does not require right angles

For the displayed Q_0, Q_1,

$$Q_0 + Q_1 = I, \qquad Q_i^2 = Q_i, \qquad Q_0 Q_1 = Q_1 Q_0 = 0,$$

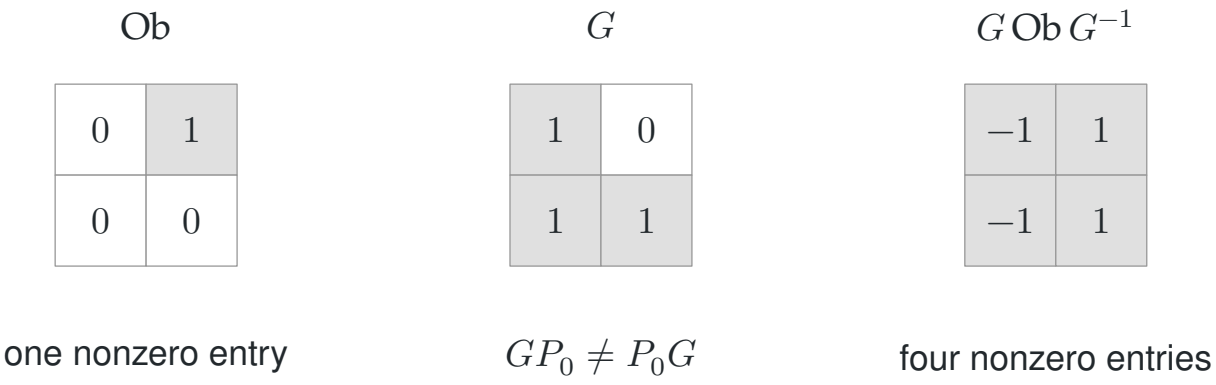
but $Q_0^{\mathsf{T}} \neq Q_0$. Expanding both copies of I still proves

$$\sum_{i,j} Q_i \,\mathrm{Ob}\, Q_j = \mathrm{Ob}\,.$$

The block reconstruction identity itself uses the condition that the projectors sum to the identity. Idempotence is additionally used when constructing a witness that remains supported in one packet after projection. The general formal reconstruction statement does not require pairwise annihilation.

> **Read this as:** Test every block from input to output of a complete resolution. Testing only the diagonal, or only the packets supplied so far, answers a weaker question.

Plate III.18 / MODEL E / FIXED VERSUS TRANSPORTED PROJECTORS



A gauge can move every packet label

Chapter III, mathematical text: Proposition 7.7

The diagonal gauge on Plate III.14 commuted with each standard projector. Now use the gauge that mixes packets

$$G = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \qquad \mathrm{Ob} = E_{01}.$$

The total obstruction transforms by conjugation, but its pattern in the *fixed* standard packets changes.

The first obstruction has one nonzero entry. Its conjugate has four. Both have rank one and are nonzero. The change in fixed block pattern is not a change in whether the connection is flat.

Direct multiplication gives

$$G\,\mathrm{Ob}\,G^{-1} = \begin{pmatrix} -1 & 1 \\ -1 & 1 \end{pmatrix}.$$

For example, the original $(0,0)$ block vanishes, while the new $(0,0)$ block relative to the old coordinate projectors does not. This is why the theorem about preservation of each block's zero status requires $GP_i = P_iG$.

Transporting the packet frame as well

Define $Q_i = GP_iG^{-1}$. Then the identities cancel exactly:

$$Q_i(G\,\mathrm{Ob}\,G^{-1})Q_j = G(P_i\,\mathrm{Ob}\,P_j)G^{-1}.$$

Relative to these transported packets, the corresponding labeled blocks again have matching vanishing status. These are the same oblique projectors displayed on Plate III.17. One must distinguish moving the operator alone in a fixed resolution from moving the entire resolved description.

> **Read this as:** The total obstruction is intrinsic under gauge. Its location in a fixed packet grid is not, unless the gauge preserves that grid.

Plate III.19 / MODEL G / THE QUANTIFIERS ARE THE CONTENT

An obstruction rejects one candidate

Chapter III, mathematical text: Theorem 7.2

Let the candidates be rational numbers and the packet labels be $0, 1$. Define

$$r(x, 0) = x^2 - 1, \qquad r(x, 1) = x - 1.$$

A candidate is a solution when both residuals vanish. The five candidate columns below are a display of this explicit residual function, not a search over an unspecified class.

candidate x	-2	-1	0	1	2
$r(x, 0) = x^2 - 1$	3	0	-1	0	3
$r(x, 1) = x - 1$	-3	-2	-1	0	1
	rejected	rejected	rejected	solution	rejected

$$x = -1 : \quad r(-1, 0) = 0, \quad r(-1, 1) = -2$$

A shaded cell is a nonzero exact residual. At $x = -1$, the first equation passes but the second supplies an obstruction. At $x = 1$, both pass. The rejected candidate does not obstruct the successful one.

The statement proved by the generic certificate has the form

$$\neg(\forall p,\ r(x, p) = 0) \quad \Longleftrightarrow \quad \exists p,\ r(x, p) \neq 0.$$

The same candidate x appears on both sides. A certificate consists of the packet label and its nonvanishing proof. The general converse uses classical reasoning and does not itself provide an algorithm to find the label.

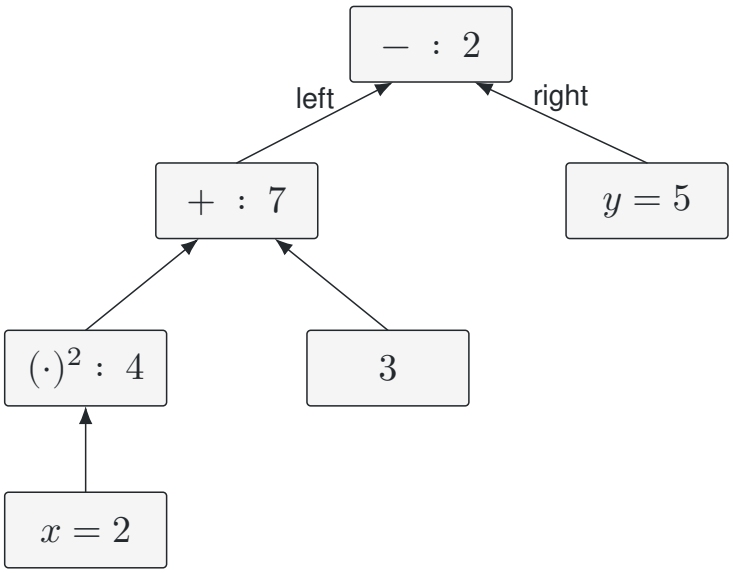
What would be required to rule out all solutions?

One would need the stronger assertion $\forall x \exists p,\ r(x, p) \neq 0$. The value $x = 1$ disproves that assertion in this example. A witness for $x = -1$ supplies no evidence for it. Likewise, finding an obstruction block for one triangle of one chosen connection does not classify every possible connection.

The term *obstruction* in this generic interface does not automatically mean a cokernel class, a cohomology group, a norm bound, or a minimal certificate. Those require additional constructions and theorems.

> **Read this as:** Keep the candidate attached to the witness. The theorem's strength is its exact logical scope, not a universal existence or nonexistence claim.

Plate III.20 / MODEL H / ACTUAL SYNTAX, ARBITRARY SEMANTICS



A tree reads its named leaves

Chapter III, mathematical text: Definition 11.1, Theorem 11.2

Use the grammar's constant, input, unary, and binary constructors to build

$$t = (x^2 + 3) - y.$$

Here "square," "add," and "subtract" are explicitly supplied meanings of operation symbols. At $x = 2, y = 5$, every node value can be evaluated exactly.

$\text{inputs}(t) = \{x, y\}$

unused input: -100 or 100

same value: 2

$x - x : \{x\}$ syntactically

but always zero

The rooted tree records the order of input slots. Arrows indicate evaluation from children to parent, not chart transport. An environment may contain additional variables, but this tree does not read them.

The input set is $\text{inputs}(t) = \{x, y\}$. If two environments agree at x and y, structural induction proves that the two evaluations agree: input leaves agree, constants agree, and every parent applies the same supplied operation to equal child values.

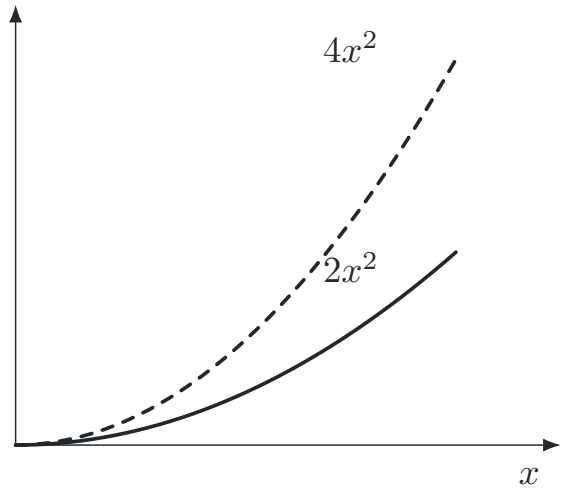
Syntactic locality is not minimal dependence

The tree $x - x$ has input set $\{x\}$, although its value is always zero under ordinary subtraction. Locality provides a sufficient agreement condition. It does not compute the smallest set of semantically relevant variables. Nor does it prove that two different trees are equivalent.

The semantics may act on arbitrary values. For example, a binary concatenation symbol applied to strings "ab" and "cd" gives "abcd." No linearity or differentiability is required. Conversely, swapping the ordered inputs of the subtraction root above changes the value from 2 to -2.

> **Read this as:** The proved tree theorem controls which input labels are read. It does not supply a nonlinear chain rule, a stability estimate, or a solution of a tree equation.

Plate III.21 / MODEL H / EXACT COORDINATES VERSUS A CHOSEN RULE



Where a nonlinear defect can enter

Chapter III, mathematical text: Proposition 10.1, Formalization target 11.7, Theorem 20.2

Take the unary operation $f(x) = x^2$ over $\mathbb{Q}$. Suppose both input and output transport are chosen as multiplication by two, while the same numerical formula f is reused at the target. The two routes give

$$2f(x) = 2x^2, \qquad f(2x) = 4x^2.$$

Their difference is $-2x^2$, which is generally nonzero.

x	0	1	2
$2f(x)$	0	2	8
$f(2x)$	0	4	16
$2f(x) - f(2x)$	0	-2	-8

correct chart formula: $f_b(v) = v^2/2$

Solid: $2x^2$. Dashed: $4x^2$. The curves are a real visualization of exact polynomial formulas. The table contains exact evaluations over the rationals. The mismatch is caused by the specified combination of transport and formula.

For a canonical coordinate change with input and output chart $v = 2x$, the target formula is not still v^2. It is

$$\hat{f}_b(v) = 2f(v/2) = \frac{v^2}{2}.$$

Consequently $\hat{f}_b(2x) = 2x^2$, and the exact coordinate defect vanishes. This is the same distinction illustrated in the example in two dimensions on Plate III.10.

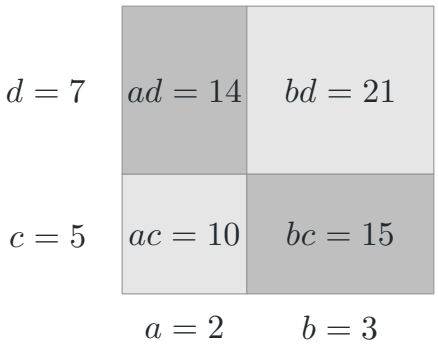
An example is not a general propagation theorem

The polynomial calculation here is exact and checked symbolically. It explains a chosen node defect, while the mathematical text develops composition identities, iterated defects, fixed point stability, and derivative defects under explicit hypotheses. Those broader ordinary proofs must be read on their own terms. This one example and the finite Lean locality theorem do not certify them.

> **Read this as:** A nonzero nonlinear route difference must come from identifiable extra data: a changed transport, an approximation, a restricted model, or a reused formula that was not conjugated correctly.

Plate III.22 / FINITE EXAMPLES / WHY MULTILINEARITY MATTERS

Mixed terms are not optional



Chapter III, mathematical text: Formalization target 11.6, Theorem 18.3

A bilinear node distributes over two independently resolved inputs:

$$(a+b)(c+d) = ac + ad + bc + bd.$$

The four terms correspond to all ordered choices of one input packet from each slot. Keeping only matching packet labels loses the mixed terms.

$$(2+3)(5+7) = 60$$

Diagonal pieces are not the whole product

$$ac + bd = 10 + 21 = 31$$

$$ad + bc = 14 + 15 = 29$$

$$(2+3)^2 = 25 \neq 2^2 + 3^2 = 13$$

missing square term: $2 \cdot 2 \cdot 3 = 12$

The rectangle has width $2 + 3$ and height $5 + 7$, with differently scaled horizontal and vertical display units. Each cell is labeled by its actual product. The lighter diagonal pair contributes only 31 of the total 60.

For a unary square, inserting $a+b$ does not give a^2+b^2. The extra $2ab$ arises because the operation is nonlinear in its single argument. It can be analyzed by representing the square using a binary multiplication node with a repeated input, but that is an additional choice of syntax and semantics.

The broader tree theorem needs its hypotheses

General packet tree expansion needs correctly typed input slots, finite sets of packet labels at each node, and multilinearity in every slot used for distributive expansion. Empty inputs and unary nodes need explicit conventions. Slot order must survive even when values or operations do not commute. The mathematical text supplies rooted tree reconstruction and pruning results in its ordinary mathematical development.

This page supplies elementary exact examples of the issue. The finite algebraic Lean contract remains narrower: it contains syntactic input locality, not the general dependent tree expansion or the mathematical text's analytic convergence results.

Read this as: A branching picture does not justify throwing away mixed interactions. Exact packet expansion requires the appropriate multilinearity and typing, not merely a diagram that appears finite.

Plate III.23 / CAPSTONE / A COMPLETE FINITE DIAGNOSIS

From loop data to a packet witness

Chapter III, mathematical text: Theorem 5.10, Theorem 6.2, Corollary 7.6

Supply a reversible connection on three copies of $\mathbb{Q}^2$ by choosing

$$\Gamma_{1\leftarrow 0} = A, \qquad \Gamma_{2\leftarrow 1} = B, \qquad \Gamma_{2\leftarrow 0} = C = I,$$

and declaring every reverse edge to be the inverse. This time both nontrivial forward matrices are retained.

A

1	1
0	1

B

1	0
1	1

$H = BA$

1	1
1	2

$H - I$

0	1
1	1

$$e_0 = (1,0) \;\mapsto\; (1,0) \;\mapsto\; (1,1) \;\mapsto\; (1,1)$$

$$P_1(H - I)e_0 = e_1 \neq 0$$

---

replace direct edge $C = I$ by $C = BA$: then $C^{-1}BA = I$

The vector row starts with the source witness e_0 and follows it through A, then B, then C^{-1}. Returning to the base produces $(1,1)^{\mathsf{T}}$, whose displacement from the input is e_1.

The calculation gives

$$\Delta = BA - C = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}, \qquad H = C^{-1}BA = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}.$$

Choose the standard packet projectors. The $(1,0)$ block is nonzero, and the explicit candidate vector satisfies $P_1(H - I)e_0 = e_1$. This proves nonflatness of the supplied connection at the supplied triangle.

Repairing data is not the same as changing gauge

Replacing the direct map $C = I$ by $C = BA$, and updating its reverse, makes the new loop equal to I. That changes the connection. It cannot be a gauge of the original nonflat connection, because gauge preserves whether holonomy is the identity. For this complete example on three charts all cocycles then hold. Changing one edge in a larger network would require checking the other affected loops as well.

> **Read this as:** Declare the data, multiply in traversal order, form the defect, resolve all blocks, and exhibit an input on which one block acts nontrivially. Each step has a checkable mathematical object.

Plate III.24 / EVIDENCE / EXAMPLES, PROOFS, AND FORMAL SCOPE

Read the evidence with the pictures

Chapter III, mathematical text: Section 12

The 24 worked plates and 22 exact figures connect finite models with the main text's broader nonlinear and analytic theory.

Read each evidence record in its scope

Evidence	What it supports
Formal development	The finite declarations and the additions in Sections 16 and 17 were compiled in the pinned environment. The Lean guide records the source scope, axiom audit, and kernel replay.
Ordinary mathematics	The mathematical text's expanded proofs, including nonlinear, obstruction, lifting, and smooth transport results. Inclusion in that text does not add these results to the finite Lean contract.
Exact model checks	The recorded run passed all 124 exact checks and rejected all four deliberately false controls. The scope is the displayed finite matrices, paths, polynomials, candidate tables, and trees.
Figure regeneration	All 22 editable TikZ figures are supplied with their exact model data and generators. The original figure sources and their earlier regeneration record remain preserved.

The computation record also contains 18,630 exact assertions for the examples in Sections 16 and 17. These finite calculations support the displayed mechanisms. General claims rest on their mathematical proofs and, where mapped, their Lean declarations.

Boundaries that remain in force

The formal edge system uses a single scalar coefficient semiring. The heterogeneous path theorem for arbitrary lengths uses a common packet index, with forms allowing changing types for two and three factors. General dependent tree expansion and analytic convergence lie outside this finite formal contract. The mathematical text states and proves its broader results with their own hypotheses.

The generic obstruction theorem rejects its named candidate. A nonzero holonomy block rejects flatness for its named loop data. Neither conclusion supplies a universal classification, a new arithmetic realization, or an algorithmic search guarantee.

Replay the worked layer

Check the exact examples with `python checks/verify_examples.py`.

Regenerate the figures with `python source/generate_graphics.py`.

Use a temporary copy to preserve the recorded evidence. The finite algebraic source distribution supplies the formal sources separately.

> **Read this as:** Use the figures to understand the mechanisms, the mathematical text to read the mathematical proofs, and the Lean guide to identify the exact formal contract. These are related records with distinct scopes.

CHAPTER IV

Projector Resolved Seed Calculus IV

Cyclic analytic functions, reciprocal families, and spectral zero data

The focus shifts from the general packet language to a particular analytic family.

A cyclic analytic family connects coefficient selection, differential transport, reciprocal polynomials and spectral zero data.

IN THIS CHAPTER

Mathematical text 280

Visual studies 355

Formal companion 1815

Sources and references 2672

Scope

The analytic statements retain their branch choices, multiplicities and integer-order hypotheses. Universal zero simplicity and a zeta functional equation remain outside these results.

The next chapter turns to signals, where filters, packet trees and reconstruction make changes of resolution concrete.

How to use this volume

Begin with cyclic projection and the signed differential cycle. The reciprocal sections then build parameter polynomials, Appell systems, and theta polynomials from a unit series. The second half follows the same denominator through large zero geometry, canonical products, and zero zeta functions.

The visual atlas at the end of this chapter supplies twenty-six worked plates. The companion Lean guide follows the formal declarations and their hypotheses. The main text contains sixty-eight theorem-like results and ninety-five numbered records.

Overview

Fix a positive integer N. Root of unity projection of the exponential produces residue-class sections that, for $\lambda \neq 0$, form a basis for $y^{(N)} = \lambda^N y$. The signed sections for $y^{(N)} = -y$ yield the denominator D_N and its reduced form Δ_N. We derive reciprocal coefficient polynomials, Bell and Newton recurrences, an additive parameter law, and residue section Appell and theta families. For $N \geq 2$, Δ_N has order $1/N$. We specialize classical two term zero theory for exponential sums to the regular exponent polygon. In this equal-weight family, conjugation symmetry combined with unique near-model localization places all sufficiently large zeros exactly on the symmetry rays, and direct expansion gives their leading displacement and derivative sign. The classical perimeter law yields zero-counting asymptotics with explicit leading constants and bounded error. These results give genus-zero products, the standard diagonal Fredholm representation, zero-power-sum formulas for reciprocal and logarithmic coefficients, nearest-zero coefficient asymptotics, and meromorphic continuation of the symmetry-orbit zero zeta by comparison with the Hurwitz zeta function. Complex powers are interpreted either formally or through a fixed logarithm on a zero-free domain. This chapter treats only this cyclic analytic family. Arithmetic interpolation, general nonlinear trees, general resolvent theory, and abstract completion are reserved for Chapters IX, III, VI, and X.

Formal scope and evidence

The recorded formal contract covers all sixty-eight theorem-like manuscript results under their stated hypotheses. The formalization ledger identifies the corresponding declarations.

Imported standard fact 11.1 is used in the ordinary manuscript growth argument. The Lean growth-order proofs establish that step separately. Open questions, branch choices, multiplicities, and the hypotheses of coefficient asymptotics remain explicit. Finite computations support the worked models. The companion Lean guide records the replay using pinned sources, declaration-kind checks, axiom audit, and their limits.

1 Introduction

For a power series

$$F(z) = \sum_{m \geq 0} a_m z^m$$

and a positive integer N, the coefficients may be separated according to the residue of m modulo N. Root of unity averaging gives exact projection operators for this separation. This elementary construction is usually called a multisection or a root filter. It appears throughout the classical theory of generating functions and special functions. Background on multisections, hypergeometric functions, and related coefficient systems may be found in [Rai60, AAR99, Com74].

Chapters I and II developed typed seed grammars, exact projector packets, and finite residue-projector algebra, while Chapter III treated typed edge operators and exact coordinate transport [P.26a, P.26b, P.26c]. The root filter used below is the finite cyclic scalar specialization of that earlier projector calculus. The signed companion matrix is likewise a concrete cyclic instance, not a replacement for Chapter III's general typed-edge theory.

This chapter follows the consequences of applying the cyclic projections to the exponential function. The projected exponentials form a finite differential system. After one sign is inserted around the derivative cycle, they form a basis for

$$y^{(N)} = -y.$$

The section with initial value one is

$$\mathsf{D}_N(z) = \sum_{n \geq 0} (-1)^n \frac{z^{Nn}}{(Nn)!}.$$

Its reciprocal powers produce polynomial coefficient families. Its logarithmic derivative produces a scalar higher Riccati identity. The same reciprocal construction applied to every exponential section gives normalized residue section functions and ordinary Appell polynomial sequences. These cyclic exponential sections and their matrix addition laws belong to the generalized hyperbolic function literature [Sch92, Mul05]. Appell and binomial-type sequences are discussed in [Rom84, Com74].

The second half of this chapter concerns the zeros of D_N. The finite exponential sum

$$\mathsf{D}_N(z) = \frac{1}{N} \sum_{\eta^N = -1} e^{\eta z}$$

has a regular polygon of exponents. The general relation between an exponent polygon and the zero strips of an exponential sum goes back to Pólya and Langer. Later developments include the work of Moreno and the treatment in Levin's monograph [Pól20, Lan31, Mor73, Lev80]. Bleher and Mallison give a particularly close general result: for convex-polygon exponential sums they locate all sufficiently large zeros in two term strips and prove exponential localization and simplicity [BM06]. The regular polygon and conjugation symmetry of the present family specialize that theory to N exact rays. We give a self-contained specialization because its notation is used throughout the product and zeta theory, and we compute the leading displacement term for this family. The resulting counting formulas have explicit leading constants and bounded error.

The rotational symmetry is more useful after the change of variable $w = z^N$. There is an entire function

$$\Delta_N(w) = \sum_{n\geq 0}(-1)^n \frac{w^n}{(Nn)!}$$

with

$$\mathsf{D}_N(z) = \Delta_N(z^N).$$

For $N \geq 2$, the order of Δ_N is $1/N$. Its Hadamard product therefore has genus zero. The logarithm of this product identifies the transfer tangent coefficients with power sums of the reduced zeros. The large zero formula also compares the reduced zero zeta with a Hurwitz zeta function. Standard material on entire functions, canonical products, and exponential sums appears in [Boa54, Lev80, Tit39]. We use singularity analysis in the form described in [FS09] and the classical continuation of the Hurwitz zeta function from [Apo76].

The cyclic exponential sections and their matrix addition laws have a classical literature. The tools used below include Appell and binomial-type sequences, canonical products, singularity analysis, and Fredholm determinants. These tools are also standard. Our aim is to organize this symmetric specialization and link its reciprocal coefficients to reduced-zero data. No historical priority is asserted for the component constructions.

2 A map of the construction

The central idea

The same object is read in different coordinates. Selecting residues makes its Taylor coefficients visible. A signed shift makes the differential system finite. Passing to $w = z^N$ removes rotational repetition from its zeros. The formulas below identify these descriptions under their stated hypotheses.

Two variables appear throughout this chapter. The variable z carries the differential equation and the rotational symmetry. The reduced variable

$$w = z^N$$

records one representative from each rotational orbit. Confusing these variables hides the main simplification. The denominator D_N has order one as a function of z, while Δ_N has order $1/N$ as a function of w.

The analytic objects are introduced in the following order. First,

$$\mathsf{E}_{N,j}(z) = \sum_{n\geq 0} \frac{z^{Nn+j}}{(Nn+j)!}$$

is the residue j part of the exponential. Second,

$$\mathsf{D}_{N,j}(z) = \sum_{n\geq 0}(-1)^n \frac{z^{Nn+j}}{(Nn+j)!}$$

is the signed basis for $y^{(N)} = -y$. The section $\mathsf{D}_N = \mathsf{D}_{N,0}$ is the denominator used in the reciprocal family

$$\mathsf{S}_N^{(r)} = \mathsf{D}_N^{-r}.$$

Set $\mathsf{T}_N = -\mathsf{D}_N'/\mathsf{D}_N$. Equivalently, T_N is the logarithmic derivative of $\mathsf{S}_N^{(1)}$.

A different reciprocal family comes from normalizing each exponential section at the origin. The function

$$\mathsf{C}_{N,j}(z) = \frac{z^j/j!}{\mathsf{E}_{N,j}(z)}$$

is a unit series in z^N. Its powers, after multiplication by e^{xz}, give Appell polynomials. The theta family couples a scaled argument with a reciprocal order.

The zero theory begins only after these algebraic relations have been established. The factorization

$$\mathsf{D}_N(z) = \Delta_N(z^N)$$

turns every orbit of N zeros in the z plane into one zero in the w plane. The large zeros in the z plane are located by two dominant exponentials. The zeros in the w plane then give a genus zero product. The logarithm of that product returns to the coefficient theory through

$$\text{zero power sums} = \text{logarithmic coefficients}.$$

This equality is the bridge between the first and second halves of this chapter.

All powers with a complex parameter are first defined as formal series at the origin. To represent this germ analytically, use a simply connected zero-free region containing the origin and the logarithm normalized to vanish there. On other regions, specify a branch separately. Integer reciprocal powers are globally meromorphic and do not require a branch choice.

The main statements fall into five groups. The finite algebra model in section 6 explains the derivative cycles and addition laws through one exponential identity. The coefficient theory in section 7 gives two complementary recurrences, one from the original denominator and one from its logarithm. The Appell theory in section 9 supplies both formal differential-operator formulas and a convolution law in the space and order parameters. The zero analysis in section 11 specializes classical two term exponential-sum theory, uses symmetry to place the uniquely localized large zeros on the rays, and computes a leading correction. The product theory in section 12 gives the standard diagonal Fredholm encoding of the genus zero product.

This chapter keeps formal and analytic statements separate. A formal identity needs only the unit constant term of the relevant series. A holomorphic complex power also needs a zero-free domain and a chosen logarithm. A meromorphic coefficient asymptotic is stated only for positive integral reciprocal order unless an additional branch domain is specified.

Part I Cyclic resolution and differential transport

3 Cyclic projection of analytic functions

A route through this section

The root filter asks which coefficient addresses belong to a packet. It is an exact selector. Multiplication then asks how two selected packets interact. Their residue labels add modulo N, so mixed inputs remain part of the product.

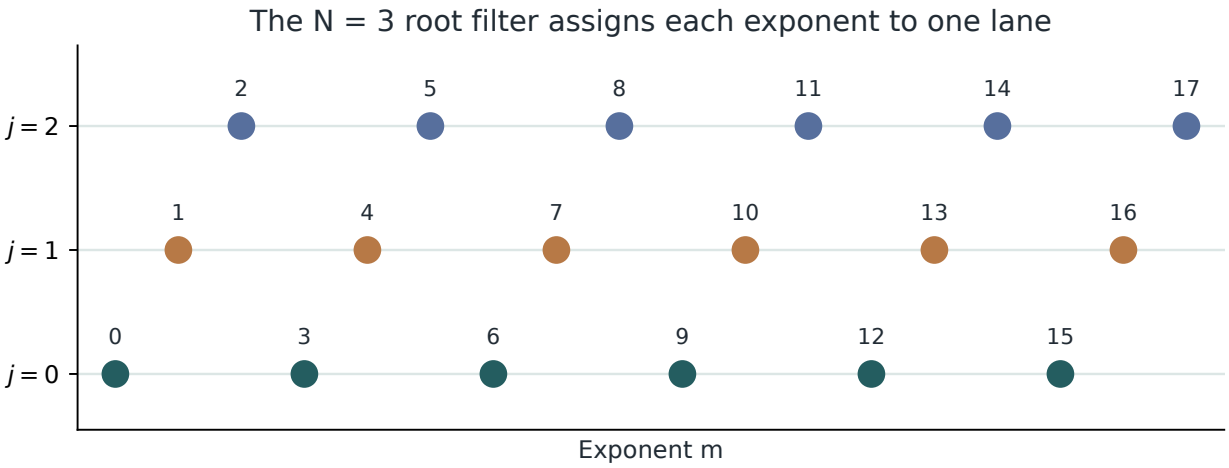


Figure 1. An exact address model for $N = 3$. Every displayed exponent belongs to one residue lane. The drawing records labels rather than coefficient magnitudes.

Fix $N \geq 1$ and write

$$\omega = e^{2\pi i/N}.$$

Let Ω be a disk centered at the origin, with the whole plane allowed, and assume that Ω is invariant under multiplication by ω. For a holomorphic function F on Ω, define

$$(\mathcal{B}_{N,j}F)(z) = \frac{1}{N}\sum_{\ell=0}^{N-1} \omega^{-j\ell} F(\omega^{\ell} z), \qquad 0 \leq j < N.$$

The same formula is valid for formal power series.

Theorem 3.1 (Root filter). *If*

$$F(z) = \sum_{m \geq 0} a_m z^m,$$

then

$$\mathcal{B}_{N,j}F(z) = \sum_{m \equiv j \bmod N} a_m z^m.$$

The operators satisfy

$$\mathcal{B}_{N,i}\mathcal{B}_{N,j} = \delta_{ij}\mathcal{B}_{N,j}$$

and

$$\sum_{j=0}^{N-1} \mathcal{B}_{N,j} = I.$$

Proof. Substitution of the power series gives

$$\mathcal{B}_{N,j}F(z) = \sum_{m \geq 0} a_m z^m \left(\frac{1}{N} \sum_{\ell=0}^{N-1} \omega^{(m-j)\ell} \right).$$

The inner average is one when $m \equiv j \bmod N$ and zero otherwise. The operator identities follow from the disjoint residue classes. □

Proposition 3.2 (Covariance characterization)**.** *A holomorphic function F belongs to the range of $\mathcal{B}_{N,j}$ if and only if*

$$F(\omega z) = \omega^j F(z).$$

Proof. Every monomial selected by $\mathcal{B}_{N,j}$ has the stated covariance. Conversely, write $F = \sum_k \mathcal{B}_{N,k}F$. Replacing z by ωz gives

$$\sum_k \omega^k \mathcal{B}_{N,k}F = \omega^j \sum_k \mathcal{B}_{N,k}F.$$

Application of $\mathcal{B}_{N,k}$ gives

$$(\omega^k - \omega^j)\mathcal{B}_{N,k}F = 0.$$

The powers $1, \omega, \ldots, \omega^{N-1}$ are distinct, so $\mathcal{B}_{N,k}F = 0$ for $k \neq j$. □

Multiplication is not diagonal in these coordinates. The residue labels add modulo N. This is the scalar cyclic instance of the packet product from Chapter I.

Theorem 3.3 (Cyclic product law)**.** *If F and G are holomorphic on the same rotation-invariant domain, then*

$$\mathcal{B}_{N,k}(FG) = \sum_{\substack{0 \leq i,j < N \\ i+j \equiv k \bmod N}} (\mathcal{B}_{N,i}F)(\mathcal{B}_{N,j}G).$$

Proof. Write $F = \sum_i F_i$ and $G = \sum_j G_j$, where $F_i = \mathcal{B}_{N,i}F$ and $G_j = \mathcal{B}_{N,j}G$. Their covariance gives

$$(F_i G_j)(\omega z) = \omega^{i+j} F_i(z) G_j(z),$$

so $F_i G_j$ belongs to the packet labeled by $i + j$ modulo N. Expanding the finite product and applying $\mathcal{B}_{N,k}$ gives the formula. □

Remark 3.4. Every identity in this section holds formally. In the holomorphic setting, the finite projector sums preserve local uniform convergence. No choice of branch is involved.

4 The transfer exponential basis

Definition 4.1. For $\lambda \in \mathbb{C}$ and $0 \le j < N$, define

$$\mathsf{E}_{N,j}(\lambda z) = \mathcal{B}_{N,j}(e^{\lambda z}) = \sum_{n \ge 0} \frac{(\lambda z)^{Nn+j}}{(Nn+j)!}.$$

Theorem 4.2 (Differential cycle and initial data)**.** *For $1 \le j < N$,*

$$\frac{d}{dz}\mathsf{E}_{N,j}(\lambda z) = \lambda \mathsf{E}_{N,j-1}(\lambda z),$$

while

$$\frac{d}{dz}\mathsf{E}_{N,0}(\lambda z) = \lambda \mathsf{E}_{N,N-1}(\lambda z).$$

Thus

$$\frac{d^N}{dz^N}\mathsf{E}_{N,j}(\lambda z) = \lambda^N \mathsf{E}_{N,j}(\lambda z).$$

For $0 \le k < N$,

$$\frac{d^k}{dz^k}\mathsf{E}_{N,j}(\lambda z)\Big|_{z=0} = \delta_{kj}\lambda^j.$$

If $\lambda \neq 0$, the N functions $\mathsf{E}_{N,j}(\lambda z)$ form a basis of the solution space of $y^{(N)} = \lambda^N y$.

Proof. Termwise differentiation gives the cyclic derivative formulas. One full cycle contributes λ^N. The first nonzero term of $\mathsf{E}_{N,j}(\lambda z)$ is $(\lambda z)^j/j!$, which gives the initial data. The initial value vectors are linearly independent when $\lambda \neq 0$. The solution space of an order N constant coefficient equation has dimension N, so these functions form a basis. □

Corollary 4.3 (Wronskian of the transfer basis)**.** *Assume $N \ge 2$. For $\lambda \neq 0$, the Wronskian of the ordered basis*

$$\mathsf{E}_{N,0}(\lambda z), \dots, \mathsf{E}_{N,N-1}(\lambda z)$$

is the constant

$$\lambda^{N(N-1)/2}.$$

Proof. At the origin, the derivative matrix is diagonal with entries

$$1, \lambda, \dots, \lambda^{N-1}.$$

For an explicit determinant proof, write each basis function as a finite sum of exponentials with exponents $a_\ell = \lambda\omega^\ell$. Its derivative matrix factors as

$$W(z) = V\ \mathrm{diag}(e^{a_\ell z})\, C, \qquad V_{k\ell} = a_\ell^k,$$

where C is the constant matrix of Fourier weights. Thus

$$\det W(z) = e^{z\sum_\ell a_\ell} \det W(0) = \det W(0),$$

because $N \geq 2$ implies $\sum_{\ell} \omega^{\ell} = 0$. The product of the diagonal initial values is the stated power of λ. □

Corollary 4.4 (Addition law)**.** *For* $0 \leq k < N$,

$$\mathsf{E}_{N,k}(\lambda(z+w)) = \sum_{\substack{0 \leq i,j < N \\ i+j \equiv k \bmod N}} \mathsf{E}_{N,i}(\lambda z)\mathsf{E}_{N,j}(\lambda w).$$

Proof. Expand $e^{\lambda(z+w)} = e^{\lambda z}e^{\lambda w}$ as a bivariate power series. A term $z^a w^b$ contributes to the kth section exactly when $a + b \equiv k \bmod N$. Grouping first by $i \equiv a \bmod N$ and $j \equiv b \bmod N$ gives the displayed sum. □

The basis also has a scalar hypergeometric form.

Theorem 4.5 (Hypergeometric form)**.** *Let*

$$A_{N,j} = \left\{ \frac{j+m}{N} : 1 \leq m \leq N \text{ and } j+m \neq N \right\}.$$

Then

$$\mathsf{E}_{N,j}(\lambda z) = \frac{(\lambda z)^j}{j!} {}_0F_{N-1}\left(\begin{matrix} - \\ A_{N,j} \end{matrix} , \frac{(\lambda z)^N}{N^N} \right).$$

Proof. The multiplication formula for the gamma function gives

$$(Nn+j)! = j! N^{Nn} n! \prod_{a \in A_{N,j}} (a)_n.$$

Indeed, the N Pochhammer factors supplied by the multiplication formula are $((j+m)/N)_n$ for $1 \leq m \leq N$. The excluded factor is $((j+N-j)/N)_n = (1)_n = n!$. Insertion into the defining series gives the stated hypergeometric expansion. □

Example 4.6. For $N = 1$, the only section is $e^{\lambda z}$. For $N = 2$,

$$\mathsf{E}_{2,0}(z) = \cosh z, \qquad \mathsf{E}_{2,1}(z) = \sinh z.$$

These are classical instances of the same cyclic basis.

5 Signed cyclic sections and the distinguished denominator

Definition 5.1. For $0 \leq j < N$, define

$$\mathsf{D}_{N,j}(z) = \sum_{n \geq 0} (-1)^n \frac{z^{Nn+j}}{(Nn+j)!}.$$

The distinguished signed denominator is

$$\mathsf{D}_N(z) = \mathsf{D}_{N,0}(z).$$

Fix any $\rho \in \mathbb{C}$ with $\rho^N = -1$.

Proposition 5.2 (Relation with the transfer exponential)**.** *For every j,*

$$\mathsf{D}_{N,j}(z) = \rho^{-j}\mathsf{E}_{N,j}(\rho z).$$

Proof. The coefficient of z^{Nn+j} on the right is

$$\rho^{-j}\rho^{Nn+j}\frac{1}{(Nn+j)!} = (-1)^n\frac{1}{(Nn+j)!}.$$

□

Theorem 5.3 (Signed derivative cycle)**.** *For $1 \le j < N$,*

$$\mathsf{D}'_{N,j} = \mathsf{D}_{N,j-1},$$

and

$$\mathsf{D}'_{N,0} = -\mathsf{D}_{N,N-1}.$$

Every signed section satisfies

$$\mathsf{D}^{(N)}_{N,j} = -\mathsf{D}_{N,j}.$$

The N signed sections form the basis of $y^{(N)} = -y$ determined by

$$\mathsf{D}^{(k)}_{N,j}(0) = \delta_{jk}$$

for $0 \le j, k < N$.

Proof. The derivative formulas follow directly from the series. The first nonzero term of $\mathsf{D}_{N,j}$ is $z^j/j!$, so the initial value matrix is the identity. The basis statement follows from the dimension of the solution space. □

Corollary 5.4 (Wronskian of the signed basis)**.** *Assume $N \ge 2$. The Wronskian of*

$$\mathsf{D}_{N,0}(z), \dots, \mathsf{D}_{N,N-1}(z)$$

is one.

Proof. The derivative matrix at the origin is the identity. The determinant factorization in the proof of corollary 4.3 applies with $a_\ell = \rho\omega^\ell$ and with the signed-section Fourier weights. Since $\sum_\ell a_\ell = 0$, the determinant is constant and equals one. □

Proposition 5.5 (Twisted addition law)**.** *For $0 \le k < N$,*

$$\mathsf{D}_{N,k}(z+w) = \sum_{\substack{0 \le i,j < N \\ i+j \equiv k \bmod N}} (-1)^{\lfloor (i+j)/N \rfloor}\mathsf{D}_{N,i}(z)\mathsf{D}_{N,j}(w).$$

Proof. Use proposition 5.2 and corollary 4.4. The factor introduced by a pair (i, j) is

$$\rho^{i+j-k}.$$

Since $0 \le i+j \le 2N-2$ and $i+j \equiv k \bmod N$, this factor is one when $i+j=k$ and -1 when $i+j=k+N$. □

Theorem 5.6 (Finite exponential representation)**.** *Let*

$$\mathcal{R}_N = \{\eta \in \mathbb{C} : \eta^N = -1\}.$$

Then

$$\mathsf{D}_N(z) = \frac{1}{N} \sum_{\eta \in \mathcal{R}_N} e^{\eta z}.$$

More generally,

$$\mathsf{D}_{N,j}(z) = \frac{\rho^{-j}}{N} \sum_{\ell=0}^{N-1} \omega^{-j\ell} e^{\rho\omega^\ell z}.$$

Proof. The second formula is the root filter expression for $\rho^{-j}\mathsf{E}_{N,j}(\rho z)$. The first is the case $j=0$. □

Definition 5.7. Define the reduced denominator

$$\Delta_N(w) = \sum_{n \ge 0} (-1)^n \frac{w^n}{(Nn)!}.$$

Then

$$\mathsf{D}_N(z) = \Delta_N(z^N).$$

Corollary 5.8 (Symmetries)**.** *The denominator satisfies*

$$\mathsf{D}_N(\omega z) = \mathsf{D}_N(z)$$

and

$$\mathsf{D}_N(\overline{z}) = \overline{\mathsf{D}_N(z)}.$$

Its nonzero zeros occur in orbits under multiplication by the Nth roots of unity and under complex conjugation.

Proof. The first identity follows from the powers z^{Nn}. The second follows from the real coefficients. Both symmetries preserve the zero set and multiplicity. □

Example 5.9. The first denominators are

$$\mathsf{D}_1(z) = e^{-z}, \qquad \mathsf{D}_2(z) = \cos z.$$

For $N=3$,

$$\mathsf{D}_3(z) = \frac{1}{3}\left(e^{-z} + 2e^{z/2}\cos\left(\frac{\sqrt{3}z}{2}\right)\right).$$

For $N=4$,

$$\mathsf{D}_4(z) = \cos\left(\frac{z}{\sqrt{2}}\right)\cosh\left(\frac{z}{\sqrt{2}}\right).$$

6 A finite algebra and matrix model

The central idea

The signed shift is a finite carrier for the differential cycle. At order four, three basis steps have coefficient one and the final step has coefficient minus one. Four steps return the vector with reversed sign. The matrix exponential packages every finite path length in one analytic expression.

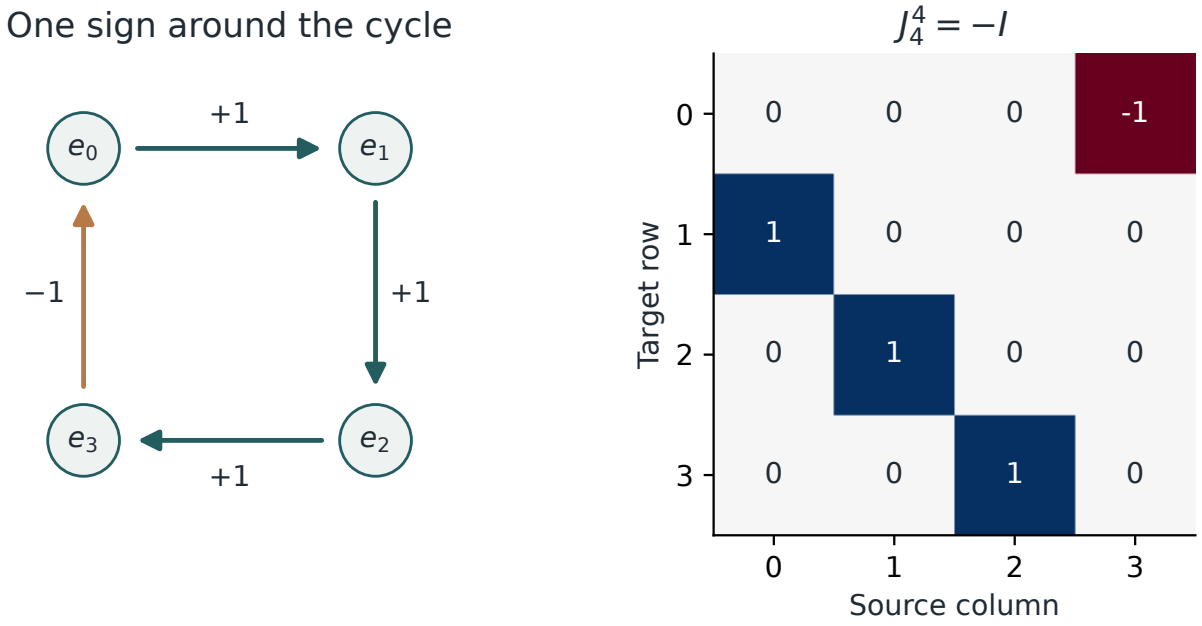

Figure 2. The exact signed shift J_4. Source columns and target rows describe the same action as the cycle on the left. Direct integer multiplication verifies $J_4^4 = -I$.

The derivative and addition laws can be read from one finite algebra identity. This formulation also identifies the exponent polygon as the spectrum of a signed cyclic shift.

Definition 6.1. Let

$$\mathfrak{A}_N^+ = \mathbb{C}[\xi]/(\xi^N - 1)$$

and

$$\mathfrak{A}_N^- = \mathbb{C}[\xi]/(\xi^N + 1).$$

Every element has a unique representative of degree below N.

Theorem 6.2 (Finite algebra exponential identities). *In $\mathfrak{A}_N^+$ one has*

$$e^{\lambda z \xi} = \sum_{j=0}^{N-1} \mathsf{E}_{N,j}(\lambda z)\xi^j.$$

In $\mathfrak{A}_N^-$ one has

$$e^{z\xi} = \sum_{j=0}^{N-1} \mathsf{D}_{N,j}(z)\xi^j.$$

Differentiation and multiplication of these identities recover the cyclic derivative systems and the two addition laws.

Proof. Expand the exponential and write every exponent uniquely as $Nn+j$. In $\mathfrak{A}_N^+$, the relation $\xi^{Nn+j} = \xi^j$ gives the transfer sections. In $\mathfrak{A}_N^-$, the relation $\xi^{Nn+j} = (-1)^n\xi^j$ gives the signed sections.

Differentiation multiplies by $\lambda\xi$ in the first algebra and by ξ in the second. Reduction of the product by the defining relation gives the derivative cycles. The identity

$$e^{(z+w)\xi} = e^{z\xi}e^{w\xi}$$

gives the addition laws after comparison of the coefficients of $1, \xi, \dots, \xi^{N-1}$. □

Definition 6.3. Let J_N be the signed cyclic shift on the standard basis $e_0, \dots, e_{N-1}$ of $\mathbb{C}^N$, defined by

$$J_N e_j = e_{j+1} \quad (0 \le j < N-1), \qquad J_N e_{N-1} = -e_0.$$

Then $J_N^N = -I$.

Theorem 6.4 (Companion matrix realization)**.** *Put*

$$\mathbf{D}_N(z) = \begin{pmatrix} \mathsf{D}_{N,0}(z) \\ \mathsf{D}_{N,1}(z) \\ \vdots \\ \mathsf{D}_{N,N-1}(z) \end{pmatrix}.$$

Then

$$\mathbf{D}_N(z) = e^{zJ_N}e_0$$

and

$$\mathsf{D}_N(z) = \frac{1}{N}\,\mathsf{tr}(e^{zJ_N}).$$

The eigenvalues of J_N are the N roots of -1, each with multiplicity one.

Proof. The vector $e^{zJ_N}e_0$ has derivative $J_N e^{zJ_N}e_0$ and initial value e_0. Its components therefore satisfy the same signed derivative cycle and initial data as $\mathbf{D}_N$. Uniqueness for the linear system gives the first identity.

The vectors

$$e_0, J_N e_0, \dots, J_N^{N-1}e_0$$

are the standard basis. Thus e_0 is cyclic for J_N, so the minimal polynomial of J_N has degree N. Since $J_N^N = -I$, that minimal polynomial divides $x^N + 1$ and therefore equals $x^N + 1$. The characteristic polynomial has the same degree and is divisible by the minimal polynomial, so it too equals $x^N + 1$.

This polynomial has distinct roots. Consequently J_N is diagonalizable and its spectrum consists of all N roots of -1, each once. Hence

$$\operatorname{tr}(e^{zJ_N}) = \sum_{\eta^N=-1} e^{\eta z} = N\mathsf{D}_N(z)$$

by theorem 5.6. □

Corollary 6.5 (Entries of the fundamental matrix)**.** *For $0 \le p, q < N$, let d_{pq} be the member of $\{0, \dots, N-1\}$ congruent to $p - q$ modulo N. Put*

$$\varepsilon_{pq} = \begin{cases} 1, & p \ge q, \\ -1, & p < q. \end{cases}$$

Then

$$\left(e^{zJ_N}\right)_{pq} = \varepsilon_{pq}\mathsf{D}_{N,d_{pq}}(z).$$

Thus every entry of the fundamental matrix is one of the signed sections, with the sign recording whether the cyclic path from q to p crosses the signed edge.

Proof. For every nonnegative integer n,

$$J_N^{Nn+d_{pq}} e_q = (-1)^n \varepsilon_{pq} e_p.$$

Only powers whose exponent is congruent to d_{pq} modulo N contribute to the (p, q) entry of the exponential. Therefore

$$\left(e^{zJ_N}\right)_{pq} = \varepsilon_{pq} \sum_{n \ge 0} (-1)^n \frac{z^{Nn+d_{pq}}}{(Nn + d_{pq})!}.$$

This is the stated formula. □

Corollary 6.6 (Addition and inversion laws for the companion matrix)**.** *Assume $N \ge 2$. The matrix*

$$U_N(z) = e^{zJ_N}$$

satisfies

$$U_N(z+w) = U_N(z)U_N(w), \qquad U_N(z)^{-1} = U_N(-z), \qquad \det U_N(z) = 1.$$

Its first column is $\mathbf{D}_N(z)$, and all of its entries are given by corollary 6.5.

Proof. The first two identities are the exponential group law. Since $\operatorname{tr} J_N = 0$,

$$\det(e^{zJ_N}) = e^{z \operatorname{tr} J_N} = 1.$$

The first column statement is theorem 6.4. □

Part II Reciprocal coefficients and polynomial families

7 Reciprocal powers and parameter polynomials

A route through this section

A unit constant term makes the formal reciprocal unambiguous. To compute one coefficient, only finitely many earlier coefficients are needed. The later analytic theory explains how those exact coefficients relate to the full zero set.

The factorial normalization carries the same coefficients in two forms

	n = 0	n = 1	n = 2	n = 3	n = 4
$P_{2,n}(1)$	1	1	5	61	1385
$[z^{2n}]\sec z$	1	1/2	5/24	61/720	1385/40320

Figure 3. At $N = 2$ and $r = 1$, the reciprocal is $\sec z$. The upper row gives block exponential coefficients and the lower row gives ordinary Taylor coefficients. Both rows encode the same five terms.

Since $\mathsf{D}_N(0) = 1$, its formal logarithm is defined at the origin. On a simply connected zero-free region containing the origin, there is a unique holomorphic branch normalized by $\log \mathsf{D}_N(0) = 0$, and its germ at the origin agrees with the formal logarithm.

Definition 7.1. For $r \in \mathbb{C}$, define

$$\mathsf{S}_N^{(r)}(z) = \mathsf{D}_N(z)^{-r} = \exp(-r \log \mathsf{D}_N(z)).$$

Write

$$\mathsf{S}_N^{(r)}(z) = \sum_{n \geq 0} P_{N,n}(r) \frac{z^{Nn}}{(Nn)!}.$$

Define the logarithmic coefficients $\kappa_{N,m}$ by

$$-\log \Delta_N(w) = \sum_{m \geq 1} \kappa_{N,m} \frac{w^m}{m}.$$

The polynomial dependence on r can be read directly from the formal logarithm. We use the complete exponential Bell polynomials B_n defined by

$$\exp\left(\sum_{m\geq 1} x_m \frac{t^m}{m!}\right) = \sum_{n\geq 0} B_n(x_1,\dots,x_n)\frac{t^n}{n!}.$$

Theorem 7.2 (Bell polynomial formula)**.** *For every $n \geq 0$,*

$$P_{N,n}(r) = \frac{(Nn)!}{n!} B_n(r\kappa_{N,1}, r\,1!\,\kappa_{N,2}, \dots, r\,(n-1)!\,\kappa_{N,n}).$$

For $n \geq 1$, this is a polynomial in r of exact degree n. Its leading coefficient is

$$\frac{(Nn)!}{n!(N!)^n}.$$

Proof. The identity

$$\Delta_N(w)^{-r} = \exp\left(r\sum_{m\geq 1}\kappa_{N,m}\frac{w^m}{m}\right)$$

fits the defining generating function for B_n with

$$x_m = r(m-1)!\kappa_{N,m}.$$

The coefficient of w^n is therefore the displayed Bell polynomial divided by $n!$. Multiplication by $(Nn)!$ gives $P_{N,n}(r)$. Since

$$\Delta_N(w) = 1 - \frac{w}{N!} + O(w^2),$$

we have $\kappa_{N,1} = 1/N!$. The term x_1^n gives the stated leading coefficient, which is nonzero. □

The coefficients also satisfy a triangular recurrence that does not require the logarithmic coefficients to be known first.

Theorem 7.3 (Parameter recurrence)**.** *We have $P_{N,0}(r) = 1$. For $n \geq 1$,*

$$\begin{aligned} P_{N,n}(r) = &-\sum_{k=1}^{n-1}(-1)^k\binom{Nn-1}{Nk}P_{N,n-k}(r) \\ &- r\sum_{k=1}^{n}(-1)^k\binom{Nn-1}{Nk-1}P_{N,n-k}(r). \end{aligned}$$

Proof. Set $S = \mathsf{D}_N^{-r}$. Logarithmic differentiation gives

$$\mathsf{D}_N S' + r\mathsf{D}_N' S = 0.$$

Taking the coefficient of $z^{Nn-1}/(Nn-1)!$ gives

$$\sum_{k=0}^{n-1}(-1)^k\binom{Nn-1}{Nk}P_{N,n-k}(r) + r\sum_{k=1}^{n}(-1)^k\binom{Nn-1}{Nk-1}P_{N,n-k}(r) = 0.$$

The term with $k = 0$ in the first sum is $P_{N,n}(r)$, and every other term has a smaller block index. Rearrangement gives the formula. □

Theorem 7.4 (Additive parameter law for reciprocal powers)**.** *For all $r, s \in \mathbb{C}$,*

$$\mathsf{S}_N^{(r)}(z)\mathsf{S}_N^{(s)}(z) = \mathsf{S}_N^{(r+s)}(z)$$

as a formal identity and on every common zero-free region with a fixed logarithm. Consequently,

$$P_{N,n}(r+s) = \sum_{q=0}^{n} \binom{Nn}{Nq} P_{N,q}(r) P_{N,n-q}(s).$$

Proof. Both statements follow by adding the exponents of the same logarithm and then multiplying the block exponential generating series. □

Corollary 7.5 (A sequence of binomial type)**.** *Define*

$$A_{N,n}(r) = \frac{n!}{(Nn)!} P_{N,n}(r).$$

Then

$$A_{N,n}(r+s) = \sum_{q=0}^{n} \binom{n}{q} A_{N,q}(r) A_{N,n-q}(s).$$

Thus $(A_{N,n})_{n\geq 0}$ is a polynomial sequence of binomial type.

Proof. Multiply the coefficient identity in theorem 7.4 by $n!/(Nn)!$ and simplify the factorials. □

The recurrence in theorem 7.3 uses the coefficients of the original denominator. A second recurrence uses only the logarithmic coefficients and is often shorter.

Theorem 7.6 (Logarithmic Newton recurrence)**.** *Set*

$$b_{N,n}(r) = \frac{P_{N,n}(r)}{(Nn)!}.$$

Then $b_{N,0}(r) = 1$ and for every $n \geq 1$,

$$n b_{N,n}(r) = r \sum_{k=1}^{n} \kappa_{N,k} b_{N,n-k}(r).$$

Equivalently,

$$P_{N,n}(r) = \frac{r}{n} \sum_{k=1}^{n} \frac{(Nn)!}{(N(n-k))!} \kappa_{N,k} P_{N,n-k}(r).$$

If $p_k = r\kappa_{N,k}$, then, for $n \geq 1$,

$$b_{N,n}(r) = \frac{1}{n!} \det \begin{pmatrix} p_1 & -1 & 0 & \cdots & 0 \\ p_2 & p_1 & -2 & \cdots & 0 \\ p_3 & p_2 & p_1 & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & -(n-1) \\ p_n & p_{n-1} & \cdots & p_2 & p_1 \end{pmatrix}.$$

Proof. Let

$$B_r(w) = \Delta_N(w)^{-r} = \sum_{n \geq 0} b_{N,n}(r) w^n.$$

Logarithmic differentiation gives

$$\frac{B_r'(w)}{B_r(w)} = r \sum_{k \geq 1} \kappa_{N,k} w^{k-1}.$$

Comparison of the coefficient of w^{n-1} proves the recurrence.

Let D_n denote the displayed determinant, with $D_0 = 1$. Expansion along the last row gives

$$D_n = \sum_{k=1}^{n} \frac{(n-1)!}{(n-k)!} p_k D_{n-k}.$$

Here the cofactor sign is canceled by the product of the negative superdiagonal entries $-(n-k+1), \dots, -(n-1)$. Thus $D_n/n!$ satisfies the same recurrence and initial value as $b_{N,n}(r)$. □

Corollary 7.7 (The first three reciprocal polynomials)**.** *For every $N \geq 1$,*

$$P_{N,1}(r) = r,$$

$$P_{N,2}(r) = r\left[\frac{1}{2}\binom{2N}{N}(r+1) - 1\right],$$

and

$$P_{N,3}(r) = r\left[\frac{(3N)!}{6(N!)^3}(r+1)(r+2) - \binom{3N}{N}(r+1) + 1\right].$$

Proof. The first logarithmic coefficients are

$$\kappa_{N,1} = \frac{1}{N!},$$

$$\kappa_{N,2} = \frac{1}{(N!)^2} - \frac{2}{(2N)!},$$

and

$$\kappa_{N,3} = \frac{1}{(N!)^3} - \frac{3}{N!(2N)!} + \frac{3}{(3N)!}.$$

Insert these values into theorem 7.2 and simplify. □

Corollary 7.8. *For $n \geq 1$, the polynomial $P_{N,n}(r)$ is divisible by r.*

Proof. At $r = 0$, the reciprocal family is the constant function one. Every positive-index block coefficient therefore vanishes. □

Example 7.9. For $N = 1$, one has $\mathsf{D}_1(z)^{-r} = e^{rz}$ and $P_{1,n}(r) = r^n$. For $N = 2$,

$$P_{2,1}(r) = r,$$

$$P_{2,2}(r) = r(3r + 2),$$

and

$$P_{2,3}(r) = r(15r^2 + 30r + 16).$$

At $r = 1$, these are the positive secant coefficients.

8 Logarithmic derivatives and Riccati equations

A coefficient calculation at order two

Write $\Delta_2(w)^{-r} = \sum_{n\geq 0} b_n(r)w^n$. Since

$$\Delta_2(w) = 1 - \frac{w}{2} + \frac{w^2}{24} + O(w^3), \qquad -\log \Delta_2(w) = \frac{w}{2} + \frac{w^2}{12} + O(w^3),$$

the first logarithmic coefficients are $\kappa_{2,1} = 1/2$ and $\kappa_{2,2} = 1/6$. Newton's recurrence gives

$$b_1(r) = \frac{r}{2}, \qquad 2b_2(r) = r\left(\frac{r}{4} + \frac{1}{6}\right).$$

Restoring the factorial normalization yields $P_{2,1}(r) = r$ and $P_{2,2}(r) = r(3r + 2)$. At $r = 1$, the second value is five. No zero-location assumption is needed for this finite calculation.

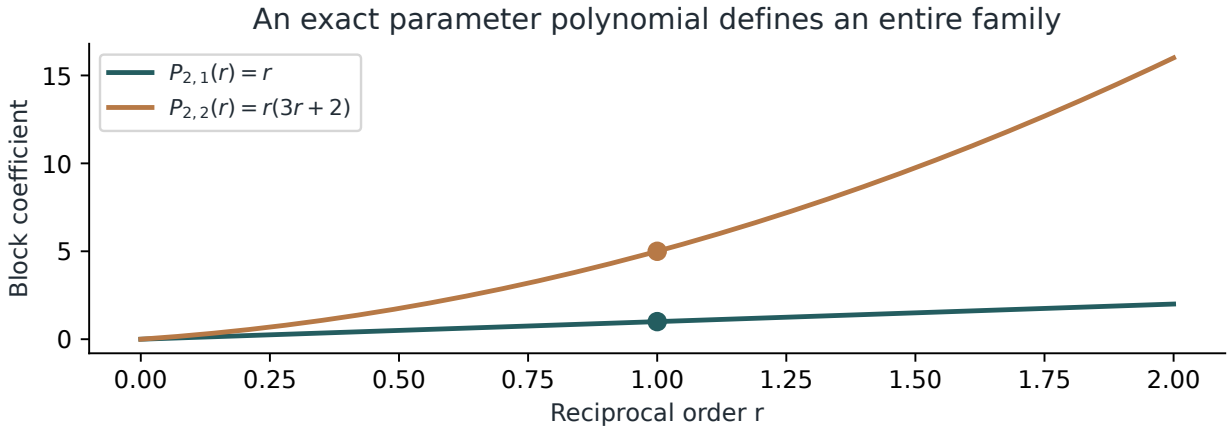

Figure 4. The two exact parameter polynomials from the worked calculation. Each plotted curve evaluates its displayed formula. The points at $r = 1$ recover the first two positive-index secant coefficients.

Definition 8.1. Define the transfer tangent

$$\mathsf{T}_N(z) = -\frac{\mathsf{D}_N'(z)}{\mathsf{D}_N(z)}.$$

Near the origin, its convergent block expansion has the form

$$\mathsf{T}_N(z) = \sum_{n\ge 0} T_N(n)\frac{z^{Nn+N-1}}{(Nn+N-1)!}.$$

Proposition 8.2 (Logarithmic coefficient formula)**.** *The transfer tangent satisfies*

$$\mathsf{T}_N(z) = N\sum_{m\ge 1}\kappa_{N,m}z^{Nm-1}.$$

Equivalently,

$$T_N(n) = N(Nn+N-1)!\kappa_{N,n+1}.$$

Proof. Since $\mathsf{D}_N(z) = \Delta_N(z^N)$,

$$-\frac{\mathsf{D}_N'(z)}{\mathsf{D}_N(z)} = -Nz^{N-1}\frac{\Delta_N'(z^N)}{\Delta_N(z^N)}.$$

Differentiate the defining series for $-\log\Delta_N$ and compare coefficients. □

Theorem 8.3 (Tangent recurrence)**.** *The coefficients satisfy $T_N(0) = 1$ and*

$$T_N(n) = (-1)^n - \sum_{k=1}^{n}(-1)^k\binom{Nn+N-1}{Nk}T_N(n-k).$$

Proof. The defining equation is

$$\mathsf{D}_N\mathsf{T}_N = -\mathsf{D}_N'.$$

Extracting the coefficient of $z^{Nn+N-1}/(Nn+N-1)!$ gives

$$\sum_{k=0}^{n}(-1)^k\binom{Nn+N-1}{Nk}T_N(n-k) = (-1)^n.$$

Isolating the $k=0$ term gives the recurrence. □

Corollary 8.4 (Derivative of the reciprocal family)**.** *For every $r\in\mathbb{C}$, the formal identity*

$$\frac{d}{dz}\mathsf{S}_N^{(r)}(z) = r\mathsf{T}_N(z)\mathsf{S}_N^{(r)}(z)$$

holds. The same identity holds analytically on every zero-free domain on which the logarithm used to define $\mathsf{S}_N^{(r)}$ is fixed.

Proof. Differentiate D_N^{-r} on a zero-free region. The formal identity follows from the same logarithmic calculation. □

For a function g, define the complete differential Bell polynomial Y_N by

$$\frac{d^N}{dz^N}e^{g(z)} = e^{g(z)}Y_N(g', g'', \dots, g^{(N)}).$$

Theorem 8.5 (Scalar higher Riccati identity). *At every point of the open set* $\{z : \mathsf{D}_N(z) \neq 0\}$,

$$Y_N(-\mathsf{T}_N, -\mathsf{T}_N', \dots, -\mathsf{T}_N^{(N-1)}) = -1.$$

Proof. Write $\mathsf{D}_N = e^g$ locally. Then $g' = -\mathsf{T}_N$. Divide the equation $\mathsf{D}_N^{(N)} = -\mathsf{D}_N$ by D_N and use the defining identity for Y_N. □

This scalar identity follows from one ordinary differential equation. It does not redevelop the general nonlinear operation-tree theory of Chapter III.

Example 8.6. For $N = 1$, $\mathsf{T}_1 = 1$. For $N = 2$, $\mathsf{D}_2 = \cos z$ and $\mathsf{T}_2 = \tan z$. The Riccati equation becomes

$$\mathsf{T}_2' = 1 + \mathsf{T}_2^2.$$

9 Residue-section reciprocals and Appell systems

The section $\mathsf{E}_{N,j}$ has a forced zero of order j at the origin. Removing it leaves a unit series in z^N.

Definition 9.1. For $0 \leq j < N$, define

$$\Phi_{N,j}(w) = j! \sum_{n \geq 0} \frac{w^n}{(Nn + j)!}.$$

Then

$$\mathsf{E}_{N,j}(z) = \frac{z^j}{j!}\Phi_{N,j}(z^N).$$

Define the residue-section reciprocal function

$$\mathsf{C}_{N,j}(z) = \Phi_{N,j}(z^N)^{-1} = \frac{z^j/j!}{\mathsf{E}_{N,j}(z)}.$$

For $j > 0$, the last quotient at $z = 0$ is interpreted by its removable continuation, namely the first expression in the display. Write

$$\mathsf{C}_{N,j}(z) = \sum_{n \geq 0} C_{N,j}(n)\frac{z^{Nn}}{(Nn)!}.$$

Theorem 9.2 (Triangular inverse system). *The coefficients are determined by $C_{N,j}(0) = 1$ and*

$$\sum_{q=0}^{n} \binom{Nn+j}{Nq} C_{N,j}(q) = \delta_{n0}.$$

For $n \geq 1$,

$$C_{N,j}(n) = -\frac{\displaystyle\sum_{q=0}^{n-1} \binom{Nn+j}{Nq} C_{N,j}(q)}{\binom{Nn+j}{Nn}}.$$

Proof. Multiply the defining series for $\mathsf{C}_{N,j}$ and $\mathsf{E}_{N,j}$. Their product is $z^j/j!$. At degree $Nn+j$, multiplication by $(Nn+j)!$ gives the stated binomial coefficient. The diagonal coefficient is nonzero, so the system is triangular. □

Definition 9.3. For $r \in \mathbb{C}$, define formal coefficients $C_{N,j,n}(r)$ by

$$\mathsf{C}_{N,j}(z)^r = \sum_{n \geq 0} C_{N,j,n}(r) \frac{z^{Nn}}{(Nn)!}.$$

On a simply connected region containing 0 and avoiding the zeros of $\Phi_{N,j}(z^N)$, interpret this power as e^{rL}, where L is the holomorphic logarithm of $\mathsf{C}_{N,j}$ normalized by $L(0) = 0$.

Theorem 9.4 (Parameter-addition law for residue-section reciprocals). *For each $n \geq 1$, the coefficient $C_{N,j,n}(r)$ is a polynomial in r of exact degree n. Its leading coefficient is*

$$\frac{(Nn)!}{n!} \left(-\frac{j!}{(N+j)!} \right)^n.$$

It satisfies

$$C_{N,j,n}(r+s) = \sum_{q=0}^{n} \binom{Nn}{Nq} C_{N,j,q}(r) C_{N,j,n-q}(s).$$

In particular,

$$C_{N,j,n}(1) = C_{N,j}(n).$$

Proof. The unit series $\Phi_{N,j}(w)^{-1}$ has a formal logarithm with zero constant term. Its linear term is

$$-\frac{j!}{(N+j)!} w.$$

Exponentiation after multiplication by r shows that the coefficient of w^n is a polynomial of degree at most n. The nth power of the linear logarithmic term gives the displayed nonzero leading coefficient,

so the degree is exactly n. Multiplication of the powers with parameters r and s gives the coefficient identity. More explicitly, before the factorial normalization the coefficient of $r^n w^n$ is

$$\frac{1}{n!}\left(-\frac{j!}{(N+j)!}\right)^n;$$

thus multiplication by $(Nn)!$ gives the displayed leading coefficient. □

Definition 9.5. Define polynomials $E_m^{(N,j,r)}(x)$ by

$$\mathsf{C}_{N,j}(z)^r e^{xz} = \sum_{m\geq 0} E_m^{(N,j,r)}(x)\frac{z^m}{m!}.$$

Theorem 9.6 (Appell laws)**.** *For $m \geq 1$, the polynomials satisfy*

$$\frac{d}{dx}E_m^{(N,j,r)}(x) = mE_{m-1}^{(N,j,r)}(x)$$

and, for $m \geq 0$,

$$E_m^{(N,j,r)}(x+y) = \sum_{q=0}^{m}\binom{m}{q}E_q^{(N,j,r)}(x)y^{m-q}.$$

Proof. Differentiate the generating function with respect to x for the first identity. Multiply it by e^{yz} and compare coefficients for the second. □

Proposition 9.7 (Explicit Appell polynomial)**.** *For every $m \geq 0$,*

$$E_m^{(N,j,r)}(x) = \sum_{0\leq n\leq m/N}\binom{m}{Nn}C_{N,j,n}(r)x^{m-Nn}.$$

Proof. Multiply the block series for $\mathsf{C}_{N,j}^r$ by the exponential series and collect the coefficient of total degree m. □

Theorem 9.8 (Joint Appell convolution in the space and order parameters)**.** *For all $r, s, x, y \in \mathbb{C}$ and $m \geq 0$,*

$$E_m^{(N,j,r+s)}(x+y) = \sum_{q=0}^{m}\binom{m}{q}E_q^{(N,j,r)}(x)E_{m-q}^{(N,j,s)}(y).$$

Proof. Multiply the generating functions

$$\mathsf{C}_{N,j}(z)^r e^{xz} \quad \text{and} \quad \mathsf{C}_{N,j}(z)^s e^{yz}.$$

Their product is the generating function with parameters $r+s$ and $x+y$. Coefficient comparison gives the formula. □

Proposition 9.9 (Formal differential-operator representation on polynomials)**.** *Let a formal series $A(z) = \sum_{q\ge 0} a_q z^q/q!$ act on polynomials by*

$$A(\partial_x) f(x) = \sum_{q\ge 0} \frac{a_q}{q!} \partial_x^q f(x).$$

The power r is applied to the formal symbol before the substitution $z = \partial_x$. Then

$$E_m^{(N,j,r)}(x) = \mathsf{C}_{N,j}(\partial_x)^r x^m.$$

The inverse relation is

$$x^m = \Phi_{N,j}(\partial_x^N)^r E_m^{(N,j,r)}(x).$$

Both sums are finite on every polynomial.

Proof. Applying $A(\partial_x)$ to e^{xz} multiplies it by $A(z)$. Taking $A = \mathsf{C}_{N,j}^r$ gives the first identity by the defining generating function. Constant coefficient operators on polynomials satisfy

$$(AB)(\partial_x) = A(\partial_x) B(\partial_x),$$

because all derivative sums are finite and powers of ∂_x commute. The two formal symbols

$$\mathsf{C}_{N,j}(z)^r = \Phi_{N,j}(z^N)^{-r} \quad \text{and} \quad \Phi_{N,j}(z^N)^r$$

multiply to one. Their substitutions at $z = \partial_x$ are therefore inverse constant coefficient operators on polynomials, which proves the second identity. □

Corollary 9.10 (Appell symmetry)**.** *Each polynomial $E_m^{(N,j,r)}$ is monic of degree m, and*

$$E_m^{(N,j,r)}(\omega x) = \omega^m E_m^{(N,j,r)}(x).$$

Proof. The term $n = 0$ in proposition 9.7 is x^m. Every other exponent is $m - Nn$, so replacement of x by ωx multiplies every term by ω^m. □

Example 9.11. For $(N, j) = (2, 0)$,

$$\mathsf{C}_{2,0}(z) = \operatorname{sech} z.$$

For $(N, j) = (2, 1)$,

$$\mathsf{C}_{2,1}(z) = \frac{z}{\sinh z}.$$

The first case is a scaled and translated Euler family. In fact, if $E_m(x)$ denotes the classical Euler polynomial, then

$$E_m^{(2,0,1)}(x) = 2^m E_m\left(\frac{x+1}{2}\right).$$

If $B_m(x)$ denotes the classical Bernoulli polynomial, the second case has the exact identification

$$E_m^{(2,1,1)}(x) = 2^m B_m\left(\frac{x+1}{2}\right),$$

obtained by substituting $t = 2z$ in $te^{yt}/(e^t - 1)$.

10 Scaled reciprocal coupling and theta polynomials

Definition 10.1. Set

$$H_N(z) = \mathsf{E}_{N,0}(z) = \sum_{n\geq 0} \frac{z^{Nn}}{(Nn)!}.$$

For $u \in \mathbb{C}$, define $\Theta_{N,n}(u)$ by

$$H_N(uz)^{-1} H_N(z)^{-u} = \sum_{n\geq 0} \Theta_{N,n}(u) \frac{z^{Nn}}{(Nn)!}.$$

This is first a formal identity at the origin. Analytically, it is interpreted on a common simply connected zero-free region with the branch of $\log H_N$ normalized by $\log H_N(0) = 0$.

Theorem 10.2 (Theta reconstruction)**.** *For every $n \geq 0$,*

$$\Theta_{N,n}(u) = (-1)^n \sum_{q=0}^{n} \binom{Nn}{Nq} P_{N,q}(1) u^{Nq} P_{N,n-q}(u).$$

Thus $\Theta_{N,n}$ is a polynomial of degree at most Nn.

Proof. Choose ρ with $\rho^N = -1$. Then

$$H_N(z) = \mathsf{D}_N(\rho z).$$

The coefficient of z^{Nn} in $H_N(z)^{-r}$ is therefore $(-1)^n P_{N,n}(r)/(Nn)!$. Apply this to $H_N(uz)^{-1}$ and $H_N(z)^{-u}$, then multiply the two block series. □

Proposition 10.3 (Trivial parameter factors)**.** *For $n \geq 1$, the polynomial $\Theta_{N,n}(u)$ is divisible by u. If N is even, it is also divisible by $u + 1$.*

Proof. At $u = 0$, the defining product is one. Hence every positive-index coefficient vanishes. If N is even, then $H_N(-z) = H_N(z)$. At $u = -1$, the product is again one, so every positive-index coefficient vanishes there as well. □

Proposition 10.4 (Theta Newton recurrence)**.** *Put*

$$\theta_{N,n}(u) = \frac{\Theta_{N,n}(u)}{(Nn)!}.$$

Then $\theta_{N,0}(u) = 1$ and

$$n\theta_{N,n}(u) = \sum_{m=1}^{n} (-1)^m \kappa_{N,m}(u^{Nm} + u)\theta_{N,n-m}(u).$$

In particular,

$$\Theta_{N,1}(u) = -(u^N + u).$$

Proof. Write $w = z^N$. Since $H_N(z) = \Delta_N(-w)$,

$$-\log H_N(z) = \sum_{m \geq 1} (-1)^m \kappa_{N,m} \frac{w^m}{m}.$$

The logarithm of the theta generating function is therefore

$$\sum_{m \geq 1} (-1)^m \kappa_{N,m} (u^{Nm} + u) \frac{w^m}{m}.$$

Logarithmic differentiation and coefficient comparison give the recurrence. The case $n = 1$ uses $\kappa_{N,1} = 1/N!$. □

Example 10.5. For $N = 2$,

$$\Theta_{2,1}(u) = -u(u+1)$$

and

$$\Theta_{2,2}(u) = u(u+1)(5u^2 + u + 2).$$

The two factors predicted by proposition 10.3 are visible.

Part III The geometry of zeros

11 Growth and the geometry of the large zeros

A route through this section

The finite exponential representation gives a polygon of exponents. Large zeros can occur where two dominant terms nearly cancel. The proof first localizes those zeros and then uses symmetry and uniqueness to place them on the rays. Finite exceptional zeros remain part of the later products and sums.

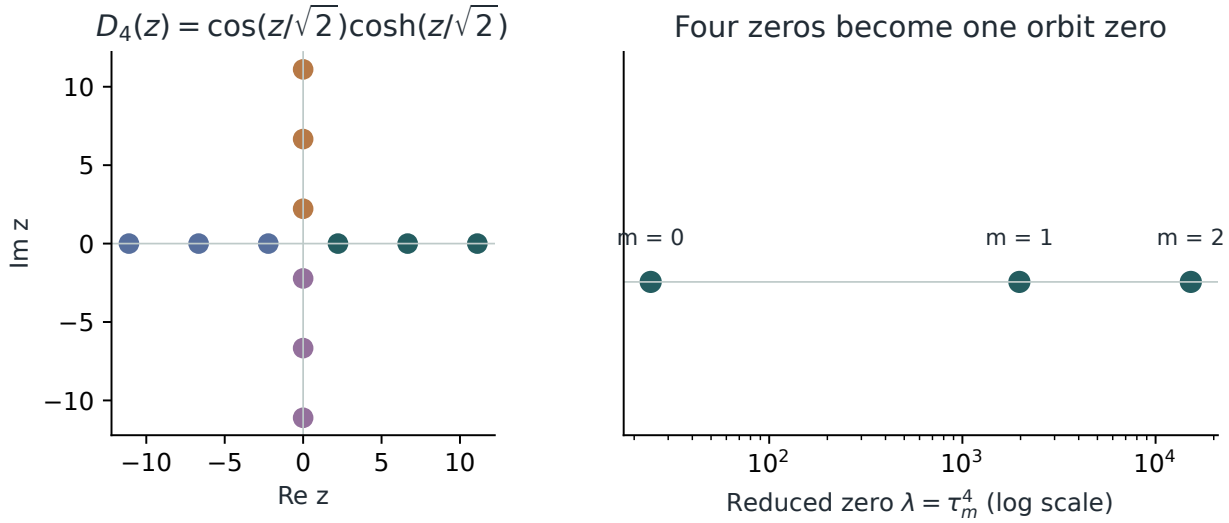

Figure 5. The exact order-four model. The first three zeros on each of four rays are mapped by $w = z^4$ to three positive reduced zeros. The reduced axis uses a logarithmic scale. This complete order-four example does not classify the finite exceptional set at other orders.

We now assume $N \geq 2$. Write

$$\eta_k = e^{(2k+1)\pi i/N}, \qquad 0 \leq k < N.$$

These are the vertices of a regular polygon and

$$\mathsf{D}_N(z) = \frac{1}{N} \sum_{k=0}^{N-1} e^{\eta_k z}.$$

Standard Fact 11.1 (Order from Taylor coefficients)**.** If $f(w) = \sum_{n\ge 0} a_n w^n$ is an entire function with infinitely many nonzero coefficients, then

$$\operatorname{ord} f = \limsup_{\substack{n\to\infty \\ a_n\neq 0}} \frac{n \log n}{\log(1/|a_n|)}.$$

Canonical products for entire functions of order below one have genus zero. We use these standard facts in the form given in [Boa54, Tit39].

Proposition 11.2 (Orders and exponential type)**.** *For $N \ge 2$,*

$$\operatorname{ord} \Delta_N = \frac{1}{N}.$$

The function D_N has order one and exponential type one.

Proof. The coefficient of w^n in Δ_N has modulus $1/(Nn)!$. Stirling's formula and standard fact 11.1 give order $1/N$. Since $M_{f(\cdot^N)}(r) = M_f(r^N)$ for the maximum modulus, composition with z^N multiplies the order by N and gives order one for D_N.

The finite exponential representation gives

$$|\mathsf{D}_N(z)| \le e^{|z|},$$

so the type is at most one. Choose a root η_0 and put $z = t\overline{\eta_0}$ with $t > 0$. The term $e^{\eta_0 z} = e^t$ has strictly larger real exponent than every other term. Hence

$$\mathsf{D}_N(t\overline{\eta_0}) = \frac{1}{N} e^t (1 + o(1)).$$

The type is therefore one. □

Definition 11.3. For $\theta \in \mathbb{R}$, define

$$h_N(\theta) = \max_{0\le k<N} \cos\left(\theta + \frac{(2k+1)\pi}{N}\right).$$

The tie directions are

$$\mathfrak{T}_N = \left\{ \frac{2\pi k}{N} : 0 \le k < N \right\} \mod 2\pi.$$

Theorem 11.4 (Indicator polygon and dominant sectors)**.** *The indicator of D_N equals h_N, with the limsup taken over radii where $\mathsf{D}_N(re^{i\theta}) \neq 0$:*

$$\limsup_{r\to\infty} \frac{1}{r} \log|\mathsf{D}_N(re^{i\theta})| = h_N(\theta).$$

If K is a compact set of directions disjoint from $\mathfrak{T}_N$, then there are $\delta > 0$ and $R > 0$ such that, for each $\theta \in K$, one root $\eta(\theta)$ of -1 satisfies

$$\mathsf{D}_N(re^{i\theta}) = \frac{1}{N}\exp(\eta(\theta)re^{i\theta})\left(1 + O(e^{-\delta r})\right)$$

uniformly for $r \geq R$. In particular, no sufficiently large zero can lie in those directions.

Proof. For $z = re^{i\theta}$, the real part of the exponent $\eta_k z$ is

$$r\cos\left(\theta + \frac{(2k+1)\pi}{N}\right).$$

The triangle inequality gives the upper indicator bound $h_N(\theta)$.

Away from a tie direction, the maximizing vertex is unique. It is constant on each connected component of the complement of the tie directions. A compact set avoiding all ties meets only finitely many such components, and compactness gives one uniform positive lower bound for every relevant projection gap. Division by the maximizing exponential gives the stated uniform asymptotic and the zero-free conclusion.

At a tie direction exactly two adjacent vertices attain the maximum. After rotation it is enough to take $\theta = 0$. With $c_N = \cos(\pi/N)$ and $s_N = \sin(\pi/N)$, the two dominant terms give

$$\frac{2}{N}e^{c_N r}\cos(s_N r)$$

and every other term is exponentially smaller. Along a sequence on which $|\cos(s_N r)| \geq 1/2$, the lower indicator bound is $c_N = h_N(0)$. Rotational symmetry treats every tie direction. □

The zero strings are governed by two adjacent exponents. Put

$$a_N = \frac{\pi}{N}, \qquad s_N = \sin a_N, \qquad c_N = \cos a_N,$$

and

$$A_N = \frac{\pi}{s_N}, \qquad t_m = A_N\left(m + \frac{1}{2}\right).$$

For $N \geq 3$, also put

$$\gamma_N = c_N - \cos(3a_N) > 0.$$

Lemma 11.5 (Two term dominance)**.** *Assume $N \geq 3$. There are positive constants Y, R, and C with the following properties.*

If $z = x + iy$ lies in the sector $|\arg z| \leq a_N$, has $x \geq R$, and is a zero of D_N, then $|y| \leq Y$.

On the strip $x \geq R$ and $|y| \leq Y$, define

$$R_N(z) = \sum_{\substack{\eta^N=-1 \\ \eta \neq e^{ia_N}, e^{-ia_N}}} \exp((\eta - e^{-ia_N})z).$$

Then

$$Ne^{-e^{-ia_N}z}\mathsf{D}_N(z) = 1 + e^{2is_N z} + R_N(z),$$

and, for $q = 0, 1, 2$,

$$|R_N^{(q)}(z)| \le Ce^{-\gamma_N x}.$$

Proof. A direct projection estimate gives the stronger bound

$$Y = \frac{\log(N-1)}{2s_N}$$

for every zero in the sector, without a large-radius assumption. Write $z = re^{i\theta}$ with $0 \le \theta \le a_N$ and $r \ge 0$. For $0 \le \ell \le N-2$, the angle $\theta + (2\ell+1)a_N$ lies between $a_N + \theta$ and $2\pi - a_N - \theta$. Monotonicity of cosine on $[0, \pi]$, followed by reflection about π, therefore gives

$$\Re(\eta_\ell z) \le r\cos(a_N + \theta).$$

The remaining vertex e^{-ia_N} has projection $r\cos(a_N - \theta)$. Their difference is at least $2s_N r\sin\theta = 2s_N y$. If $\mathsf{D}_N(z) = 0$, divide its finite exponential sum by the term with exponent $e^{-ia_N}z$ and apply the triangle inequality:

$$1 \le (N-1)e^{-2s_N y}.$$

Thus $y \le Y$. Conjugation gives the same bound for $-y$ on the lower half sector. Since $N \ge 3$ and $s_N > 0$, this Y is positive.

On the resulting strip, the roots e^{ia_N} and e^{-ia_N} have real part c_N, while each remaining root $\eta = u+iv$ satisfies $u \le \cos(3a_N) = c_N - \gamma_N$. Hence

$$\Re\big((\eta - e^{-ia_N})z\big) \le -\gamma_N x + 2Y.$$

Division by $e^{e^{-ia_N}z}$ gives the displayed normalization. Each differentiation multiplies a remainder term by $\eta - e^{-ia_N}$, whose modulus is at most two. Thus, for $q = 0, 1, 2$,

$$|R_N^{(q)}(z)| \le (N-2)2^q e^{2Y}e^{-\gamma_N x}.$$

One may take $R = 1$ and $C = 4(N-2)e^{2Y}$. □

Lemma 11.6 (Near cancellation of two exponentials)**.** *For every* $M > 0$*, there are constants* $\varepsilon_M > 0$ *and* $C_M > 0$ *such that the following holds. If*

$$|\Re w| \le M$$

and

$$|1 + e^w| \le \varepsilon_M,$$

then there is a unique integer m *with*

$$|w - (2m+1)\pi i| \le C_M|1 + e^w|.$$

Proof. In fact, the constants $\varepsilon_M = 1/2$ and $C_M = 3/2$ work for every complex w, without the strip restriction. Put $u = -(1 + e^w)$ and $L = \log(1+u) = \log(-e^w)$, using the principal logarithm. The elementary logarithm estimate on $|u| \le 1/2$ gives $|L| \le (3/2)|u|$. Since $e^{L+\pi i} = e^w$, there is an integer m such that

$$w = L + (2m+1)\pi i.$$

This gives the required distance bound. Distinct centers are separated by at least 2π, whereas two centers satisfying the bound would be separated by at most $3|1+e^{w}| \le 3/2$. Thus the integer is unique. The formal proof uses the convergent logarithm estimate and the exact periodicity theorem for the complex exponential. □

Theorem 11.7 (Large zero strings). *Assume $N \ge 3$. There are constants m_0, C, and $\gamma > 0$ and a sequence of positive real simple zeros $(\tau_m)_{m\ge m_0}$ of D_N such that*

$$\tau_m = t_m + O(e^{-\gamma t_m}).$$

Every zero of sufficiently large modulus is of the form

$$\omega^k \tau_m$$

for a unique $0 \le k < N$ and a unique $m \ge m_0$.
The derivatives satisfy

$$\mathsf{D}'_N(\omega^k \tau_m) = \omega^{-k} \mathsf{D}'_N(\tau_m)$$

and

$$|\mathsf{D}'_N(\tau_m)| = \frac{2s_N}{N} e^{c_N \tau_m} \left(1 + O(e^{-\gamma \tau_m})\right).$$

Proof. Work first in the sector $|\arg z| \le a_N$. By lemma 11.5, every sufficiently large zero lies in a fixed strip about the positive real axis. Put

$$G(z) = N e^{-e^{-i a_N} z} \mathsf{D}_N(z).$$

Then

$$G(z) = 1 + e^{2i s_N z} + R_N(z)$$

with an exponentially small remainder and derivative.

If $G(z) = 0$, then

$$|1 + e^{2i s_N z}| \le C e^{-\gamma_N \Re z}.$$

The real part of $2i s_N z$ is bounded in the strip. Apply lemma 11.6 with $w = 2i s_N z$. There is a unique integer m such that

$$|z - t_m| \le C_1 e^{-\gamma_N \Re z},$$

where

$$t_m = \frac{(2m+1)\pi}{2s_N}.$$

In particular, $|\Re z - t_m| = o(1)$. For all sufficiently large zeros we have $|\Re z - t_m| \le 1$, and hence

$$|z - t_m| \le C_2 e^{-\gamma_N t_m}$$

with a constant independent of m. Because $\Re z \to +\infty$ in this argument, the corresponding integers m are eventually nonnegative and tend to infinity.

Fix a large m, put $a = 2is_N$, and consider the closed disk $B_m = \{z : |z - t_m| \le 1/(2s_N)\}$. The remainder bounds hold uniformly on these fixed-radius disks. For sufficiently large m, $|R_N| \le 1/2$ and $|R_N'| \le s_N/2$ there. Define

$$\Phi_m(z) = t_m + \frac{\log(1 + R_N(z))}{2is_N},$$

using the principal logarithm. The estimate $|\log(1 + u)| \le (3/2)|u|$ shows that Φ_m maps B_m into itself. The derivative bound $|\Phi_m'| \le 1/2$ makes it a contraction. Banach's fixed-point theorem gives a unique fixed point. On B_m, $|a(z - t_m)| \le 1 < \pi$, so the principal logarithm inverts the exponential and the fixed-point equation is equivalent to $G(z) = 0$. Moreover,

$$|z - t_m| \le \frac{3}{4s_N}|R_N(z)| = O(e^{-\gamma_N t_m}).$$

At this zero,

$$|G'(z)| \ge |a|\,|1 + R_N(z)| - |R_N'(z)| \ge s_N/2 > 0,$$

so the zero is simple. The disks are mutually disjoint because their diameter $1/s_N$ is smaller than the center spacing π/s_N. Enlarging the strip if necessary, these disks lie inside the fundamental sector and the fixed strip for large m.

The localization estimate puts every sufficiently large zero in the fundamental sector into one of these disks. The zero sets of G and D_N coincide because their prefactor is nonzero. Each disk is invariant under complex conjugation, and D_N has real coefficients. The conjugate of its unique zero is therefore the same zero. It is real, positive for large m, and simple by the derivative bound above. Denote it by τ_m.

The parts of the fundamental sector away from the positive tie ray, including its boundary rays, were already excluded uniformly. Rotational invariance now gives every remaining large zero as $\omega^k\tau_m$. Distinct rays and the disjoint disks give uniqueness of k and m. Taking $\gamma = \gamma_N$ proves the zero location in the statement.

Differentiate the normalized expression. At $z = \tau_m$,

$$G'(\tau_m) = 2is_N e^{2is_N\tau_m} + R_N'(\tau_m) = -2is_N + O(e^{-\gamma_N\tau_m}).$$

Since $G(\tau_m) = 0$,

$$\mathsf{D}_N'(\tau_m) = \frac{1}{N}e^{e^{-ia_N\tau_m}}G'(\tau_m).$$

Taking absolute values gives the derivative asymptotic. Differentiating $\mathsf{D}_N(\omega z) = \mathsf{D}_N(z)$ gives the rotation formula. □

Theorem 11.8 (Leading displacement term and derivative sign)**.** *With the notation of lemma 11.5 and theorem 11.7,*

$$\tau_m = t_m + \frac{R_N(t_m)}{2is_N} + O(e^{-2\gamma_N t_m}).$$

The quotient $R_N(t_m)/(2is_N)$ is real. One also has

$$\mathsf{D}_N'(\tau_m) = (-1)^{m+1}\frac{2s_N}{N}e^{c_N\tau_m}\left(1 + O(e^{-\gamma_N\tau_m})\right).$$

Proof. Put $\delta_m = \tau_m - t_m$. The large zero theorem gives $\delta_m = O(e^{-\gamma_N t_m})$. Since $e^{2is_N t_m} = -1$,

$$1 + e^{2is_N(t_m+\delta_m)} = -2is_N\delta_m + O(\delta_m^2).$$

The remainder estimate through the first derivative gives

$$R_N(t_m + \delta_m) = R_N(t_m) + O(e^{-\gamma_N t_m}|\delta_m|).$$

Substitution in the zero equation gives the displacement formula.

At the real point t_m, the normalized value

$$Ne^{-e^{-ia_N}t_m}\mathsf{D}_N(t_m)$$

is purely imaginary. The two dominant terms cancel there, so $R_N(t_m)$ is purely imaginary and the displayed correction is real.

For the derivative, use the formula in the proof of theorem 11.7 and

$$e^{-is_N\tau_m} = (-1)^m(-i)\left(1 + O(e^{-\gamma_N\tau_m})\right).$$

The stated real sign follows. □

Corollary 11.9 (Leading correction for $N = 3$)**.** *For $N = 3$,*

$$t_m = \frac{2\pi}{\sqrt{3}}\left(m + \frac{1}{2}\right)$$

and

$$\tau_m = t_m + \frac{(-1)^m}{\sqrt{3}}e^{-3t_m/2} + O(e^{-3t_m}).$$

Proof. The only nondominant exponent is -1. Hence

$$R_3(t) = \exp\left(\left(-\frac{3}{2} + \frac{\sqrt{3}}{2}i\right)t\right).$$

At $t = t_m$, its phase is $i(-1)^m$. Insert this value into theorem 11.8. □

Corollary 11.10 (The case $N = 2$)**.** *For $N = 2$,*

$$\mathsf{D}_2(z) = \cos z.$$

Its zeros are

$$\pm\left(m + \frac{1}{2}\right)\pi, \qquad m \geq 0,$$

and all are simple. They agree with the formula $t_m = A_2(m + 1/2)$.

Proof. This is the standard zero set of the cosine function. □

Corollary 11.11 (Eventual simplicity and exact rays)**.** *For every $N \geq 2$, all but finitely many zeros of D_N are simple. Every sufficiently large zero lies on one of the rays*

$$\omega^k(0,\infty), \qquad 0 \leq k < N.$$

Proof. Use theorem 11.7 for $N \geq 3$ and corollary 11.10 for $N = 2$. □

Example 11.12 (Exact fourth-order strings)**.** For $N = 4$,

$$\mathsf{D}_4(z) = \cos\left(\frac{z}{\sqrt{2}}\right)\cosh\left(\frac{z}{\sqrt{2}}\right).$$

The positive zeros are exactly

$$\tau_m = \sqrt{2}\pi\left(m + \frac{1}{2}\right) = A_4\left(m + \frac{1}{2}\right).$$

Rotation by the fourth roots of unity gives the real and imaginary zero strings. In this case the error term in theorem 11.7 is identically zero.

Corollary 11.13 (Reduced zeros)**.** *Let Λ_N be the nonzero zero multiset of Δ_N. All but finitely many members of Λ_N are positive and simple. They can be indexed as*

$$\lambda_m = \tau_m^N$$

for all sufficiently large m. If $N \geq 3$, the notation may be chosen as in theorem 11.7, and

$$\lambda_m = t_m^N + O\left(t_m^{N-1} e^{-\gamma t_m}\right).$$

For $N = 2$, take $\tau_m = t_m = \pi(m + 1/2)$ for $m \geq 0$. Then $\lambda_m = t_m^2$ exactly.

Proof. The identity $\mathsf{D}_N(z) = \Delta_N(z^N)$ identifies each orbit of N nonzero zeros of D_N with one zero of Δ_N. For $N \geq 3$, the large orbit representatives are the positive zeros τ_m from theorem 11.7. For $N = 2$, use corollary 11.10. Simplicity is preserved because

$$\mathsf{D}_N'(z) = N z^{N-1} \Delta_N'(z^N)$$

and $z \neq 0$. The asymptotic follows by expanding τ_m^N about t_m. □

Theorem 11.14 (Zero counting asymptotics)**.** *Let $n_{\mathsf{D}_N}(R)$ count the zeros of D_N in $|z| \leq R$, with multiplicity. Let $n_{\Delta_N}(R)$ count the zeros of Δ_N in $|w| \leq R$. Then, as $R \to \infty$,*

$$n_{\mathsf{D}_N}(R) = \frac{N \sin(\pi/N)}{\pi} R + O(1)$$

and

$$n_{\Delta_N}(R) = \frac{\sin(\pi/N)}{\pi} R^{1/N} + O(1).$$

Proof. Each of the N rays contains one large zero near

$$t_m = \frac{\pi}{\sin(\pi/N)} \left(m + \frac{1}{2} \right).$$

Since $\tau_m - t_m = o(1)$ and the model spacing is the positive constant A_N, replacing $\tau_m \le R$ by $t_m \le R$ changes the count by at most a bounded amount. The number of such indices with $t_m \le R$ is

$$\frac{\sin(\pi/N)}{\pi} R + O(1).$$

Multiplication by N and addition of the finite exceptional set give the first formula. The second follows from

$$n_{\mathsf{D}_N}(R^{1/N}) = N n_{\Delta_N}(R).$$

□

Corollary 11.15 (Zero exponents)**.** *The exponent of convergence of the nonzero zeros of* D_N *is one. The exponent of convergence of the zeros of* Δ_N *is* $1/N$*.*

Proof. The asymptotic counting formulas in theorem 11.14 give the two exponents by partial summation. □

Part IV Products, moments, and zero zeta functions

12 Hadamard products and zero power sums

The central idea

The product uses every reduced zero with its multiplicity. Its logarithm turns multiplication into addition, so reciprocal-zero power sums become coefficients. This step depends on the global product theorem. A truncated zero list provides a numerical partial sum, while the identity uses the entire multiset.

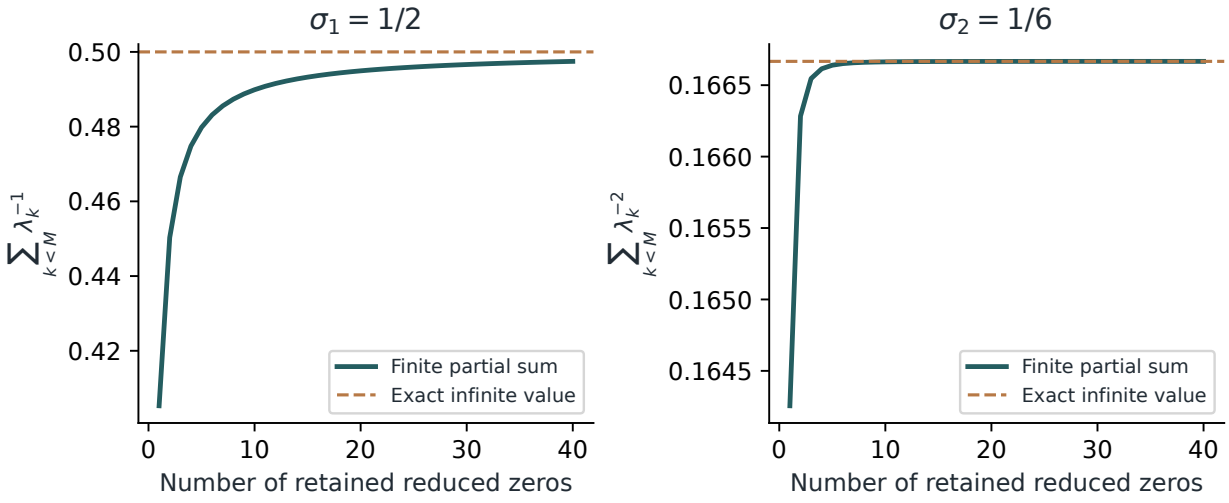

Figure 6. Order-two moment sums over the first forty reduced zeros $\lambda_k = \pi^2(k + 1/2)^2$. The curves are finite numerical partial sums. The dashed limits $1/2$ and $1/6$ follow from the exact logarithmic coefficients and the product identity.

The reduction from z to $w = z^N$ removes the rotational repetition of the zeros.

Theorem 12.1 (Genus zero product). *For $N \geq 2$, let Λ_N be the nonzero zero multiset of Δ_N. Then*

$$\Delta_N(w) = \prod_{\lambda \in \Lambda_N} \left(1 - \frac{w}{\lambda}\right),$$

where the product converges locally uniformly. Consequently,

$$\mathsf{D}_N(z) = \prod_{\lambda \in \Lambda_N} \left(1 - \frac{z^N}{\lambda}\right).$$

Proof. By proposition 11.2, the order of Δ_N is $1/N < 1$. By corollary 11.13, it has infinitely many zeros, and corollary 11.15 gives

$$\sum_{\lambda \in \Lambda_N} |\lambda|^{-1} < \infty.$$

Hadamard factorization therefore gives a canonical product of genus zero. The only possible exponential factor is a nonzero constant because the order is below one. Since $\Delta_N(0) = 1$, that constant is one. Substitution of $w = z^N$ gives the second formula. □

Theorem 12.2 (Diagonal Fredholm determinant representation)**.** *Let I_N be a multiplicity-sensitive countable index set for Λ_N and put $\mathcal{H}_N = \ell^2(I_N)$. On its standard orthonormal basis, define the diagonal operator*

$$K_N e_\lambda = \lambda^{-1} e_\lambda.$$

Then K_N is trace class and

$$\Delta_N(w) = \det_F(I - wK_N).$$

For every $m \geq 1$,

$$\kappa_{N,m} = \operatorname{tr}(K_N^m).$$

Proof. By corollary 11.15,

$$\sum_{\lambda \in \Lambda_N} |\lambda|^{-1} < \infty.$$

Thus the diagonal operator K_N is trace class. Its Fredholm determinant is the locally uniform product

$$\det_F(I - wK_N) = \prod_{\lambda \in \Lambda_N} \left(1 - \frac{w}{\lambda}\right),$$

which equals $\Delta_N(w)$ by theorem 12.1.

Taking the logarithm gives

$$-\log \Delta_N(w) = \sum_{m \geq 1} \frac{w^m}{m} \operatorname{tr}(K_N^m)$$

near the origin. Comparison with the definition of $\kappa_{N,m}$ proves the trace identity. □

This is the standard diagonal encoding of this family's genus zero product. It is not a general trace-class resolvent or Feshbach theorem.

Corollary 12.3 (Complete symmetric function form)**.** *For a positive integer r, let each eigenvalue λ^{-1} of K_N be repeated r times. If h_n denotes the complete homogeneous symmetric function of degree n in this absolutely summable multiset, then*

$$\frac{P_{N,n}(r)}{(Nn)!} = h_n.$$

For arbitrary complex r, the Bell polynomial formula is the polynomial continuation obtained by multiplying every power sum by r.

Proof. The generating function for the complete homogeneous symmetric functions is

$$\prod_{\lambda \in \Lambda_N} \left(1 - \frac{w}{\lambda}\right)^{-r} = \Delta_N(w)^{-r}.$$

Coefficient comparison gives the first identity. Power sums determine the complete homogeneous functions through the Newton recurrence. Replacing each power sum by r times itself gives theorems 7.2 and 7.6. □

Proposition 12.4 (Products for the normalized sections)**.** *For every $0 \le j < N$, the entire function*

$$\Phi_{N,j}(w) = j! \sum_{n \ge 0} \frac{w^n}{(Nn+j)!}$$

has order $1/N$. If $N \ge 2$ and $\Lambda_{N,j}$ is its nonzero zero multiset, then

$$\Phi_{N,j}(w) = \prod_{\mu \in \Lambda_{N,j}} \left(1 - \frac{w}{\mu}\right).$$

For $m \ge 1$, put

$$\sigma_{N,j,m} = \sum_{\mu \in \Lambda_{N,j}} \mu^{-m}.$$

Then

$$C_{N,j,n}(r) = \frac{(Nn)!}{n!} B_n(r\sigma_{N,j,1}, r1!\sigma_{N,j,2}, \dots, r(n-1)!\sigma_{N,j,n}).$$

Proof. The coefficient formula for the order gives $1/N$. The function is not a polynomial. An entire function of order below one with only finitely many zeros would be a polynomial times a constant by Hadamard factorization, which is impossible here. The genus zero product follows as in theorem 12.1.

Taking the logarithm gives

$$-\log \Phi_{N,j}(w) = \sum_{m \ge 1} \sigma_{N,j,m} \frac{w^m}{m}.$$

Since $\mathsf{C}_{N,j}(z)^r = \Phi_{N,j}(z^N)^{-r}$, the Bell polynomial calculation from theorem 7.2 gives the coefficient formula. □

Definition 12.5. For $m \ge 1$, define

$$\sigma_{N,m} = \sum_{\lambda \in \Lambda_N} \lambda^{-m},$$

with multiplicities.

The series converges absolutely because the exponent of convergence of Λ_N is $1/N < 1$.

Theorem 12.6 (Newton sums for the reduced zeros)**.** *For $|w|$ below the least zero modulus, with the analytic logarithm normalized to zero at the origin,*

$$-\log \Delta_N(w) = \sum_{m \ge 1} \sigma_{N,m} \frac{w^m}{m}.$$

Thus

$$\kappa_{N,m} = \sigma_{N,m}.$$

If

$$a_m = \frac{(-1)^m}{(Nm)!}, \qquad a_0 = 1,$$

then

$$\sigma_{N,m} = -m a_m - \sum_{k=1}^{m-1} a_k \sigma_{N,m-k}.$$

Proof. Take the logarithm of the product in theorem 12.1. Absolute convergence in a disk below the first zero permits termwise expansion

$$-\log\Big(1 - \frac{w}{\lambda}\Big) = \sum_{m \geq 1} \frac{w^m}{m \lambda^m}.$$

This gives the logarithmic formula and identifies $\kappa_{N,m}$ with $\sigma_{N,m}$.

Differentiate the product identity in logarithmic form to obtain

$$\Delta_N'(w) = -\Delta_N(w) \sum_{m \geq 1} \sigma_{N,m} w^{m-1}.$$

Comparison of the coefficient of w^{m-1} gives

$$m a_m = -\sum_{k=0}^{m-1} a_k \sigma_{N,m-k}.$$

Solving for $\sigma_{N,m}$ gives the recurrence. □

Corollary 12.7 (Convergent Mittag–Leffler partial-fraction form)**.** *Away from the zeros of* D_N*,*

$$\mathsf{T}_N(z) = N z^{N-1} \sum_{\lambda \in \Lambda_N} \frac{1}{\lambda - z^N}.$$

The series converges absolutely and locally uniformly on compact sets away from the poles. Thus no regularizing terms are required.

Proof. Logarithmic differentiation of the genus zero product gives

$$-\frac{\Delta_N'(w)}{\Delta_N(w)} = \sum_{\lambda \in \Lambda_N} \frac{1}{\lambda - w}.$$

The series is locally uniform because $\sum_\lambda |\lambda|^{-1} < \infty$. Substitute $w = z^N$ and use the chain rule. □

Proposition 12.8 (Theta Bell polynomial formula)**.** *Put*

$$\tilde{\sigma}_{N,m} = (-1)^m \sigma_{N,m}.$$

Then

$$\Theta_{N,n}(u) = \frac{(Nn)!}{n!} B_n(\tilde{\sigma}_{N,1}(u^N + u), 1!\tilde{\sigma}_{N,2}(u^{2N} + u), \dots, (n-1)!\tilde{\sigma}_{N,n}(u^{nN} + u)).$$

Proof. The reduced unsigned denominator is

$$\Psi_N(w) = \sum_{n\geq 0} \frac{w^n}{(Nn)!} = \Delta_N(-w).$$

By theorem 12.6,

$$-\log \Psi_N(w) = \sum_{m\geq 1} \tilde{\sigma}_{N,m} \frac{w^m}{m}.$$

With $w = z^N$, the logarithm of the theta generating function is

$$\sum_{m\geq 1} \tilde{\sigma}_{N,m}(u^{Nm} + u)\frac{w^m}{m}.$$

The complete Bell polynomial formula follows. □

Corollary 12.9 (Tangent coefficients as zero sums)**.** *For every $n \geq 0$,*

$$T_N(n) = N(Nn + N - 1)!\sigma_{N,n+1}.$$

Proof. Combine proposition 8.2 and theorem 12.6. □

Corollary 12.10 (Reciprocal coefficients from zero data)**.** *For every $n \geq 0$,*

$$P_{N,n}(r) = \frac{(Nn)!}{n!} B_n(r\sigma_{N,1}, r1!\sigma_{N,2}, \dots, r(n-1)!\sigma_{N,n}).$$

Proof. Use theorems 7.2 and 12.6. □

Example 12.11 (The cosine orbit sums)**.** For $N = 2$,

$$\Delta_2(w) = \cos\sqrt{w}.$$

Its zeros are

$$\lambda_m = \pi^2 \left(m + \frac{1}{2}\right)^2, \qquad m \geq 0.$$

Hence

$$\sigma_{2,q} = \frac{2^{2q} - 1}{\pi^{2q}} \zeta(2q).$$

The identity in corollary 12.9 recovers the classical tangent coefficients from these zero power sums.

13 Coefficient asymptotics from the nearest zeros

For an entire function f, let $\mathcal{Z}(f)$ denote its multiset of nonzero zeros. Let r be a positive integer. Then D_N^{-r} is meromorphic and a simple zero of D_N becomes a pole of order r.

Theorem 13.1 (Nearest-pole coefficient expansion). *Let $r \in \mathbb{Z}_{>0}$. Suppose the zeros of D_N of least modulus R are simple and form the finite set $\mathcal{Z}_R$. Suppose the next zero modulus is $R_2 > R$. At each $\rho \in \mathcal{Z}_R$, write the principal part*

$$\mathsf{D}_N(z)^{-r} = \sum_{\ell=1}^{r} a_{\rho,\ell} \left(1 - \frac{z}{\rho}\right)^{-\ell} + O(1).$$

Then, for every R_* with $R < R_* < R_2$ and $m = Nn$, as $n \to \infty$,

$$P_{N,n}(r) = m! \sum_{\rho \in \mathcal{Z}_R} \sum_{\ell=1}^{r} a_{\rho,\ell} \binom{m+\ell-1}{\ell-1} \rho^{-m} + O_{R_*}(m! R_*^{-m}).$$

The leading Laurent coefficient is

$$a_{\rho,r} = (-\rho \mathsf{D}_N'(\rho))^{-r}.$$

Proof. Subtract the complete principal parts at the zeros on $|z| = R$. The remainder is holomorphic on $|z| < R_2$, hence on a neighborhood of every closed disk $|z| \le R_* < R_2$. Cauchy's estimate gives an ordinary coefficient bound $O_{R_*}(R_*^{-m})$. The coefficient of z^m in

$$\left(1 - \frac{z}{\rho}\right)^{-\ell}$$

is

$$\binom{m+\ell-1}{\ell-1} \rho^{-m}.$$

Multiplication by $m!$ converts the ordinary coefficient to $P_{N,n}(r)$.

Near a simple zero,

$$\mathsf{D}_N(z) = -\rho \mathsf{D}_N'(\rho) \left(1 - \frac{z}{\rho}\right) + O\left(\left(1 - \frac{z}{\rho}\right)^2\right).$$

Raising to the power $-r$ gives the formula for $a_{\rho,r}$. □

Corollary 13.2 (Leading dominant zero term). *Under the hypotheses of theorem 13.1,*

$$P_{N,n}(r) = m! \binom{m+r-1}{r-1} \sum_{\rho \in \mathcal{Z}_R} \frac{\rho^{-m}}{(-\rho \mathsf{D}_N'(\rho))^r} + O\left(m! m^{r-2} R^{-m}\right) + O_{R_*}\left(m! R_*^{-m}\right).$$

For $r = 1$, the first error term is absent.

Proof. The terms with $\ell < r$ in theorem 13.1 are bounded by a constant times $m^{r-2} R^{-m}$. The term with $\ell = r$ gives the displayed main term. □

Corollary 13.3 (Orbit reduced nearest circle term)**.** *Assume the hypotheses of theorem 13.1. Choose one representative from each orbit of the nearest zeros under multiplication by ω, and call the resulting set $\mathcal{Z}_R^{\mathrm{orb}}$. With $m = Nn$,*

$$P_{N,n}(r) = Nm!\binom{m+r-1}{r-1}\sum_{\tau\in\mathcal{Z}_R^{\mathrm{orb}}}\frac{\tau^{-m}}{(-\tau\mathsf{D}_N'(\tau))^r} + O\left(m!m^{r-2}R^{-m}\right) + O_{R_*}\left(m!R_*^{-m}\right).$$

For $r = 1$, the first error term is absent.

Proof. If $\rho = \omega^k\tau$, then

$$\mathsf{D}_N'(\rho) = \omega^{-k}\mathsf{D}_N'(\tau).$$

Therefore

$$-\rho\mathsf{D}_N'(\rho) = -\tau\mathsf{D}_N'(\tau).$$

Since $m = Nn$, one also has $\rho^{-m} = \tau^{-m}$. Every orbit therefore contributes N equal terms in corollary 13.2. □

Corollary 13.4 (Secant asymptotic)**.** *For $N = 2$ and $r = 1$,*

$$P_{2,n}(1) \sim 2(2n)!\left(\frac{2}{\pi}\right)^{2n+1}.$$

Proof. The nearest zeros of $\cos z$ are $\rho = \pm\pi/2$, both simple. Their contributions in corollary 13.2 are equal. □

14 Zero zeta functions

The assumption $N \geq 2$ remains in force throughout this section. The zero counting theorem gives the exact abscissae of absolute convergence. The exponentially accurate zero locations give more. They compare the zero zeta with a Hurwitz zeta function.

Definition 14.1. Define

$$\mathfrak{Z}_N^{\mathrm{abs}}(s) = \sum_{\rho\in\mathcal{Z}(\mathsf{D}_N)}|\rho|^{-s}$$

and

$$\mathfrak{Z}_N^{\mathrm{red}}(s) = \sum_{\lambda\in\Lambda_N}|\lambda|^{-s},$$

with multiplicities. Each term means $e^{-s\log|\rho|}$ or $e^{-s\log|\lambda|}$.

Theorem 14.2 (Abscissae of absolute convergence)**.** *The series $\mathfrak{Z}_N^{\mathrm{abs}}$ converges absolutely and locally uniformly when*

$$\Re s > 1.$$

It fails to converge absolutely when $\Re s \le 1$. The series $\mathfrak{Z}_N^{\mathrm{red}}$ converges absolutely and locally uniformly when

$$\Re s > \frac{1}{N}.$$

It fails to converge absolutely when $\Re s \le 1/N$. Both functions are holomorphic on their open half-planes of absolute convergence.

Proof. By theorem 11.14, the zeros of D_N have linear counting density, while the reduced zeros have counting order $R^{1/N}$. Partial summation gives absolute convergence in the stated open half-planes. The positive terms obtained after taking absolute values diverge on the boundary and to its left. Local uniform convergence follows by the Weierstrass test on compact subsets. □

Theorem 14.3 (Meromorphic continuation of the symmetry-orbit zero zeta)**.** *Put*

$$A_N = \frac{\pi}{\sin(\pi/N)}.$$

There is an entire function Q_N^{red} such that

$$\mathfrak{Z}_N^{\mathrm{red}}(s) = A_N^{-Ns}\zeta\left(Ns, \frac{1}{2}\right) + Q_N^{\mathrm{red}}(s)$$

on $\Re s > 1/N$. The right-hand side gives a meromorphic continuation to $\mathbb{C}$ with one simple pole at $s = 1/N$. Its residue is

$$\frac{\sin(\pi/N)}{N\pi}.$$

There is an entire function Q_N^{abs} such that, initially on $\Re s > 1$,

$$\mathfrak{Z}_N^{\mathrm{abs}}(s) = NA_N^{-s}\zeta\left(s, \frac{1}{2}\right) + Q_N^{\mathrm{abs}}(s).$$

Thus $\mathfrak{Z}_N^{\mathrm{abs}}$ continues meromorphically to $\mathbb{C}$ with one simple pole at $s = 1$, of residue

$$\frac{N\sin(\pi/N)}{\pi}.$$

Proof. For $N = 2$, corollary 11.10 and $\mathsf{D}_2(z) = \Delta_2(z^2)$ give

$$\lambda_m = \pi^2\left(m + \frac{1}{2}\right)^2, \qquad m \ge 0.$$

Thus the first formula holds with $Q_2^{\mathrm{red}} = 0$.

For $N \ge 3$, corollary 11.13 writes all but finitely many reduced zeros as

$$\lambda_m = \left(A_N\left(m + \frac{1}{2}\right)\right)^N (1 + \varepsilon_m)$$

where $\lambda_m > 0$, $1 + \varepsilon_m > 0$, and

$$\varepsilon_m = O\left(t_m^{-1}e^{-\gamma t_m}\right).$$

On every compact set of s values,

$$(1+\varepsilon_m)^{-s}-1=O(|\varepsilon_m|)$$

uniformly for large m. The difference

$$\lambda_m^{-s}-A_N^{-Ns}\left(m+\frac{1}{2}\right)^{-Ns}$$

therefore has a normally convergent sum on every compact subset of $\mathbb{C}$. Indeed, the model power has at most polynomial growth in m on a compact set, while $|\varepsilon_m|$ decays exponentially. The finitely many exceptional terms $|\lambda|^{-s}$ and the finitely many omitted model terms are entire functions of s. Their addition to the normally convergent tail defines Q_N^{red} and proves the first formula. Thus that formula is established for every $N\geq 2$.

In either case, the Hurwitz zeta function has a meromorphic continuation with one simple pole at its first argument equal to one and residue one. Composition with Ns gives the stated pole and residue.

For every $N\geq 2$, each nonzero zero λ of Δ_N gives N zeros of D_N, each of modulus $|\lambda|^{1/N}$. Hence

$$\mathfrak{Z}_N^{\mathrm{abs}}(s)=N\mathfrak{Z}_N^{\mathrm{red}}(s/N).$$

Substitution gives the second formula with

$$Q_N^{\mathrm{abs}}(s)=NQ_N^{\mathrm{red}}(s/N),$$

which is entire. □

Corollary 14.4 (Exact zeta models in orders two and four)**.** *For $N=2$,*

$$\mathfrak{Z}_2^{\mathrm{red}}(s)=\pi^{-2s}\zeta\left(2s,\frac{1}{2}\right)$$

and

$$\mathfrak{Z}_2^{\mathrm{abs}}(s)=2\pi^{-s}\zeta\left(s,\frac{1}{2}\right).$$

For $N=4$, put $A_4=\sqrt{2}\pi$. Then

$$\mathfrak{Z}_4^{\mathrm{red}}(s)=A_4^{-4s}\zeta\left(4s,\frac{1}{2}\right)$$

and

$$\mathfrak{Z}_4^{\mathrm{abs}}(s)=4A_4^{-s}\zeta\left(s,\frac{1}{2}\right).$$

In these two cases the entire correction terms in theorem 14.3 vanish identically.

Proof. For $N=2$, the reduced zeros are

$$\pi^2\left(m+\frac{1}{2}\right)^2,\qquad m\geq 0.$$

For $N=4$, example 11.12 gives the reduced zeros

$$A_4^4\left(m+\frac{1}{2}\right)^4,\qquad m\geq 0.$$

Summing their negative powers proves the reduced formulas. The absolute formulas follow from

$$\mathfrak{Z}_N^{\mathrm{abs}}(s) = N\mathfrak{Z}_N^{\mathrm{red}}(s/N).$$

□

Definition 14.5. Choose a logarithm for each member of the finite exceptional part of Λ_N. Use the real logarithm for the eventual positive sequence. Define

$$\mathfrak{Z}_N^{\mathrm{orb}}(s) = \sum_{\lambda\in\Lambda_N} e^{-s\operatorname{Log}\lambda}.$$

This series is initially defined on $\Re s > 1/N$.

Corollary 14.6 (Branch-dependent symmetry-orbit continuation)**.** *The branch-dependent orbit zeta $\mathfrak{Z}_N^{\mathrm{orb}}$ continues meromorphically to $\mathbb{C}$. It has the same single pole and residue as $\mathfrak{Z}_N^{\mathrm{red}}$. Changing the logarithms of the finite exceptional zeros changes the continuation by an entire function.*

Proof. The tail consists of positive reduced zeros, so it has the same comparison with the Hurwitz zeta. Only finitely many terms depend on the branch choices. □

Definition 14.7. Let q be a positive integer. Choose logarithms of the simple zeros of D_N with arguments in a fixed bounded interval. Define

$$\mathfrak{Z}_{N,q}^{\mathrm{der}}(s) = \sum_{\substack{\mathsf{D}_N(\rho)=0\\ \mathsf{D}_N'(\rho)\neq 0}} \frac{e^{-s\operatorname{Log}\rho}}{\mathsf{D}_N'(\rho)^q}.$$

Theorem 14.8 (Derivative-weighted convergence)**.** *If $N \geq 3$ and $q \geq 1$, the series $\mathfrak{Z}_{N,q}^{\mathrm{der}}(s)$ converges locally uniformly for every $s \in \mathbb{C}$. It therefore defines an entire function.*
For $N = 2$, the series converges absolutely and locally uniformly on $\Re s > 1$, where it defines a holomorphic function.

Proof. For $N \geq 3$, theorem 11.7 gives

$$|\mathsf{D}_N'(\rho)|^{-1} \leq Ce^{-c_N|\rho|}$$

for every sufficiently large simple zero. Let L be a compact subset of the s plane. Because the chosen arguments of the zeros lie in a fixed bounded interval, there are constants C_L and M_L such that

$$\sup_{s\in L} |e^{-s\operatorname{Log}\rho}| \leq C_L|\rho|^{M_L}$$

for every sufficiently large zero. Hence the absolute value of the corresponding summand is at most

$$C_L'|\rho|^{M_L}e^{-qc_N|\rho|}.$$

The linear zero counting estimate makes this majorant summable. The Weierstrass test gives absolute local uniform convergence of the series of entire summands, so its sum is entire. The finite exceptional set causes no difficulty.

For $N = 2$, the derivative of the cosine has modulus one at every zero. The assertion then follows from the linear zero spacing. □

Remark 14.9. The derivative weighted sum omits the finitely many zeros that might be multiple. A treatment of those zeros requires the complete principal parts of D_N^{-q} rather than the single derivative weight.

Part V Scope and formal evidence

15 Scope boundaries and further questions

The large-zero theorem settles eventual simplicity but does not classify the finite exceptional set. A remaining question is whether every zero of D_N is simple and every reduced zero of Δ_N is positive. Both statements hold for $N = 2$ and $N = 4$. The argument here proves them only outside a compact set for general N.

The leading correction in theorem 11.8 may admit iteration to a full exponential expansion for τ_m. Such an expansion is an open problem, not a result of this chapter. It could refine the entire correction in the zero-zeta comparison and lead to explicit special values.

The symmetry-orbit zero zeta has a meromorphic continuation with one pole. No functional equation is obtained. A branch dependent sum over the N roots of each reduced zero must specify logarithms on the rays.

The coefficient families in sections 7, 9 and 10 have exact formal parameter-addition laws. Their arithmetic behavior, including odd-prime congruences, dyadic weighting, and p-adic or Amice–Mahler interpolation, belongs to Chapter IX. General bounded-operator semigroup, resolvent, and Feshbach theory belongs to Chapter VI. Chapter III covers general nonlinear operation trees, while abstract completion and occupancy questions belong to Chapter X. None of those theories is inferred from the scalar complex-analytic results proved here.

16 Formalization ledger

The source records specify the Lean and Mathlib environment used for the recorded verification [dMU21, The20]. Its 151 theorem-map rows resolve to 1164 unique declarations in Komorebi.PaperIV: 953 theorem declarations and 211 constructions. The namespace audit scanned 2234 declarations, including 1999 theorem declarations. The build and kernel audit, with warnings treated as errors, allowed only propext, Classical.choice, and Quot.sound as standard transitive axioms.

Manuscript records	Compiled Chapter IV scope
3.1–3.3	Actual holomorphic root filters, convergent coefficient selection, orthogonal resolution, the exact range–covariance characterization, and the complete pointwise cyclic product law. The formal versions hold as well.
4.1–4.5 and 5.1–5.8	Entire sections, finite exponential formulas, derivative cycles, both Wronskians, and unique entire ODE basis expansions. Both pointwise addition laws and denominator symmetries are checked. The exact ordinary hypergeometric formula follows from the omitted-parameter list, Gamma normalization, and Mathlib's everywhere convergent series.

Manuscript records	Compiled Chapter IV scope (continued)
6.1–6.6	Quotient-algebra power bases and actual exponential-series convergence in the finite-dimensional coefficient topology. Both pointwise section-coordinate identities. Signed-shift powers, all matrix-exponential entries, group laws and trace are checked. The characteristic polynomial $X^N + 1$, its distinct roots, exact spectrum and determinant one are proved.
7.1–7.8	Named reciprocal families, exact parameter recurrences, Bell formula, parameter degree and leading coefficient, and polynomial divisibility. Parameter addition holds with any single fixed holomorphic logarithm on the stated domain. Newton's recurrence gives the literal Hessenberg determinant. All three compact reciprocal-polynomial formulas are checked.
8.1–8.5	The full tangent coefficient series has the exact kappa and factorial normalization, including $N = 1$. Reciprocal differentiation holds on every stated fixed logarithm domain. The actual higher Riccati identity holds at every point where the denominator is nonzero.
9.1–9.10	Arbitrary-parameter residue reciprocals and their analytic germs, polynomial degree and leading term, sparse Appell laws, joint convolution, monicity and covariance. The Hasse and derivative-truncation encodings are proved equal. The named Appell polynomial satisfies both the forward action and the exact $\Phi_{N,j}(\partial_x^N)^r$ inverse formula.
10.1–10.4	Exact formal theta reconstruction, polynomial lift and degree, literal divisibility by u and, for even N, by $u + 1$, and the theta Newton recurrence with its first coefficient.
11.2, 11.4–11.11	Two-sided maximum-modulus bounds prove exact order and type. The indicator limsup formula holds in every direction, including ties. Dominant-exponential errors and zero freeness are uniform on compact sets avoiding ties. Near cancellation and the order-two zero set are checked. For $N \geq 3$, gap and remainder bounds, sector confinement, global exhaustion and multiplicity identities give the full large-zero-string theorem. The real leading correction, quadratic exponential error, signed derivative asymptotic, eventual alternating sign and cubic correction are checked.
11.13–11.15	The reduced series is entire, and $\mathsf{D}_N(z) = \Delta_N(z^N)$ preserves multiplicity away from zero. Finite exceptional sets, eventual positive simple reduced zeros, and their stated displacement are checked, including $N = 2$. Both full disk-counting laws retain all exceptional multiplicities. The full-zero reciprocal sums have exact thresholds $s > 1$ and $s > 1/N$, including boundary divergence.
12.1	For every $N \geq 2$, the complete multiplicity-indexed product converges uniformly on compact sets and equals Δ_N. Jensen and Poisson estimates prove rigidity of the actual quotient from derived growth bounds. No growth certificate remains. The original-variable product for D_N is also checked.
12.2–12.4	The actual diagonal operator is trace class, with a basis-independent trace and determinant given by limits of actual finite compressions. Infinite complete homogeneous coefficients are limits of finite monomial sums. Every normalized section has exact order $1/N$. For $N \geq 2$ its full zero product and zero-moment Bell formulas are proved. The actual complex-power germ at zero has the named residue Taylor coefficients.

Manuscript records	Compiled Chapter IV scope (continued)
12.6–12.10	The normalized logarithm on each zero-free disk has the convergent zero-moment series. Its coefficients equal $\kappa_{N,m}$ and satisfy Newton's recurrence. The Mittag–Leffler tangent expansion converges absolutely and locally uniformly away from poles. Tangent coefficients and the named reciprocal and theta families have their exact zero-moment Bell formulas. The full tangent series is identified with the analytic function.
13.1–13.4	Analytic division constructs each simple-zero principal part. Its leading coefficient is uniquely determined. Removing the principal parts gives a holomorphic remainder and the exact factorial-scaled Cauchy estimate. Both leading-term errors are bounded, with the first absent for $r = 1$. Rotation gives the orbit-reduced main term. The secant formula holds as a ratio limit, with an exponentially vanishing relative error.
14.2–14.4, 14.6	The exact all-zero sums retain analytic multiplicity. Their sharp absolute-convergence domains, boundary divergence and local uniform convergence are checked. Both Hurwitz comparisons, entire corrections, global meromorphic continuations, unique simple poles and exact residues are proved. The order-two/four models have identically zero corrections. Branch choices on the finite exceptional part change the continuation by an entire function and preserve its pole and residue.
14.8	The derivative-weighted series uses every actual simple zero and genuine logarithms with bounded arguments. Absolute and local uniform convergence and an entire sum are proved for $N \geq 3$. For $N = 2$, absolute/local uniform convergence and holomorphy hold on $\Re s > 1$.

The declaration-level theorem map is authoritative for the formal contract. It records full scoped coverage of all 68 theorem-like records: 68 full, zero partial, and zero unmapped. Rows 143–151 close the final fifteen partial records without altering their statements or assumptions. Imported standard fact 11.1 remains imported. Formal identities, normalized analytic germs, and fixed logarithm domain identities retain their respective stated meanings. Finite computations do not change these proof boundaries.

17 Conclusion

Cyclic projection turns the exponential into a finite differential basis, and the signed cycle produces the distinguished denominator D_N. Its reciprocal powers yield Bell and Newton recurrences, an additive parameter law, Appell systems, and theta polynomials. Reduction by $w = z^N$ then connects the reciprocal coefficients to a genus zero product and reduced-zero power sums.

Classical two term localization, specialized to the regular exponent polygon and combined with reflection symmetry, places all sufficiently large zeros on symmetry rays. The displacement, derivative and counting estimates yield the family-specific Hurwitz comparison for the orbit zero zeta.

A Visual atlas

The twenty-six plates retain the worked models of the separate visual guide. The stable labels for Plates IV.1–IV.26 name mathematical mechanisms and point back to the relevant statements. The plates distinguish exact identities, rational certificates, sampled curves, and inherited formal evidence.

Three routes through the atlas

For algebra, read Plates IV.3–IV.16. For zero geometry and its consequences, read Plates IV.17–IV.24. Plate IV.25 follows one coefficient through the complete calculation. Plate IV.26 explains the evidence attached to the models.

Plate IV.1 / READER'S GUIDE

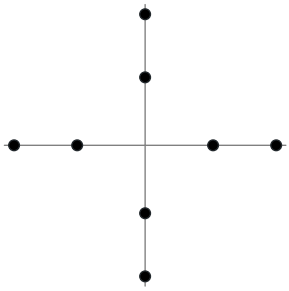
A coefficient can become zero data

Chapter IV: Section 2, Section 7, Section 11, Section 12.

This guide follows a concrete analytic family through three descriptions: selected Taylor coefficients, a finite differential system, and the zeros of an entire function. The formulas are linked, but the evidence needed for each description is different.

COEFFICIENT LANES

z^0	z^3	z^6	z^9
z^1	z^4	z^7	z^{10}
z^2	z^5	z^8	z^{11}



$m \equiv j \pmod 3$

RECIPROCAL COEFFICIENTS

1	0	0
$-\frac{1}{2}$	1	0
$\frac{1}{24}$	$-\frac{1}{2}$	1

$1, \quad \frac{1}{2}, \quad \frac{5}{24}, \ldots$

ZERO ORBITS

$\{\rho, i\rho, -\rho, -i\rho\}$

Keep three small models in view

For $N = 2$, the signed denominator is $D_2(z) = \cos z$. Its reciprocal is the familiar secant series. For $N = 3$, a third exponential perturbs the zeros of a dominant cosine. For $N = 4$, an exact factorization gives a complete zero picture:

$$D_4(z) = \cos(z/\sqrt{2})\cosh(z/\sqrt{2}).$$

The examples move between these orders deliberately. Order two makes the coefficient arithmetic transparent. Order three shows a genuine displacement. Order four makes orbit reduction completely explicit.

Three routes through the guide

Route	Pages and question
Algebra first	Plate IV.3 to Plate IV.16: how do selection, signs, reciprocals, and finite differential operators work?
Zeros first	Plate IV.17 to Plate IV.24: where can cancellation happen, and how does it determine coefficients?
One full calculation	Plate IV.25: derive the same number, 69, from denominator coefficients and from zero moments.

Read this as: The pictures carry computable objects. They do not replace the global analytic arguments or extend the inherited Lean contract.

Exact identities and rational certificates are distinguished from sampled curves. All plates are reproducible vector drawings. The source package preserves the original proofread manuscript.

Plate IV.2 / OBJECT ATLAS

Two variables, several normalizations

Chapter IV: Section 2, Definition 5.7, Definition 7.1, Definition 9.1.

The most important coordinate change is $w = z^N$. A term of degree n in w has degree Nn in z. Its coefficient does not change, but an exponential-generating-function label does.

$$\underbrace{b_{N,n}(r)\,w^n}_{\text{ordinary coefficient}} = \underbrace{P_{N,n}(r)\frac{z^{Nn}}{(Nn)!}}_{\text{block exponential coefficient}}, \qquad P_{N,n}(r) = (Nn)!\,b_{N,n}(r).$$

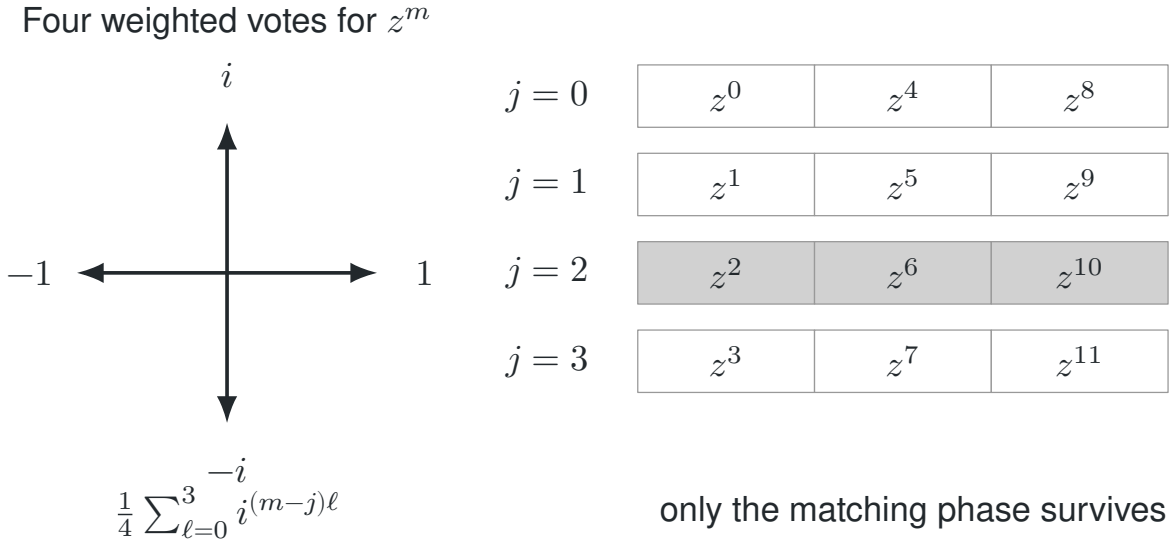
Object	Definition and role
$E_{N,j}(z)$	$\displaystyle\sum_{n\geq 0}\frac{z^{Nn+j}}{(Nn+j)!}$ selects one residue class of the exponential.
$D_{N,j}(z)$	The same series with $(-1)^n$. One full derivative cycle contributes a minus sign.
$D_N(z)$	$D_{N,0}(z)$, the denominator whose zeros control the signed reciprocal family.
$\Delta_N(w)$	$\displaystyle\sum_{n\geq 0}\frac{(-1)^n w^n}{(Nn)!}$. Thus $D_N(z) = \Delta_N(z^N)$.
$P_{N,n}(r)$	Block-EGF coefficients of D_N^{-r}. They are polynomials in r.
$\kappa_{N,m}$	$-\log \Delta_N(w) = \displaystyle\sum_{m\geq 1}\kappa_{N,m}w^m/m$.
$T_N(z)$	$-D_N'(z)/D_N(z)$, a function, not the coefficient $T_N(n)$.
$\Phi_{N,j}(w)$	$j!\displaystyle\sum_{n\geq 0}\frac{w^n}{(Nn+j)!}$ removes the forced zero of $E_{N,j}$.
$C_{N,j}(z)$	$1/\Phi_{N,j}(z^N)$. This is generally not $1/D_N(z)$.
Λ_N	Zeros of Δ_N, counted with multiplicity, one per rotational orbit of zeros of D_N.

A normalization test

The coefficient $5/24$ of w^2 in $\Delta_2(w)^{-1}$ is the same term as $5z^4/4!$. It is not $5w^2/2!$. Keeping the two factorials separate prevents errors in Bell formulas, convolution weights, and zero-moment reconstruction.

> **Read this as:** Use z for differentiation and rotational geometry. Use w for reciprocal recurrences, canonical products, and orbit-zero sums.

Plate IV.3 / CYCLIC PROJECTION



A root filter is an exact vote

Chapter IV: Theorem 3.1, Proposition 3.2.

For $N = 4$, write $\omega = i$. To extract residue j, evaluate the function at four rotated arguments and attach the phase $i^{-j\ell}$:

$$(\mathcal{B}_{4,j}F)(z) = \frac{1}{4}\sum_{\ell=0}^{3} i^{-j\ell}F(i^{\ell}z).$$

A monomial $a_m z^m$ is multiplied by the finite average of $i^{(m-j)\ell}$. Matching phases all vote 1. Nonmatching phases cancel exactly.

An example that can be checked coefficient by coefficient

Take $F(z) = \sum_{m=0}^{12}(m+1)z^m$. Then

$$\mathcal{B}_{4,2}F = 3z^2 + 7z^6 + 11z^{10}.$$

Applying the same selector again changes nothing. Applying a different selector gives zero. Summing the four selected polynomials returns the original F.

Selection is also a symmetry condition

For the selected polynomial F_2, rotation gives $F_2(iz) = -F_2(z)$. More generally, a residue-j section satisfies $F_j(\omega z) = \omega^j F_j(z)$. The phase label therefore describes both the coefficient addresses and the response to rotation.

> **Read this as:** This is not an approximate Fourier fit. The finite root sum is exactly 0 or 1 on every coefficient.

The checker compares the actual complex average with independent coefficient selection for this polynomial. The drawing shows the four complex phases, not a numerical convergence argument.

Plate IV.4 / CYCLIC CONVOLUTION

Products mix the residue lanes

Chapter IV: Theorem 3.3.

Selection separates a function additively. It does not make multiplication diagonal. A residue-i term multiplied by a residue-j term lands in residue $i + j \pmod N$. For $N = 3$, use

$$F = 1 + 2z + 3z^2 + z^3, \qquad G = 2 + z + z^2.$$

The table displays every product of their three selected sections.

	2	z	z^2
$z^3 + 1$	$2z^3 + 2$	$z^4 + z$	$z^5 + z^2$
$2z$	$4z$	$2z^2$	$2z^3$
$3z^2$	$6z^2$	$3z^3$	$3z^4$

$$\mathcal{B}_{3,0}(FG) = 2 + 7z^3$$

shaded cells: $(0,0), (1,2), (2,1)$ all land in residue 0

The shaded cells contribute to residue zero:

$$2(1 + z^3) + (2z)(z^2) + (3z^2)z = 2 + 7z^3.$$

Keeping only the product of the residue-zero inputs would give $2 + 2z^3$ and lose five units of the z^3 coefficient. The mixed cells are part of the exact result.

The general rule

$$\mathcal{B}_{N,k}(FG) = \sum_{i+j \equiv k \ (N)} (\mathcal{B}_{N,i}F)(\mathcal{B}_{N,j}G).$$

Every pair belongs to exactly one output residue. No term is discarded and no coefficient is estimated. This finite cyclic convolution is the algebra behind the later addition formulas and block-coefficient recurrences.

> **Read this as:** A packet label tells you where an interaction lands, not that interactions with other packets vanish.

All nine table entries and all three output sections are checked as exact polynomial identities. This is the scalar cyclic specialization used in this chapter.

Plate IV.5 / DIFFERENTIAL SYSTEM

One signed edge determines the cycle

Chapter IV: Theorem 5.3, Theorem 6.4, Corollary 6.5, Corollary 6.6.

Let $J_3e_0 = e_1$, $J_3e_1 = e_2$, and $J_3e_2 = -e_0$. A complete turn changes sign, so $J_3^3 = -I$. The signed sections are the coordinates of $e^{zJ_3}e_0$.

J_3

0	0	-1
1	0	0
0	1	0

e^{zJ_3}

D_0	$-D_2$	$-D_1$
D_1	D_0	$-D_2$
D_2	D_1	D_0

$$J_3^3 = -I$$

$$\mathbf{D}_3(0) = e_0$$

$$\det e^{zJ_3} = 1$$

$$D_0 \mapsto -D_2, \qquad D_1 \mapsto D_0, \qquad D_2 \mapsto D_1$$

Here D_j inside the matrix means $D_{3,j}(z)$. For example,

$$D_{3,0} = 1 - \frac{z^3}{3!} + \frac{z^6}{6!} - \cdots, \qquad D_{3,1} = z - \frac{z^4}{4!} + \cdots.$$

Rows are output coordinates and columns are input coordinates. The upper-triangular minus signs record crossing the signed edge while moving from the column to the row. They are not arbitrary orientation choices.

Two checks connect the matrix and the scalar equation

The initial derivative matrix is the identity. Each initial jet $(y(0), y'(0), y''(0))$ therefore determines a unique linear combination. Also,

$$\frac{1}{3}\operatorname{Tr}(e^{zJ_3}) = D_3(z), \qquad \det(XI - J_3) = X^3 + 1.$$

The roots of -1 appearing later in the exponential sum are already the spectrum of this concrete matrix.

> **Read this as:** The functions, their initial data, the addition law, and the exponent polygon come from one signed shift.

The exact tests check every matrix-entry Taylor coefficient through degree 14 for $N = 1, \ldots, 5$. The displayed determinant-one law is for $N \geq 2$. $N = 1$ is a separate boundary case.

Plate IV.6 / FINITE ALGEBRA

Addition is quotient multiplication

Chapter IV: Proposition 5.5, Theorem 6.2.

Work in $\mathbb{C}[\xi]/(\xi^3+1)$. Every element has coordinates in $1, \xi, \xi^2$. The entire exponential has the finite-coordinate form

$$e^{z\xi} = D_{3,0}(z) + D_{3,1}(z)\xi + D_{3,2}(z)\xi^2.$$

The multiplication table makes the carry sign unavoidable.

	1	ξ	ξ^2
1	1	ξ	ξ^2
ξ	ξ	ξ^2	-1
ξ^2	ξ^2	-1	$-\xi$

$$\xi^3 = -1$$

wrap once: change sign

$$\xi^2\xi^2 = -\xi$$

$$D_{3,0}(z+w) = D_{3,0}(z)D_{3,0}(w) - D_{3,1}(z)D_{3,2}(w) - D_{3,2}(z)D_{3,1}(w)$$

Multiply the coordinate forms of $e^{z\xi}$ and $e^{w\xi}$. Their product is $e^{(z+w)\xi}$. The coefficient of 1 receives one contribution without a wrap and two contributions with a wrap. Reading that coefficient gives the displayed addition law.

Compare the unsigned model

In $\mathbb{C}[\xi]/(\xi^3 - 1)$, the same table has no minus signs. Its exponential coordinates are the unsigned sections $E_{3,j}$. Thus the difference between the two differential systems is a single algebraic relation, not a change in how coefficients are grouped. For general N, the carry factor is

$$(-1)^{\lfloor (i+j)/N \rfloor}, \qquad 0 \le i, j < N.$$

Only zero or one wrap is possible in a product of two coordinate basis elements.

> **Read this as:** The twisted addition law is the ordinary exponential group law expressed in a signed cyclic algebra.

Bivariate Taylor identities are checked through total degree ten in every section for $N = 2, 3, 4$. Omitting the carry sign is one of the deliberately rejected controls.

Plate IV.7 / FACTORIAL NORMALIZATION

Why a hypergeometric name appears

Chapter IV: Theorem 4.5.

The hypergeometric form is another way to organize the same coefficients. It does not introduce an extra function into the construction. Split a factorial into its residue classes and divide each factor by N:

$$(Nn+j)! = j!N^{Nn}n! \prod_{a\in A_{N,j}} (a)_n.$$

The parameter equal to 1 is omitted from $A_{N,j}$ because the hypergeometric convention already supplies $(1)_n = n!$.

$$N=3,\ j=1,\ n=2: \quad 7! = 1!\,3^6\,2!\,(2/3)_2(4/3)_2$$

$\frac{2}{3}$	$\frac{5}{3}$
1	2
$\frac{4}{3}$	$\frac{7}{3}$

$(2/3)_2$

$(1)_2 = 2!$

$(4/3)_2$

$$A_{3,1} = \{2/3, 4/3\}$$

$$E_{3,1}(z) = z\,{}_0F_2\left(;\frac{2}{3},\frac{4}{3};\frac{z^3}{27}\right)$$

The omitted unit parameter is already the hypergeometric $n!$.

Check the displayed case

For $N=3, j=1, n=2$, the six factors after the initial $1!$ are $2,3,4,5,6,7$. Dividing by three and grouping them gives the three rows of the plate. The middle row supplies $2!$. The others supply $(2/3)_2$ and $(4/3)_2$. The right-hand side is exactly 5040. Consequently,

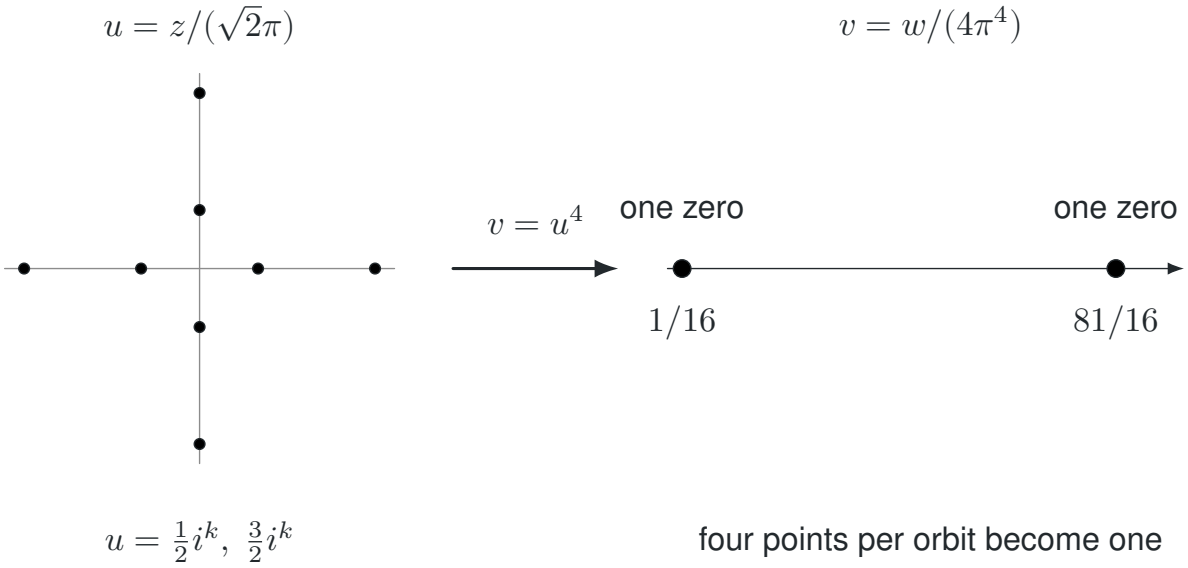
$$E_{3,1}(z) = z\left(1+\frac{z^3}{4!}+\frac{z^6}{7!}+\cdots\right).$$

The prefactor z retains the forced zero at the origin. The hypergeometric argument $z^3/27$ retains the scaling N^N.

> **Read this as:** Parameters, the omitted unit parameter, the prefactor, and the argument scaling all come from factorial bookkeeping.

Five choices of (N, j) are checked against the exact factorial identity for $n = 0, \dots, 7$. These finite checks support the example. The general analytic identification belongs to the inherited manuscript.

Plate IV.8 / THE REDUCED VARIABLE



Four zeros become one orbit zero

Chapter IV: Definition 5.7, Example 11.12, Corollary 11.13.

For $N = 4$ the factorization is exact:

$$D_4(z) = \cos(z/\sqrt{2})\cosh(z/\sqrt{2}), \qquad D_4(z) = \Delta_4(z^4).$$

Set $A_4 = \sqrt{2}\pi$. All the zeros are $A_4(m + 1/2)i^k$, with $m \geq 0$ and $0 \leq k < 4$. Each zero is simple.

The drawing uses $u = z/A_4$ and $v = w/A_4^4$, so its marked coordinates are rational. The first four-point orbit has fourth power $1/16$. The second has fourth power $81/16$.

Multiplicity is not multiplied in the reduced function

At a nonzero point, $z \mapsto z^4$ has nonzero derivative. It preserves the local multiplicity of a zero. Four distinct simple zeros of D_4 therefore correspond to one simple zero of Δ_4, not one zero of multiplicity four. The reduced zeros are

$$\lambda_m = A_4^4(m + 1/2)^4 = 4\pi^4(m + 1/2)^4.$$

This is why an orbit factor in the z plane is $1 - z^4/\lambda_m$. It is the product of the four corresponding linear factors, with their phases included.

> **Read this as:** Orbit reduction removes repetition. It changes growth and counting exponents, while preserving each nonzero zero's local multiplicity.

The quartic factorization, its differential equation, and the displayed orbit powers are checked independently. Here the complete zero set is known exactly. A finite numerical root search is not being used to establish it.

Plate IV.9 / COEFFICIENT RECONSTRUCTION

A reciprocal is a triangular solve

Chapter IV: Theorem 7.3, Theorem 7.6.

Start in the reduced variable with

$$\Delta_2(w) = 1 - \frac{w}{2} + \frac{w^2}{24} - \frac{w^3}{720} + \cdots.$$

Write $1/\Delta_2(w) = \sum b_n w^n$. Matching the product with 1 gives a unit lower-triangular system. At each row there is exactly one new unknown.

denominator convolution				b		unit series
1	0	0	0	1	$=$	1
$-\frac{1}{2}$	1	0	0	$\frac{1}{2}$		0
$\frac{1}{24}$	$-\frac{1}{2}$	1	0	$\frac{5}{24}$		0
$-\frac{1}{720}$	$\frac{1}{24}$	$-\frac{1}{2}$	1	$\frac{61}{720}$		0

$$b_1 = \tfrac{1}{2}$$

$$b_2 = \tfrac{1}{4} - \tfrac{1}{24}$$

$$b_3 = \tfrac{61}{720}$$

$$P_{2,n}(1) = (2n)!b_n : \qquad 1,\ 1,\ 5,\ 61$$

The first three equations are

$$b_1 - \tfrac{1}{2} = 0, \qquad b_2 - \tfrac{1}{2}b_1 + \tfrac{1}{24} = 0, \qquad b_3 - \tfrac{1}{2}b_2 + \tfrac{1}{24}b_1 - \tfrac{1}{720} = 0.$$

They yield $b_1 = 1/2$, $b_2 = 5/24$, and $b_3 = 61/720$. Multiplication by $(2n)!$ produces the secant coefficients $1, 5, 61$.

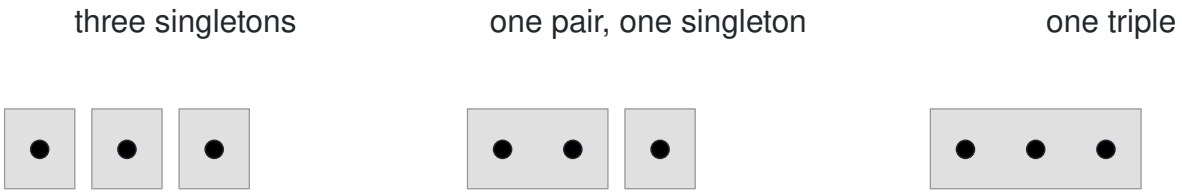
Why this is an exact finite calculation

To compute the coefficient of w^n, only denominator coefficients through w^n are needed. Later terms of the entire series cannot affect it. A finite series inverse is therefore exact at its declared truncation order, even though evaluating that truncated series is only an approximation to the full analytic function away from the origin.

> **Read this as:** A unit constant term makes coefficient recovery triangular. It does not by itself specify the radius of analytic convergence.

The checks compare an independent binomial-series expansion, the parameter recurrence, and the logarithmic Newton recurrence through block index six. The table uses ordinary coefficients, with factorial conversion shown separately.

Plate IV.10 / BELL PARTITIONS



The reciprocal order is a polynomial

Chapter IV: Theorem 7.2, Corollary 7.7.

Let r vary instead of fixing the reciprocal power. Since

$$\Delta_N(w)^{-r} = \exp\left(r \sum_{m \geq 1} \kappa_{N,m} \frac{w^m}{m} \right),$$

the coefficient of w^n is a polynomial of degree n in r. Bell polynomials collect the possible ways logarithmic terms contribute total degree n.

$$r^3\kappa_1^3 \qquad 3r^2\kappa_1\kappa_2 \qquad 2r\kappa_3$$

$$15r^3 \qquad 30r^2 \qquad 16r$$

$$P_{2,3}(r) = \tfrac{6!}{3!}\, B_3(r\kappa_1, r\kappa_2, 2r\kappa_3)$$

For $N = 2$, the first three logarithmic coefficients are

$$\kappa_1 = \frac{1}{2}, \qquad \kappa_2 = \frac{1}{6}, \qquad \kappa_3 = \frac{1}{15}.$$

The third Bell polynomial is $B_3(x_1, x_2, x_3) = x_1^3 + 3x_1x_2 + x_3$. Substituting $x_1 = r\kappa_1$, $x_2 = r\kappa_2$, $x_3 = 2r\kappa_3$ and multiplying by $6!/3!$ gives

$$P_{2,3}(r) = 15r^3 + 30r^2 + 16r.$$

At $r = 1$ this is 61. At $r = 2$ it is 272. At $r = 0$ it vanishes, as every positive-index reciprocal coefficient must.

The leading term has a simple source

Only n copies of the linear logarithmic term can contribute $r^n w^n$. Therefore

$$[r^n]P_{N,n}(r) = \frac{(Nn)!}{n!(N!)^n}.$$

> **Read this as:** The polynomial parameter records how many logarithmic pieces are combined. It is not a numerical interpolation in the reciprocal order.

The partition plate is a finite combinatorial expansion. The exact tests verify the leading coefficient and parameter polynomial through block index six for five orders.

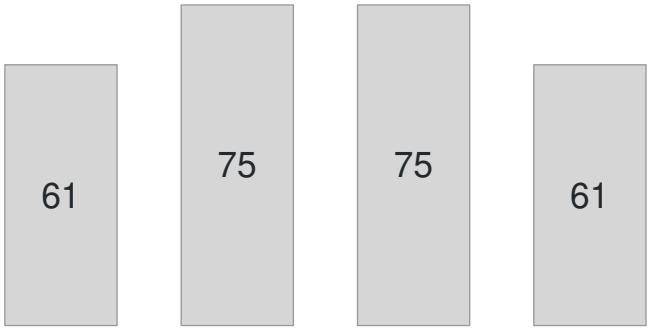
Plate IV.11 / NEWTON AND ADDITION

Two recurrences reach the same answer

Chapter IV: Theorem 7.3, Theorem 7.4, Theorem 7.6.

One recurrence uses the denominator coefficients. Another uses its logarithm. With $b_n(r) = P_{N,n}(r)/(Nn)!$, the shorter logarithmic form is

$$nb_n(r) = r\sum_{k=1}^{n} \kappa_{N,k} b_{n-k}(r), \qquad b_0 = 1.$$



The negative superdiagonal in the Newton determinant is essential.

$n!b_n(r)$ for $n = 3$

$\frac{r}{2}$	-1	0
$\frac{r}{6}$	$\frac{r}{2}$	-2
$\frac{r}{15}$	$\frac{r}{6}$	$\frac{r}{2}$

$\det /6 = P_{2,3}(r)/720$

$P_{2,3}(2) = 61 + 75 + 75 + 61 = 272$

block weights: $1, 15, 15, 1$

The additive parameter law has block weights

Using the same logarithm, $D_N^{-r} D_N^{-s} = D_N^{-(r+s)}$. Thus

$$P_{N,n}(r+s) = \sum_{q=0}^{n} \binom{Nn}{Nq} P_{N,q}(r) P_{N,n-q}(s).$$

For $N = 2, n = 3, r = s = 1$, the four weights are $1, 15, 15, 1$. The two middle terms are $15 \cdot 1 \cdot 5$ and $15 \cdot 5 \cdot 1$. Together with the endpoints, they give 272. Using $\binom{n}{q}$ instead would be incorrect for these coefficients. That ordinary binomial law belongs to the separately normalized sequence $n!P_{N,n}/(Nn)!$.

> **Read this as:** Agreement of independent recurrences is a useful check precisely because their bookkeeping is different. Neither permits silently changing the factorial convention.

The checker compares both recurrence routes and the determinant, then checks the parameter-addition identity symbolically. A deliberately incorrect ordinary-binomial substitution is rejected.

Plate IV.12 / LOGARITHMIC DIFFERENTIATION

Compress the ODE into a tangent

Chapter IV: Proposition 8.2, Corollary 8.4, Theorem 8.5.

The transfer tangent is $T_N = -D_N'/D_N$. It compresses the linear differential equation into a nonlinear scalar identity. This division is allowed only on the zero-free set of the denominator.

LINEAR EQUATION	LOGARITHMIC DERIVATIVE
$D_2'' = -D_2$	$T_2' = 1 + T_2^2$
$D_3''' = -D_3$	$T_3'' - 3T_3T_3' + T_3^3 = 1$

$$T_N = -D_N'/D_N \quad \text{only where } D_N \neq 0$$

$$T_4(z) = \frac{z^3}{3!} + 34\frac{z^7}{7!} + \cdots$$

The coefficients retain the reduced logarithmic information:

$$T_N(z) = N\sum_{m\geq 1} \kappa_{N,m} z^{Nm-1}, \qquad T_N(n) = N(Nn+N-1)!\kappa_{N,n+1}.$$

For order four, $\kappa_{4,1} = 1/24$ and $\kappa_{4,2} = 17/10080$. These give $T_4(0) = 1$ and $T_4(1) = 34$, explaining the last line of the plate.

A nonlinear equation with a precise origin

If $D = e^g$ locally, then $g' = -T$. Differentiating e^g three times gives $D'''/D = -T'' + 3TT' - T^3$. Setting $D'''/D = -1$ yields the cubic Riccati identity shown above. No additional nonlinear model has been assumed. The reciprocal family also satisfies $(D_N^{-r})' = rT_N D_N^{-r}$ on a fixed-log domain. Behavior at zeros of D_N depends on the reciprocal order and the branch conventions stated on Plate IV.13.

> **Read this as:** The nonlinear tangent equation is exact where division is legal. It is not a global regular differential equation across the zeros.

The tests verify the tangent coefficient recurrence, the exact cubic ODE, and the symbolic Riccati reduction after clearing denominators. The order-one tangent is the separate constant function $T_1 = 1$.

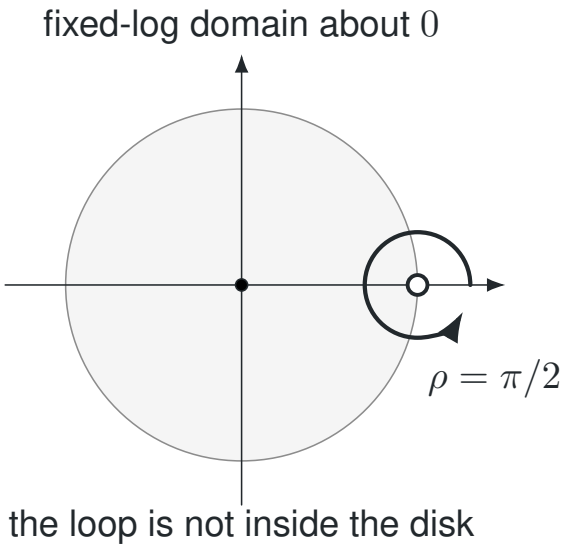


Plate IV.13 / BRANCH BOOKKEEPING

A complex power needs a domain

Chapter IV: Section 2, Definition 7.1, Corollary 8.4.

A formal unit series has a formal logarithm at the origin. To interpret that germ analytically, choose a simply connected zero-free region containing 0 and normalize the logarithm to vanish there.

$$D_N(z)^{-r} = \exp(-rL(z)), \qquad e^{L(z)} = D_N(z), \quad L(0) = 0.$$

$$D(z) \sim D'(\rho)(z - \rho)$$

$$\log D \longmapsto \log D + 2\pi i$$

$$D^{-r} \longmapsto e^{-2\pi i r} D^{-r}$$

$$r = 1/2 : \ -1 \qquad r \in \mathbb{Z} : \ 1$$

For $D_2 = \cos z$, the open disk $|z| < \pi/2$ is an admissible domain. A small loop around the simple zero $\rho = \pi/2$ is not contained in that disk. Analytic continuation around the zero changes the local logarithm by $2\pi i$, and the power by $e^{-2\pi i r}$.

Three different kinds of statement

A *formal* identity compares coefficients at the origin. A *holomorphic* identity for complex powers uses a common specified logarithm. A positive *integer* reciprocal power is globally meromorphic and needs no branch choice. These scopes cannot be exchanged without a further argument. For example, $D^{-r}D^{-s} = D^{-(r+s)}$ is immediate using one fixed logarithm. Combining values built from unrelated branches can introduce additional phase factors.

> **Read this as:** The branch choice is mathematical data. It is not a plotting convention that can be removed by drawing a cleaner curve.

The domain picture is schematic. The phase change comes from the local simple-zero model and winding number, not from a sampled loop. Later nearest-pole asymptotics retain positive integral reciprocal order.

Plate IV.14 / NORMALIZED SECTIONS

Three similar reciprocals differ

Chapter IV: Definition 9.1, Theorem 9.2, Example 9.11.

The signed denominator and the normalized unsigned sections produce different reciprocal families. In order two,

$$D_2^{-1} = \sec z, \qquad C_{2,0} = \operatorname{sech} z, \qquad C_{2,1} = z/\sinh z.$$

Their first block-EGF coefficients make the difference visible.

function	1	$z^2/2!$	$z^4/4!$	$z^6/6!$
$\sec z$	1	1	5	61
$\operatorname{sech} z$	1	-1	5	-61
$z/\sinh z$	1	$-\frac{1}{3}$	$\frac{7}{15}$	$-\frac{31}{21}$

$$E_{2,1}(z) = \sinh z = z\Phi_{2,1}(z^2), \qquad C_{2,1}(0) = 1$$

Remove the forced zero before taking a reciprocal

The section $E_{N,j}$ begins with $z^j/j!$. Define

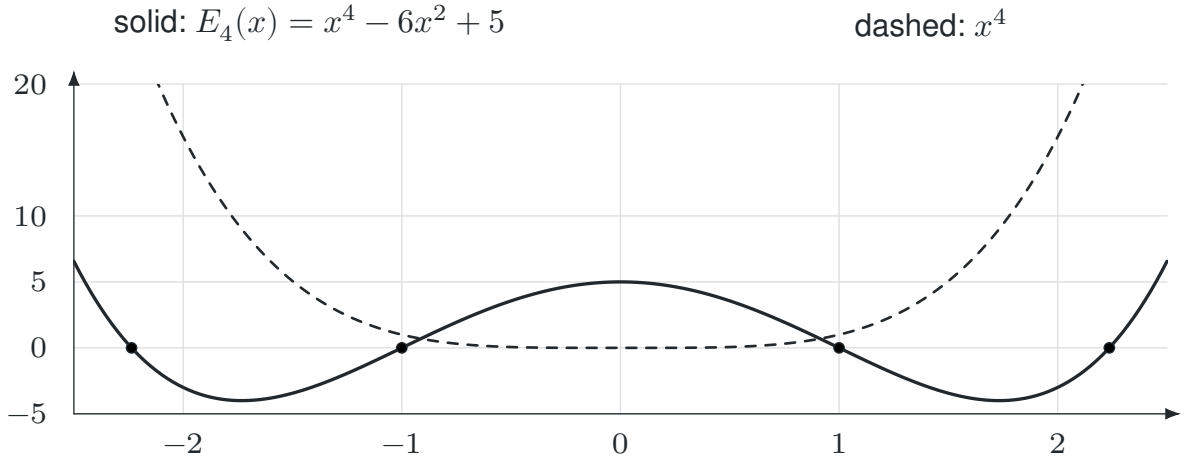
$$E_{N,j}(z) = \frac{z^j}{j!}\Phi_{N,j}(z^N), \qquad \Phi_{N,j}(0) = 1.$$

Then $C_{N,j}(z) = 1/\Phi_{N,j}(z^N)$ has value 1 at the origin. For $j > 0$, the notation $(z^j/j!)/E_{N,j}(z)$ means this removable continuation. It does not mean evaluating an undefined $0/0$ expression. For $N = 2, j = 1$, the first nontrivial coefficient is $-1/3$ in front of $z^2/2!$, equivalently $-z^2/6$. Dropping the numerator z would instead produce the pole of $1/\sinh z$.

> **Read this as:** A minus sign in the denominator series and removal of an initial zero are different operations. Their reciprocal coefficients should not be interchanged.

All entries in the table are exact rationals computed from independent triangular inverses. The table explicitly uses block-EGF columns. Ordinary coefficients are obtained by dividing by the displayed factorials.

Plate IV.15 / APPELL POLYNOMIALS



An infinite symbol acts finitely

Chapter IV: Theorem 9.6, Theorem 9.8, Proposition 9.9.

For $C_{2,0}(z) = \operatorname{sech} z$, define $E_m(x)$ by $\operatorname{sech} z\, e^{xz} = \sum E_m(x) z^m/m!$. The formal differential-operator formula is

$$E_m(x) = \operatorname{sech}(\partial_x) x^m.$$

Although the symbol is an infinite series, derivatives above degree m vanish.

$$\cosh(\partial_x) E_4 = E_4 + \tfrac{1}{2} E_4'' + \tfrac{1}{24} E_4^{(4)} = x^4$$

For $m = 4$, only three terms survive:

$$\left(1 - \frac{\partial_x^2}{2!} + 5\frac{\partial_x^4}{4!}\right) x^4 = x^4 - 6x^2 + 5.$$

The four real roots of this polynomial are $\pm 1, \pm\sqrt{5}$. They are not the zeros of the original analytic denominator. The plot distinguishes the input polynomial and its transformed output.

An inverse operation, not a truncation error

Applying $\cosh(\partial_x)$ returns x^4 exactly. The general inverse uses the reciprocal formal symbol. The lowering and translation identities are

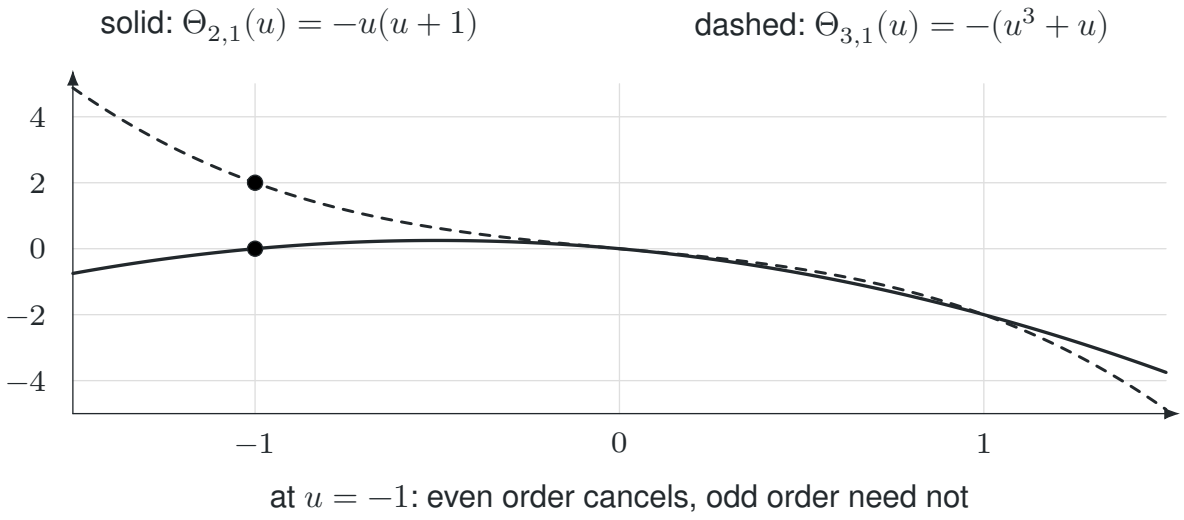
$$E_m' = m E_{m-1}, \qquad E_m(x+y) = \sum_{q=0}^{m} \binom{m}{q} E_q(x) y^{m-q}.$$

Both follow from the generating function. No operator-series convergence assumption on an infinite-dimensional function space is needed for this polynomial calculation.

> **Read this as:** Formal substitution into the derivative is safe here because every polynomial sees only finitely many derivatives. That is a domain statement.

The polynomial, its inverse image, and the Appell identities are checked symbolically through degree eight in four normalized-section families. The displayed curves are samples of exact polynomials.

Plate IV.16 / THETA COUPLING



Scale and order enter differently

Chapter IV: Theorem 10.2, Proposition 10.3, Proposition 10.4.

Let $H_N(z) = E_{N,0}(z)$. The theta family uses the same parameter u twice, but in two different roles:

$$H_N(uz)^{-1} H_N(z)^{-u} = \sum_{n \geq 0} \Theta_{N,n}(u) \frac{z^{Nn}}{(Nn)!}.$$

Argument scaling contributes u^{Nm} at logarithmic block m. Reciprocal order contributes u.

Their combined logarithm has coefficient

$$(-1)^m \kappa_{N,m} \frac{u^{Nm} + u}{m}.$$

At the first block this gives $\Theta_{N,1}(u) = -(u^N + u)$. Every positive-index theta polynomial vanishes at $u = 0$. For even N, $H_N(-z) = H_N(z)$, so the defining product is also 1 at $u = -1$.

The odd-order boundary is visible

For $N = 3$, $\Theta_{3,1}(-1) = 2$, not zero. The factor $u + 1$ is not a uniform law across orders. In contrast,

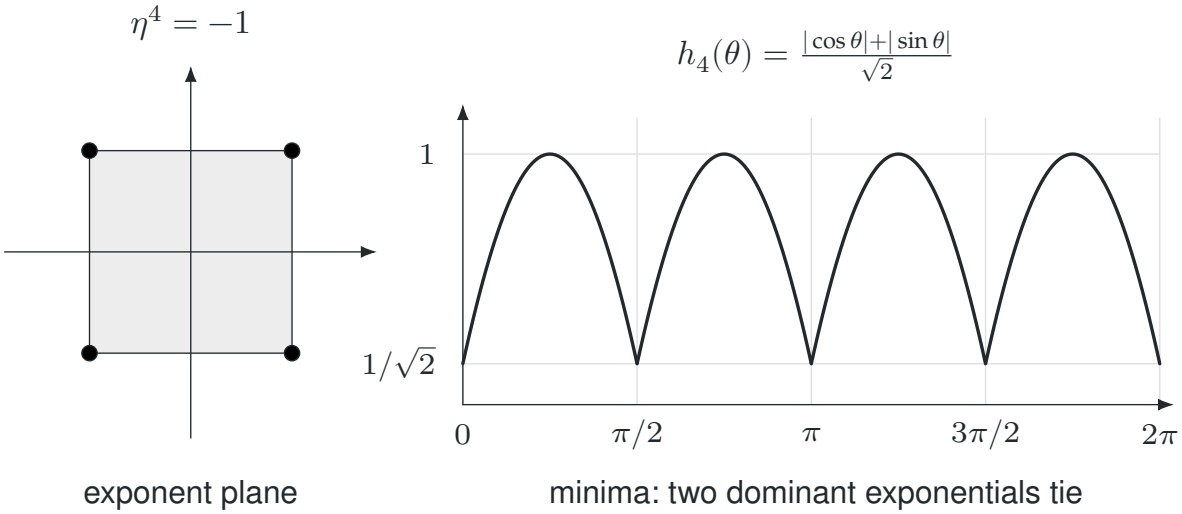
$$\Theta_{2,2}(u) = u(u+1)(5u^2 + u + 2).$$

The two guaranteed factors follow from the whole generating function, not from guessing the first few polynomial roots.

> **Read this as:** A common parameter does not make argument scaling and reciprocal order interchangeable. Their powers must be tracked separately.

The exact checker compares theta convolution with its logarithmic Newton recurrence through block index four. The odd-order factor claim is explicitly rejected as an invalid control.

Plate IV.17 / DOMINANT EXPONENTS



Growth comes from a polygon

Chapter IV: Definition 11.3, Theorem 11.4.

Write the signed denominator as a finite exponential sum:

$$D_N(z) = \frac{1}{N} \sum_{\eta^N=-1} e^{\eta z}.$$

For $z = re^{i\theta}$, the size of one exponential is $e^{r\Re(\eta e^{i\theta})}$. The maximal projection determines the directional exponential growth.

The indicator is

$$h_N(\theta) = \max_{0\le k<N} \cos\left(\theta + \frac{(2k+1)\pi}{N}\right).$$

Away from a tie direction, one exponential dominates all the others by a uniform positive projection gap on compact angular sets. For sufficiently large radius, smaller terms cannot cancel it. Those sectors are eventually zero-free.

Why zeros remain possible on a growing ray

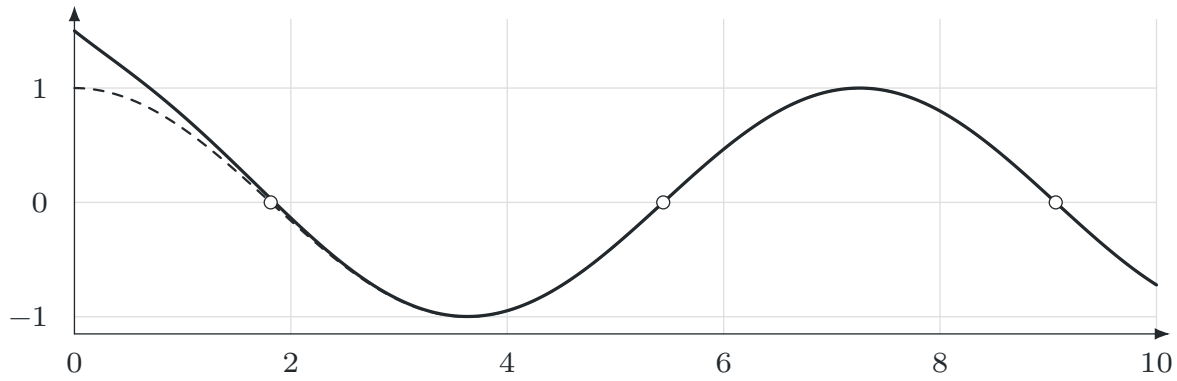
At a tie, two adjacent exponents have the same real projection. Their complex phases can be opposite. Their sum can therefore vanish even though each term is exponentially large. The minima in the order-four indicator plot occur precisely at the tie directions $\theta = k\pi/2$. The indicator uses a limsup in radius. It does not assert that $r^{-1}\log|D_N(re^{i\theta})|$ has an ordinary limit through the zeros on a tie ray.

> **Read this as:** The polygon predicts where large cancellation is possible. It does not, by itself, enumerate zeros or prove their simplicity.

The order-four polygon and support-function formula are explicit. The curve is a sampled display of that formula. Eventual localization and uniqueness require the separate zero-analysis arguments.

Plate IV.18 / THE CUBIC MODEL

Two large terms nearly cancel



Chapter IV: Lemma 11.5, Theorem 11.7, Corollary 11.9.

For real t, order three has the exact formula

$$D_3(t) = \frac{e^{-t} + 2e^{t/2}\cos(\sqrt{3}t/2)}{3}.$$

Divide by the nonzero factor $2e^{t/2}/3$. The resulting equation separates the dominant cosine from the small third exponential.

$$\tfrac{3}{2}e^{-t/2}D_3(t) = \cos(\sqrt{3}t/2) + \tfrac{1}{2}e^{-3t/2}$$

solid: full expression; dashed: two-term model; circles: model zeros

Ignoring the last term gives model zeros

$$t_m = \frac{2\pi}{\sqrt{3}}(m + 1/2).$$

At t_m, the full normalized expression equals $\frac{1}{2}e^{-3t_m/2} > 0$, so t_m is not an exact zero. Linearizing the cosine at that point predicts

$$\delta_m^{(1)} = \frac{(-1)^m}{\sqrt{3}}e^{-3t_m/2}.$$

The alternating slope explains why the true zero is to the right of the first model zero, then to the left of the second, and so on in the eventual regime.

Symmetry needs uniqueness

Real coefficients alone allow nonreal conjugate pairs. The manuscript first proves that a near-model disk contains exactly one zero. Conjugation preserves that disk, so the unique zero must equal its conjugate. This additional uniqueness step, not the symmetry alone, places it exactly on the ray.

> **Read this as:** The correction is caused by a real, nonzero remainder. A good cosine approximation does not make its model zeros exact.

The curves are sampled analytic expressions. The next page independently certifies four narrow real-zero intervals rather than trusting the plotted crossing or the floating-point root finder.

Plate IV.19 / EXACT RATIONAL BRACKETS

A root estimate becomes a certificate

Chapter IV: Theorem 11.7, Theorem 11.8, Corollary 11.9.

The root finder is used only to suggest intervals. Each displayed interval is accepted by exact rational arithmetic: opposite endpoint signs prove existence, and an interval bound for D_3' excludes zero throughout the interval, proving uniqueness inside it.

	certified lower endpoint	$\tau_m - t_m$	$\delta_m/\delta_m^{(1)} - 1$
$m = 0$	1.84981279919014347629	$+3.60134 \times 10^{-2}$	-5.243×10^{-2}
$m = 1$	$5.441233355023663355 40$	-1.64738×10^{-4}	$+2.471 \times 10^{-4}$
$m = 2$	$9.068997534871577658 05$	$+7.13700 \times 10^{-7}$	-1.071×10^{-6}
$m = 3$	$12.696595546546757294 40$	-3.09277×10^{-9}	$+4.639 \times 10^{-9}$

Each upper endpoint is the displayed lower endpoint plus 10^{-20}.

Root intervals: exact rational certificates. Displacement columns: numerical diagnostics.

How the certificate works

Evaluate the Taylor polynomial

$$S_{90}(t) = \sum_{n=0}^{90} \frac{(-1)^n t^{3n}}{(3n)!}$$

at the two rational endpoints. From the next term onward, magnitudes decrease, because their successive ratio is

$$\frac{t^3}{(3n+1)(3n+2)(3n+3)} < 1$$

there. The alternating-series remainder is bounded by the first omitted term. A separate outward interval evaluation of the differentiated polynomial, plus its tail bound, certifies the derivative sign. The first bracket is

$$1.84981279919014347629 < \tau_0 < 1.84981279919014347630.$$

Its displacement differs from the leading asymptotic prediction by about five percent. The later examples have much smaller relative discrepancies, as the plate records.

> **Read this as:** A small residual is not a root certificate. Endpoint signs plus a derivative bound give a checkable local existence-and-uniqueness statement.

Four certified intervals do not establish that no other real or complex zeros exist. The displacement columns are high-precision diagnostics, not a finite verification of a global big-O theorem. All rational enclosures are included in the checks file.

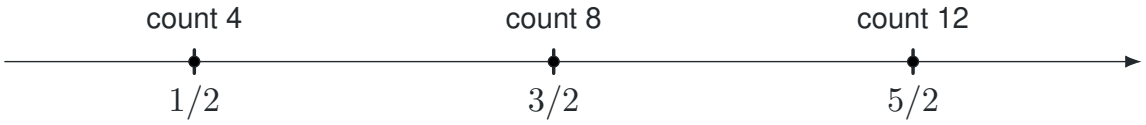


Plate IV.20 / EXACT FOURTH-ORDER STRINGS

Counting changes under the power map

Chapter IV: Example 11.12, Theorem 11.14.

Order four gives a case with no asymptotic displacement at all. In normalized coordinates the positive radial locations are $u = m + 1/2$, while the reduced-zero locations are $v = (m + 1/2)^4$.

$$u = |z|/(\sqrt{2}\pi)$$

$$v = |w|/(4\pi^4)$$

$$n_{D_4}(\sqrt{2}\pi u) = 4\lfloor u + 1/2 \rfloor, \quad n_{\Delta_4}(4\pi^4 v) = \lfloor v^{1/4} + 1/2 \rfloor$$

The two rows describe the same zero orbits. The upper row counts four zeros each time a new radius is reached. The lower row counts one reduced zero each time its fourth-power location is reached. Both formulas include zeros on the boundary of the disk.

Separate radius conversion from orbit multiplicity

In unscaled variables the general relation is

$$n_{D_N}(R^{1/N}) = N n_{\Delta_N}(R).$$

There are two operations here: replace the radius by its Nth root and divide the count by N. Forgetting either operation changes the leading constant. For this family the asymptotics are

$$n_{D_N}(R) = \frac{N \sin(\pi/N)}{\pi} R + O(1), \qquad n_{\Delta_N}(R) = \frac{\sin(\pi/N)}{\pi} R^{1/N} + O(1).$$

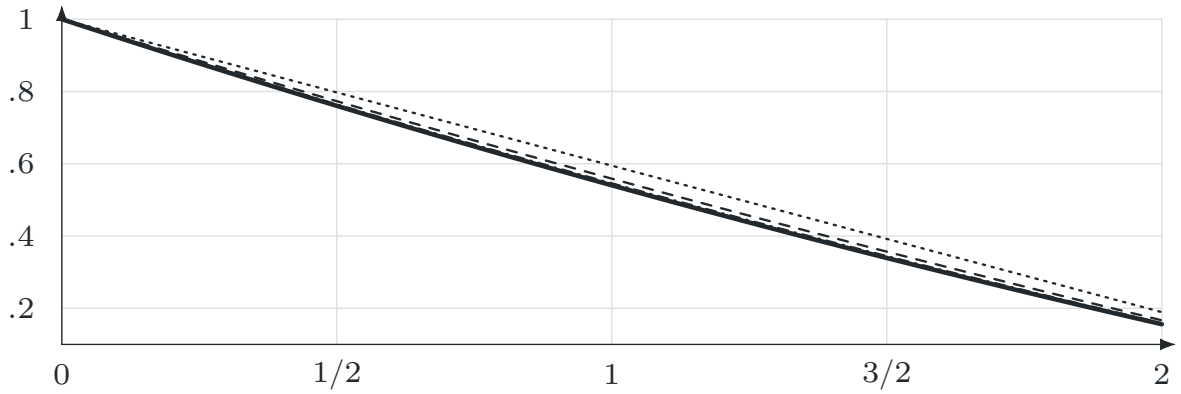
The different powers agree with the entire-function orders 1 and $1/N$.

> **Read this as:** The reduced function has fewer repeated zeros and a different radius scale. Its counting law is not obtained by dividing a same-radius count alone.

The exact order-four staircase formulas are tested at rational radii including jump points. The large-zero theorem for general N permits finitely many exceptions. These exact order-four identities do not justify discarding that boundary elsewhere.

Plate IV.21 / CANONICAL PRODUCT

A product and an operator share zeros



Chapter IV: Theorem 12.1, Theorem 12.2.

For $N \geq 2$, the reduced entire function has order $1/N < 1$. Its multiplicity-sensitive genus-zero product is

$$\Delta_N(w) = \prod_{\lambda \in \Lambda_N} (1 - w/\lambda).$$

Putting $K_N e_\lambda = \lambda^{-1} e_\lambda$ on $\ell^2(\Lambda_N)$ gives the corresponding diagonal Fredholm determinant. Repeated zeros require repeated diagonal entries.

$$\Delta_2(w) = \cos\sqrt{w}, \qquad P_L(w) = \prod_{m=0}^{L-1}(1 - w/\lambda_m)$$

thick: entire function; dotted $L = 1$; dashed $L = 3$; dash-dot $L = 10$

Finite compression is an approximation

For $N = 2$, $\lambda_m = \pi^2(m + 1/2)^2$. The finite determinant P_L is exactly the displayed finite product, but it is not exactly Δ_2. For $0 \leq w \leq 1$ and $L \geq 1$, an elementary tail estimate gives

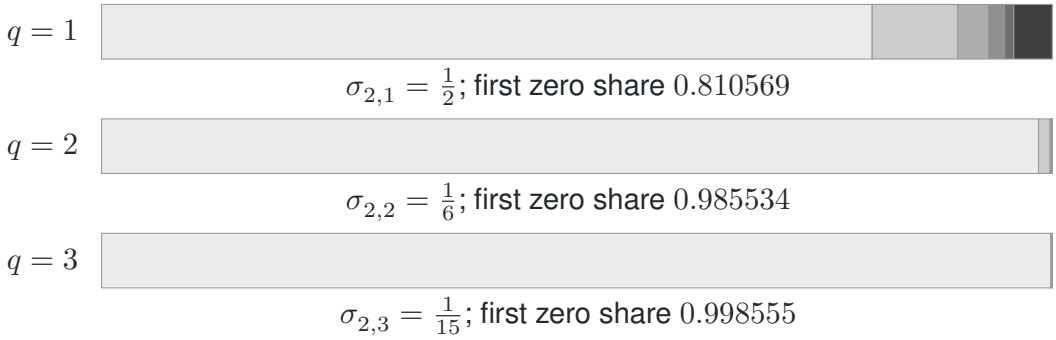
$$0 \leq 1 - \frac{\Delta_2(w)}{P_L(w)} \leq w \sum_{m \geq L} \lambda_m^{-1} \leq \frac{1}{9(L - 1/2)}.$$

The last bound uses $\pi > 3$ and integral comparison. Thus truncation has an explicit error mechanism.

> **Read this as:** The infinite product is justified by the analytic theorem. Finite determinants provide controlled approximations, not substitutes for that theorem.

The exact finite determinant test includes a repeated eigenvalue and rejects deduplication. The curves use known cosine zeros. Order one is excluded: $\Delta_1(w) = e^{-w}$ has no zeros, so its empty product would be 1, not the function.

Plate IV.22 / ZERO POWER SUMS



Finite coefficients give infinite moments

Chapter IV: Theorem 12.6, Corollary 12.7, Corollary 12.9, Corollary 12.10.

Taking the logarithm of the canonical product identifies

$$\kappa_{N,q} = \sigma_{N,q} := \sum_{\lambda \in \Lambda_N} \lambda^{-q} = \mathrm{Tr}(K_N^q), \qquad q \geq 1.$$

The same exact numbers can be computed from finitely many denominator coefficients by Newton's recurrence. No numerical zero list is needed for that calculation.

five finite contributions plus the remaining tail; higher moments emphasize the nearest zero

For order two,

$$\sigma_{2,1} = \frac{1}{2}, \quad \sigma_{2,2} = \frac{1}{6}, \quad \sigma_{2,3} = \frac{1}{15}, \quad \sigma_{2,4} = \frac{17}{630}.$$

The plate shows how successive inverse powers emphasize the nearest zero. Its shaded pieces are contributions from the first five positive reduced zeros, followed by the remaining tail. The total in each row is the exact rational moment.

The tangent is a sum of poles

Logarithmic differentiation also gives

$$T_N(z) = N z^{N-1} \sum_{\lambda \in \Lambda_N} \frac{1}{\lambda - z^N}$$

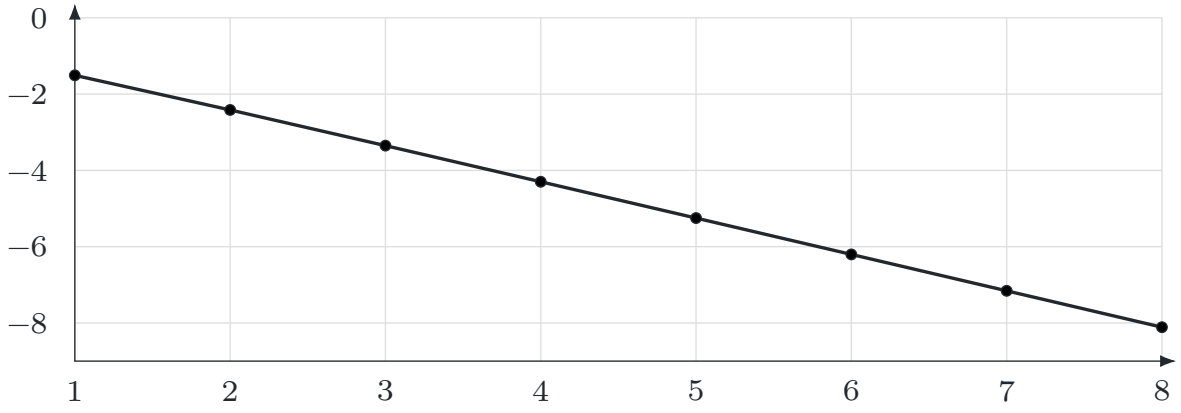
away from poles. Summability of $|\lambda|^{-1}$ permits the locally uniform partial-fraction expansion without added regularizing terms.

> **Read this as:** A global analytic product theorem connects the infinite zero sum to a finite algebraic recurrence. The recurrence alone does not prove the product theorem.

Displayed moments are checked against formal logarithm coefficients and exact order-two/order-four zeta values. Bar widths are numerical shares. General power sums use λ^{-q}, not $|\lambda|^{-q}$ when exceptional nonpositive zeros are present.

Plate IV.23 / SINGULARITY ANALYSIS

Nearest poles set coefficient growth



Chapter IV: Theorem 13.1, Corollary 13.2, Corollary 13.3, Corollary 13.4.

For $1/\cos z$, the nearest poles are $\rho = \pm\pi/2$. They contribute equally to even-degree coefficients. Including both poles gives

$$P_{2,n}(1) \sim 2(2n)! \left(\frac{2}{\pi}\right)^{2n+1}.$$

The factor two is orbit multiplicity, not an adjustable fitted constant.

$$\log_{10}(1 - R_n), \quad R_n = \frac{P_{2,n}(1)}{2(2n)!(2/\pi)^{2n+1}}$$

Each ratio is enclosed with a rational Machin-formula bound for π.

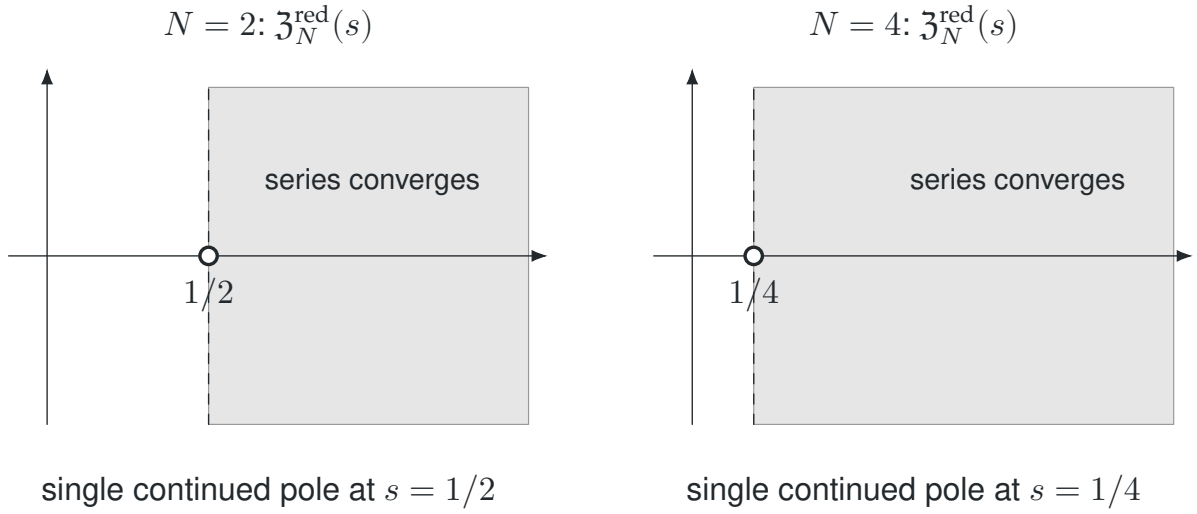
A finite quantitative check

For $n = 1, \dots, 8$, the exact integer coefficients and a rational enclosure for π bound the ratio R_n strictly between zero and one. In this tested range, $1 - R_n < 3^{-(2n+1)}$. The plot displays the logarithm of the enclosed error, not an independently asserted all-n bound.

Higher reciprocal powers need more Laurent data

For positive integral order r, a simple denominator zero becomes a pole of order r. The highest Laurent term contributes a factor $\binom{m+r-1}{r-1}$, but lower Laurent terms still contribute on the same exponential scale. Subtracting *all* principal parts is what leaves a holomorphic remainder controlled by the next zero radius.

> **Read this as:** Nearest-zero geometry explains factorial-times-exponential growth. Multiplicity, reciprocal order, and lower principal parts determine its precise normalization.



The ratio certificates use a rational Machin-formula enclosure for π. The inherited general theorem retains simple nearest zeros, a gap to the next modulus, and positive integral reciprocal order. The plot does not remove those hypotheses.

Plate IV.24 / ZERO ZETA FUNCTIONS

Convergence is not continuation

Chapter IV: Theorem 14.2, Theorem 14.3, Corollary 14.4.

Reduced zeros grow like m^N. Their absolute zero-zeta series therefore has half-plane of absolute convergence $\Re s > 1/N$. The absolute zero zeta in the original variable instead requires $\Re s > 1$.

For $N = 2$ and $N = 4$, the lattices are exact:

$$\mathfrak{Z}_2^{\mathrm{red}}(s) = \pi^{-2s}\zeta(2s, 1/2), \qquad \mathfrak{Z}_4^{\mathrm{red}}(s) = (\sqrt{2}\pi)^{-4s}\zeta(4s, 1/2).$$

Each identity first holds where its defining series converges. The right side supplies its meromorphic continuation. There is a single pole, at $1/2$ or $1/4$, with residue $1/(2\pi)$ or $1/(4\sqrt{2}\pi)$ respectively.

The factor N matters twice

For every order in this chapter,

$$\mathfrak{Z}_N^{\mathrm{abs}}(s) = N\mathfrak{Z}_N^{\mathrm{red}}(s/N).$$

For general N, exponentially accurate zero locations leave an entire correction to the Hurwitz model. A finite exceptional zero set also contributes entire terms. This reasoning establishes continuation, not a zeta functional equation.

> **Read this as:** An analytic continuation can exist at points where the original infinite sum diverges. It must not be evaluated there by naively summing that series.

The shaded regions show convergence, and the open circles mark poles of the continued functions. They are not zeros of the zeta functions. Branch-dependent orbit zetas and derivative-weighted zetas retain their separately stated conventions.

Plate IV.25 / COEFFICIENT AND ZERO WORKED MODEL

One closed calculation: the number 69

Chapter IV: Corollary 7.7, Example 11.12, Theorem 12.6.

Use $N = 4$ throughout this page. Its denominator, its exact zero lattice, and the reciprocal recurrences provide two routes to the same coefficient. All symbols in the plate refer to this one order.

denominator	$1 - w/24 + w^2/40320 + \cdots$
negative logarithm	$w/24 + (17/20160)w^2 + \cdots$
zero moments	$\sigma_1 = 1/24, \quad \sigma_2 = 17/10080$
reciprocal	$1 + w/24 + 69w^2/40320 + \cdots$
tangent	$z^3/3! + 34z^7/7! + \cdots$

$$69 = 8!\,\tfrac{\sigma_1^2+\sigma_2}{2}, \qquad 34 = 4 \cdot 7!\,\sigma_2$$

Route one: invert the denominator

The w^2 coefficient of Δ_4^{-1} is

$$\frac{1}{24^2} - \frac{1}{8!} = \frac{69}{8!}.$$

Thus $P_{4,2}(1) = 69$. Keeping r variable gives $P_{4,2}(r) = 35r^2 + 34r$.

Route two: use the zero moments

The exact reduced zeros are $4\pi^4(m + 1/2)^4$. Their first two power sums are $\sigma_1 = 1/24$ and $\sigma_2 = 17/10080$. The Bell/Newton identity gives the same reciprocal coefficient $(\sigma_1^2 + \sigma_2)/2$. The tangent independently reads off the second moment as $4 \cdot 7!\sigma_2 = 34$. This links coefficients, geometry, and derivatives without a fitted parameter or an inferred zero list.

> **Read this as:** The content is the agreement of precisely normalized descriptions. A matching small example illustrates the general bridges. It is not a proof of all their analytic hypotheses.

Every rational value and polynomial identity on this page is checked exactly. The infinite zero-sum interpretation uses the inherited canonical-product theorem and the exact order-four zero formula.

Plate IV.26 / FORMAL AND COMPUTATIONAL BOUNDARIES

What is evidence, and for what?

Chapter IV: Section 15, Section 16.

These twenty-six worked plates connect explicit mathematical models with the main text and its formal companion. Each evidence record states the scope of the model, computation, or formal result.

Evidence layer	What it supports
Formal record	The sources, theorem map, dependency pins, saved axiom reports, and mathematical review retain their own scope. The 68-result contract and its replay using pinned sources are described in the Lean guide.
Exact and symbolic suite	The recorded isolated execution passed all 147 finite, symbolic, and enclosure checks and rejected five deliberately false controls. The unchanged checker and models were run with SymPy 1.14.0 and mpmath 1.3.0.
Certified zero brackets	Four rational intervals of width 10^{-20} establish local existence and uniqueness only. The full suite reproduced all four rational brackets, opposite endpoint signs, and derivative exclusion throughout each interval. These are local certificates, not a global zero census.
Numerical visualization	Sampled analytic curves, finite products, moment shares, and displacement diagnostics have the roles stated on their pages. They are not exact global zero censuses.
Figure provenance	Regeneration from the models reproduced all twenty-four editable TikZ files. The mathematical labels and objects are preserved.
Editorial preservation	The original worked formulas, model code, checker, and vector figure sources are preserved. Locators refer to the main text.

Boundaries that remain in force

The general family has eventual positivity and simplicity of its reduced zeros, not an assertion that every reduced zero is positive and simple. This chapter leaves universal simplicity, positivity of every reduced zero, full displacement expansions, and a zeta functional equation open. The exact order-two and order-four models do not settle those questions for every order. Imported standard fact 11.1 stays outside the 68-result contract. Fixed logarithms, zero-free domains, multiplicities, and the hypotheses of nearest-pole asymptotics remain explicit. No historical priority is inferred from successful computation or formal verification.

Replay the worked layer

The model checker is `checks/verify_examples.py`. The plate generator is `source/generate_graphics.py`. They require the listed Python dependencies. Run those mathematical tools in a temporary copy to preserve the delivered evidence.

> **Read this as:** A proof, a finite exact test, a root enclosure, and a sampled curve answer different questions. Keeping their scopes explicit makes the pictures useful mathematical evidence.

Exact certificates and formal verification records accompany the source. Each retains its stated mathematical scope.

How to use this volume

Twenty-six worked pages and twenty-four editable vector figures connect finite coefficient calculations with differential equations, zero orbits, canonical products, and spectral moments. Exact identities and rational certificates are distinguished from sampled analytic displays throughout.

A route through the examples

Plates IV.1–IV.26 identify worked pages independently of PDF pagination. Each page names the corresponding statements in Chapter IV. The formal companion records the separate formal contract.

IV.1 A coefficient can become zero data
IV.2 Two variables, several normalizations
IV.3 A root filter is an exact vote

IV.18 Two large terms nearly cancel
IV.19 A root estimate becomes a certificate
IV.20 Counting changes under the power map
IV.21 A product and an operator share zeros
IV.22 Finite coefficients give infinite moments
IV.23 Nearest poles set coefficient growth
IV.24 Convergence is not continuation
IV.25 One closed calculation: the number 69
IV.26 What is evidence, and for what?

Three reading routes

Algebra first: Plates IV.3–IV.16. Zeros first: Plates IV.17–IV.24. Full calculation: Plate IV.25. Evidence: Plate IV.26.

Keep the two variables distinct

Use z for differentiation and rotational geometry. Use $w = z^N$ for reciprocal recurrences, canonical products, and orbit-zero sums. An ordinary coefficient in w becomes a block exponential coefficient in z only after multiplication by $(Nn)!$.

Exact models and analytic conclusions

The order-four factorization gives its complete zero set. The four rational cubic brackets give local existence and uniqueness in their stated intervals. General zero localization, infinite products, and zeta continuation require the traditional paper's analytic hypotheses and arguments.

PLATE IV.1 / READER'S GUIDE

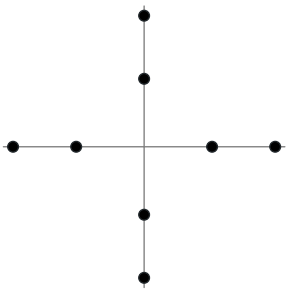
A coefficient can become zero data

Chapter IV: Section 2, Section 7, Section 11, Section 12.

This guide follows a concrete analytic family through three descriptions: selected Taylor coefficients, a finite differential system, and the zeros of an entire function. The formulas are linked, but the evidence needed for each description is different.

COEFFICIENT LANES

z^0	z^3	z^6	z^9
z^1	z^4	z^7	z^{10}
z^2	z^5	z^8	z^{11}



$$m \equiv j \pmod 3$$

RECIPROCAL COEFFICIENTS

1	0	0
$-\frac{1}{2}$	1	0
$\frac{1}{24}$	$-\frac{1}{2}$	1

$$1, \quad \tfrac{1}{2}, \quad \tfrac{5}{24}, \ldots$$

ZERO ORBITS

$$\{\rho, i\rho, -\rho, -i\rho\}$$

Keep three small models in view

For $N = 2$, the signed denominator is $D_2(z) = \cos z$. Its reciprocal is the familiar secant series. For $N = 3$, a third exponential perturbs the zeros of a dominant cosine. For $N = 4$, an exact factorization gives a complete zero picture:

$$D_4(z) = \cos(z/\sqrt{2})\cosh(z/\sqrt{2}).$$

The examples move between these orders deliberately. Order two makes the coefficient arithmetic transparent. Order three shows a genuine displacement. Order four makes orbit reduction completely explicit.

Three routes through the guide

Route	Pages and question
Algebra first	Plates IV.3–IV.16: selection, signs, reciprocals, and finite differential operators.
Zeros first	Plates IV.17–IV.24: cancellation and its consequences for coefficients.
One full calculation	Plate IV.25: derive the integer 69 from denominator coefficients and from zero moments.

Read this as: The pictures carry computable objects. They do not replace the global analytic arguments or extend the inherited Lean contract.

Exact identities and rational certificates are distinguished from sampled curves. All plates are reproducible vector drawings. The source package preserves the original proofread manuscript.

PLATE IV.2 / OBJECT ATLAS

Two variables, several normalizations

Chapter IV: Section 2, Definition 5.7, Definition 7.1, Definition 9.1.

The most important coordinate change is $w = z^N$. A term of degree n in w has degree Nn in z. Its coefficient does not change, but an exponential-generating-function label does.

$$\underbrace{b_{N,n}(r)\,w^n}_{\text{ordinary coefficient}} = \underbrace{P_{N,n}(r)\frac{z^{Nn}}{(Nn)!}}_{\text{block exponential coefficient}}, \qquad P_{N,n}(r) = (Nn)!\,b_{N,n}(r).$$

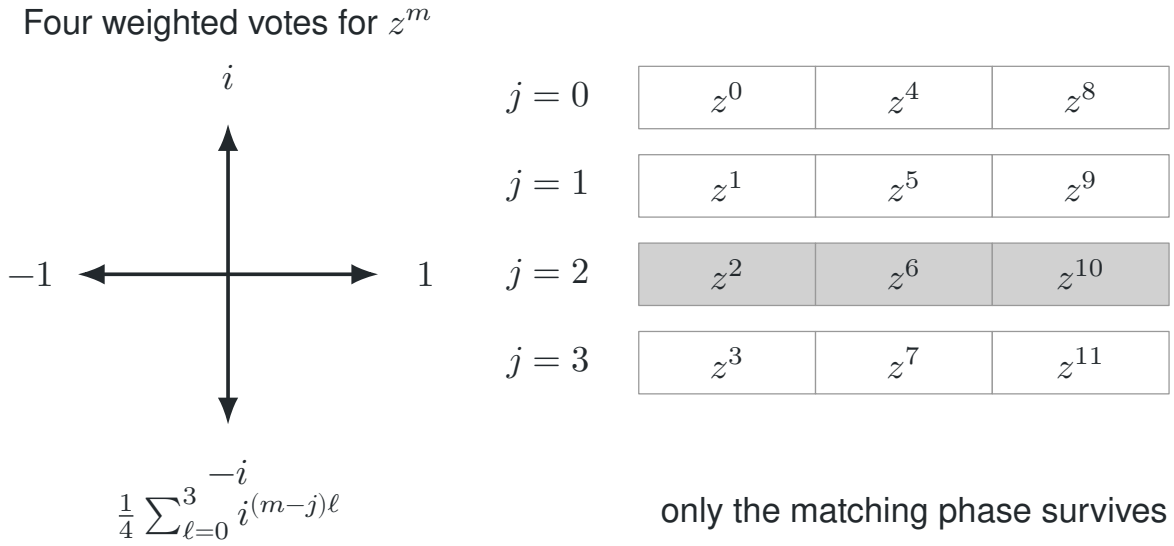
Object	Definition and role
$E_{N,j}(z)$	$\displaystyle\sum_{n\geq 0}\frac{z^{Nn+j}}{(Nn+j)!}$ selects one residue class of the exponential.
$D_{N,j}(z)$	The same series with $(-1)^n$. One full derivative cycle contributes a minus sign.
$D_N(z)$	$D_{N,0}(z)$, the denominator whose zeros control the signed reciprocal family.
$\Delta_N(w)$	$\displaystyle\sum_{n\geq 0}\frac{(-1)^n w^n}{(Nn)!}$. Thus $D_N(z) = \Delta_N(z^N)$.
$P_{N,n}(r)$	Block-EGF coefficients of D_N^{-r}. They are polynomials in r.
$\kappa_{N,m}$	$-\log \Delta_N(w) = \displaystyle\sum_{m\geq 1}\kappa_{N,m}w^m/m$.
$T_N(z)$	$-D_N'(z)/D_N(z)$, a function, not the coefficient $T_N(n)$.
$\Phi_{N,j}(w)$	$j!\displaystyle\sum_{n\geq 0}\frac{w^n}{(Nn+j)!}$ removes the forced zero of $E_{N,j}$.
$C_{N,j}(z)$	$1/\Phi_{N,j}(z^N)$. This is generally not $1/D_N(z)$.
Λ_N	Zeros of Δ_N, counted with multiplicity, one per rotational orbit of zeros of D_N.

A normalization test

The coefficient $5/24$ of w^2 in $\Delta_2(w)^{-1}$ is the same term as $5z^4/4!$. It is not $5w^2/2!$. Keeping the two factorials separate prevents errors in Bell formulas, convolution weights, and zero-moment reconstruction.

> **Read this as:** Use z for differentiation and rotational geometry. Use w for reciprocal recurrences, canonical products, and orbit-zero sums.

PLATE IV.3 / CYCLIC PROJECTION



A root filter is an exact vote

Chapter IV: Theorem 3.1, Proposition 3.2.

For $N = 4$, write $\omega = i$. To extract residue j, evaluate the function at four rotated arguments and attach the phase $i^{-j\ell}$:

$$(\mathcal{B}_{4,j}F)(z) = \frac{1}{4}\sum_{\ell=0}^{3} i^{-j\ell}F(i^{\ell}z).$$

A monomial $a_m z^m$ is multiplied by the finite average of $i^{(m-j)\ell}$. Matching phases all vote 1. Nonmatching phases cancel exactly.

An example that can be checked coefficient by coefficient

Take $F(z) = \sum_{m=0}^{12}(m+1)z^m$. Then

$$\mathcal{B}_{4,2}F = 3z^2 + 7z^6 + 11z^{10}.$$

Applying the same selector again changes nothing. Applying a different selector gives zero. Summing the four selected polynomials returns the original F.

Selection is also a symmetry condition

For the selected polynomial F_2, rotation gives $F_2(iz) = -F_2(z)$. More generally, a residue-j section satisfies $F_j(\omega z) = \omega^j F_j(z)$. The phase label therefore describes both the coefficient addresses and the response to rotation.

> **Read this as:** This is not an approximate Fourier fit. The finite root sum is exactly 0 or 1 on every coefficient.

The checker compares the actual complex average with independent coefficient selection for this polynomial. The drawing shows the four complex phases, not a numerical convergence argument.

PLATE IV.4 / CYCLIC CONVOLUTION

Products mix the residue lanes

Chapter IV: Theorem 3.3.

Selection separates a function additively. It does not make multiplication diagonal. A residue-i term multiplied by a residue-j term lands in residue $i + j \pmod N$. For $N = 3$, use

$$F = 1 + 2z + 3z^2 + z^3, \qquad G = 2 + z + z^2.$$

The table displays every product of their three selected sections.

	2	z	z^2
$z^3 + 1$	$2z^3 + 2$	$z^4 + z$	$z^5 + z^2$
$2z$	$4z$	$2z^2$	$2z^3$
$3z^2$	$6z^2$	$3z^3$	$3z^4$

$$\mathcal{B}_{3,0}(FG) = 2 + 7z^3$$

shaded cells: $(0,0), (1,2), (2,1)$ all land in residue 0

The shaded cells contribute to residue zero:

$$2(1 + z^3) + (2z)(z^2) + (3z^2)z = 2 + 7z^3.$$

Keeping only the product of the residue-zero inputs would give $2 + 2z^3$ and lose five units of the z^3 coefficient. The mixed cells are part of the exact result.

The general rule

$$\mathcal{B}_{N,k}(FG) = \sum_{i+j \equiv k \ (N)} (\mathcal{B}_{N,i}F)(\mathcal{B}_{N,j}G).$$

Every pair belongs to exactly one output residue. No term is discarded and no coefficient is estimated. This finite cyclic convolution is the algebra behind the later addition formulas and block-coefficient recurrences.

> **Read this as:** A packet label tells you where an interaction lands, not that interactions with other packets vanish.

All nine table entries and all three output sections are checked as exact polynomial identities. This is the scalar cyclic specialization used by the paper.

PLATE IV.5 / DIFFERENTIAL SYSTEM

One signed edge determines the cycle

Chapter IV: Theorem 5.3, Theorem 6.4, Corollary 6.5, Corollary 6.6.

Let $J_3e_0 = e_1$, $J_3e_1 = e_2$, and $J_3e_2 = -e_0$. A complete turn changes sign, so $J_3^3 = -I$. The signed sections are the coordinates of $e^{zJ_3}e_0$.

J_3

0	0	-1
1	0	0
0	1	0

e^{zJ_3}

D_0	$-D_2$	$-D_1$
D_1	D_0	$-D_2$
D_2	D_1	D_0

$$J_3^3 = -I$$

$$\mathbf{D}_3(0) = e_0$$

$$\det e^{zJ_3} = 1$$

$$D_0 \mapsto -D_2, \qquad D_1 \mapsto D_0, \qquad D_2 \mapsto D_1$$

Here D_j inside the matrix means $D_{3,j}(z)$. For example,

$$D_{3,0} = 1 - \frac{z^3}{3!} + \frac{z^6}{6!} - \cdots, \qquad D_{3,1} = z - \frac{z^4}{4!} + \cdots.$$

Rows are output coordinates and columns are input coordinates. The upper-triangular minus signs record crossing the signed edge while moving from the column to the row. They are not arbitrary orientation choices.

Two checks connect the matrix and the scalar equation

The initial derivative matrix is the identity. Each initial jet $(y(0), y'(0), y''(0))$ therefore determines a unique linear combination. Also,

$$\frac{1}{3}\operatorname{Tr}(e^{zJ_3}) = D_3(z), \qquad \det(XI - J_3) = X^3 + 1.$$

The roots of -1 appearing later in the exponential sum are already the spectrum of this concrete matrix.

> **Read this as:** The functions, their initial data, the addition law, and the exponent polygon come from one signed shift.

The exact tests check every matrix-entry Taylor coefficient through degree 14 for $N = 1, \dots, 5$. The displayed determinant-one law is for $N \geq 2$. $N = 1$ is a separate boundary case.

PLATE IV.6 / FINITE ALGEBRA

Addition is quotient multiplication

Chapter IV: Proposition 5.5, Theorem 6.2.

Work in $\mathbb{C}[\xi]/(\xi^3+1)$. Every element has coordinates in $1, \xi, \xi^2$. The entire exponential has the finite-coordinate form

$$e^{z\xi} = D_{3,0}(z) + D_{3,1}(z)\xi + D_{3,2}(z)\xi^2.$$

The multiplication table makes the carry sign unavoidable.

	1	ξ	ξ^2
1	1	ξ	ξ^2
ξ	ξ	ξ^2	-1
ξ^2	ξ^2	-1	$-\xi$

$$\xi^3 = -1$$

wrap once: change sign

$$\xi^2\xi^2 = -\xi$$

$$D_{3,0}(z+w) = D_{3,0}(z)D_{3,0}(w) - D_{3,1}(z)D_{3,2}(w) - D_{3,2}(z)D_{3,1}(w)$$

Multiply the coordinate forms of $e^{z\xi}$ and $e^{w\xi}$. Their product is $e^{(z+w)\xi}$. The coefficient of 1 receives one contribution without a wrap and two contributions with a wrap. Reading that coefficient gives the displayed addition law.

Compare the unsigned model

In $\mathbb{C}[\xi]/(\xi^3-1)$, the same table has no minus signs. Its exponential coordinates are the unsigned sections $E_{3,j}$. Thus the difference between the two differential systems is a single algebraic relation, not a change in how coefficients are grouped. For general N, the carry factor is

$$(-1)^{\lfloor (i+j)/N \rfloor}, \qquad 0 \le i, j < N.$$

Only zero or one wrap is possible in a product of two coordinate basis elements.

> **Read this as:** The twisted addition law is the ordinary exponential group law expressed in a signed cyclic algebra.

Bivariate Taylor identities are checked through total degree ten in every section for $N = 2, 3, 4$. Omitting the carry sign is one of the deliberately rejected controls.

PLATE IV.7 / FACTORIAL NORMALIZATION

Why a hypergeometric name appears

Chapter IV: Theorem 4.5.

The hypergeometric form is another way to organize the same coefficients. It does not introduce an extra function into the construction. Split a factorial into its residue classes and divide each factor by N:

$$(Nn+j)! = j!N^{Nn}n! \prod_{a\in A_{N,j}} (a)_n.$$

The parameter equal to 1 is omitted from $A_{N,j}$ because the hypergeometric convention already supplies $(1)_n = n!$.

$$N=3,\ j=1,\ n=2: \quad 7! = 1!\,3^6\,2!\,(2/3)_2(4/3)_2$$

$\frac{2}{3}$	$\frac{5}{3}$
1	2
$\frac{4}{3}$	$\frac{7}{3}$

$(2/3)_2$

$(1)_2 = 2!$

$(4/3)_2$

$$A_{3,1} = \{2/3, 4/3\}$$

$$E_{3,1}(z) = z\,{}_0F_2\left(;\frac{2}{3},\frac{4}{3};\frac{z^3}{27}\right)$$

The omitted unit parameter is already the hypergeometric $n!$.

Check the displayed case

For $N=3, j=1, n=2$, the six factors after the initial $1!$ are $2,3,4,5,6,7$. Dividing by three and grouping them gives the three rows of the plate. The middle row supplies $2!$. The others supply $(2/3)_2$ and $(4/3)_2$. The right-hand side is exactly 5040. Consequently,

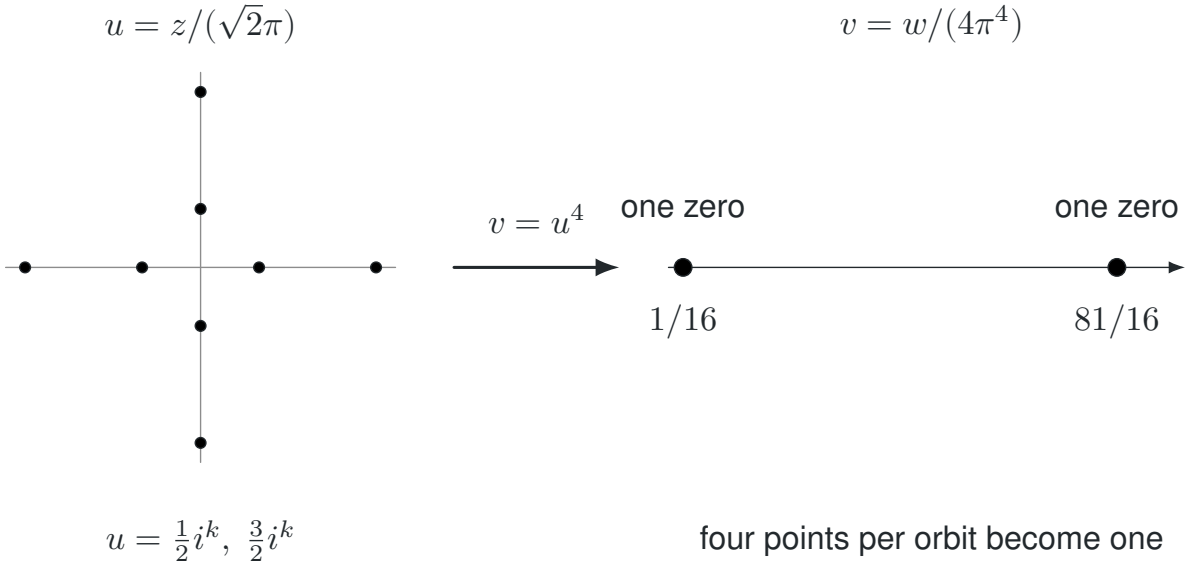
$$E_{3,1}(z) = z\left(1+\frac{z^3}{4!}+\frac{z^6}{7!}+\cdots\right).$$

The prefactor z retains the forced zero at the origin. The hypergeometric argument $z^3/27$ retains the scaling N^N.

> **Read this as:** Parameters, the omitted unit parameter, the prefactor, and the argument scaling all come from factorial bookkeeping.

Five choices of (N, j) are checked against the exact factorial identity for $n = 0, \dots, 7$. These finite checks support the example. The general analytic identification belongs to the inherited manuscript.

PLATE IV.8 / THE REDUCED VARIABLE



Four zeros become one orbit zero

Chapter IV: Definition 5.7, Example 11.12, Corollary 11.13.

For $N = 4$ the factorization is exact:

$$D_4(z) = \cos(z/\sqrt{2})\cosh(z/\sqrt{2}), \qquad D_4(z) = \Delta_4(z^4).$$

Set $A_4 = \sqrt{2}\pi$. All the zeros are $A_4(m + 1/2)i^k$, with $m \geq 0$ and $0 \leq k < 4$. Each zero is simple.

The drawing uses $u = z/A_4$ and $v = w/A_4^4$, so its marked coordinates are rational. The first four-point orbit has fourth power $1/16$. The second has fourth power $81/16$.

Multiplicity is not multiplied in the reduced function

At a nonzero point, $z \mapsto z^4$ has nonzero derivative. It preserves the local multiplicity of a zero. Four distinct simple zeros of D_4 therefore correspond to one simple zero of Δ_4, not one zero of multiplicity four. The reduced zeros are

$$\lambda_m = A_4^4(m + 1/2)^4 = 4\pi^4(m + 1/2)^4.$$

This is why an orbit factor in the z plane is $1 - z^4/\lambda_m$. It is the product of the four corresponding linear factors, with their phases included.

> **Read this as:** Orbit reduction removes repetition. It changes growth and counting exponents, while preserving each nonzero zero's local multiplicity.

The quartic factorization, its differential equation, and the displayed orbit powers are checked independently. Here the complete zero set is known exactly. A finite numerical root search is not being used to establish it.

PLATE IV.9 / COEFFICIENT RECONSTRUCTION

A reciprocal is a triangular solve

Chapter IV: Theorem 7.3, Theorem 7.6.

Start in the reduced variable with

$$\Delta_2(w) = 1 - \frac{w}{2} + \frac{w^2}{24} - \frac{w^3}{720} + \cdots.$$

Write $1/\Delta_2(w) = \sum b_n w^n$. Matching the product with 1 gives a unit lower-triangular system. At each row there is exactly one new unknown.

denominator convolution				b		unit series
1	0	0	0	1	$=$	1
$-\frac{1}{2}$	1	0	0	$\frac{1}{2}$		0
$\frac{1}{24}$	$-\frac{1}{2}$	1	0	$\frac{5}{24}$		0
$-\frac{1}{720}$	$\frac{1}{24}$	$-\frac{1}{2}$	1	$\frac{61}{720}$		0

$$b_1 = \tfrac{1}{2}$$

$$b_2 = \tfrac{1}{4} - \tfrac{1}{24}$$

$$b_3 = \tfrac{61}{720}$$

$$P_{2,n}(1) = (2n)!b_n : \qquad 1,\ 1,\ 5,\ 61$$

The first three equations are

$$b_1 - \tfrac{1}{2} = 0, \qquad b_2 - \tfrac{1}{2}b_1 + \tfrac{1}{24} = 0, \qquad b_3 - \tfrac{1}{2}b_2 + \tfrac{1}{24}b_1 - \tfrac{1}{720} = 0.$$

They yield $b_1 = 1/2$, $b_2 = 5/24$, and $b_3 = 61/720$. Multiplication by $(2n)!$ produces the secant coefficients $1, 5, 61$.

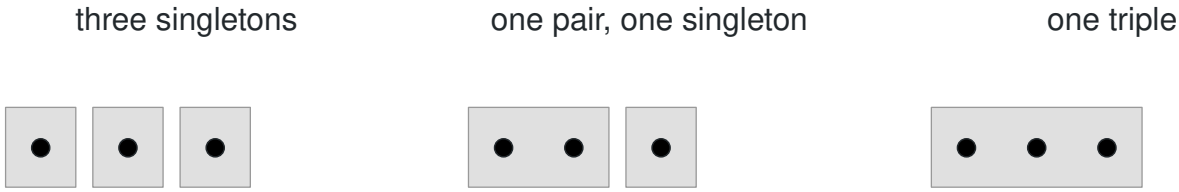
Why this is an exact finite calculation

To compute the coefficient of w^n, only denominator coefficients through w^n are needed. Later terms of the entire series cannot affect it. A finite series inverse is therefore exact at its declared truncation order, even though evaluating that truncated series is only an approximation to the full analytic function away from the origin.

> **Read this as:** A unit constant term makes coefficient recovery triangular. It does not by itself specify the radius of analytic convergence.

The checks compare an independent binomial-series expansion, the parameter recurrence, and the logarithmic Newton recurrence through block index six. The table uses ordinary coefficients, with factorial conversion shown separately.

PLATE IV.10 / BELL PARTITIONS



The reciprocal order is a polynomial

Chapter IV: Theorem 7.2, Corollary 7.7.

Let r vary instead of fixing the reciprocal power. Since

$$\Delta_N(w)^{-r} = \exp\left(r \sum_{m\geq 1} \kappa_{N,m} \frac{w^m}{m} \right),$$

the coefficient of w^n is a polynomial of degree n in r. Bell polynomials collect the possible ways logarithmic terms contribute total degree n.

$r^3\kappa_1^3$	$3r^2\kappa_1\kappa_2$	$2r\kappa_3$
$15r^3$	$30r^2$	$16r$

$$P_{2,3}(r) = \tfrac{6!}{3!}\, B_3(r\kappa_1, r\kappa_2, 2r\kappa_3)$$

For $N = 2$, the first three logarithmic coefficients are

$$\kappa_1 = \frac{1}{2}, \qquad \kappa_2 = \frac{1}{6}, \qquad \kappa_3 = \frac{1}{15}.$$

The third Bell polynomial is $B_3(x_1, x_2, x_3) = x_1^3 + 3x_1x_2 + x_3$. Substituting $x_1 = r\kappa_1$, $x_2 = r\kappa_2$, $x_3 = 2r\kappa_3$ and multiplying by $6!/3!$ gives

$$P_{2,3}(r) = 15r^3 + 30r^2 + 16r.$$

At $r = 1$ this is 61. At $r = 2$ it is 272. At $r = 0$ it vanishes, as every positive-index reciprocal coefficient must.

The leading term has a simple source

Only n copies of the linear logarithmic term can contribute $r^n w^n$. Therefore

$$[r^n]P_{N,n}(r) = \frac{(Nn)!}{n!(N!)^n}.$$

> **Read this as:** The polynomial parameter records how many logarithmic pieces are combined. It is not a numerical interpolation in the reciprocal order.

The partition plate is a finite combinatorial expansion. The exact tests verify the leading coefficient and parameter polynomial through block index six for five orders.

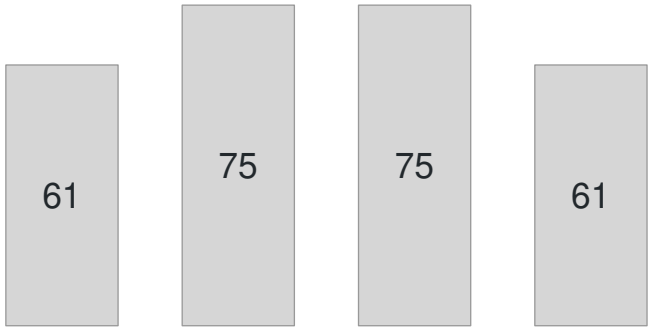
PLATE IV.11 / NEWTON AND ADDITION

Two recurrences reach the same answer

Chapter IV: Theorem 7.3, Theorem 7.4, Theorem 7.6.

One recurrence uses the denominator coefficients. Another uses its logarithm. With $b_n(r) = P_{N,n}(r)/(Nn)!$, the shorter logarithmic form is

$$nb_n(r) = r\sum_{k=1}^{n} \kappa_{N,k} b_{n-k}(r), \qquad b_0 = 1.$$



The negative superdiagonal in the Newton determinant is essential.

$n!b_n(r)$ for $n = 3$

$\frac{r}{2}$	-1	0
$\frac{r}{6}$	$\frac{r}{2}$	-2
$\frac{r}{15}$	$\frac{r}{6}$	$\frac{r}{2}$

$\det /6 = P_{2,3}(r)/720$

$P_{2,3}(2) = 61 + 75 + 75 + 61 = 272$

block weights: $1, 15, 15, 1$

The additive parameter law has block weights

Using the same logarithm, $D_N^{-r} D_N^{-s} = D_N^{-(r+s)}$. Thus

$$P_{N,n}(r+s) = \sum_{q=0}^{n} \binom{Nn}{Nq} P_{N,q}(r) P_{N,n-q}(s).$$

For $N = 2, n = 3, r = s = 1$, the four weights are $1, 15, 15, 1$. The two middle terms are $15 \cdot 1 \cdot 5$ and $15 \cdot 5 \cdot 1$. Together with the endpoints, they give 272. Using $\binom{n}{q}$ instead would be incorrect for these coefficients. That ordinary binomial law belongs to the separately normalized sequence $n!P_{N,n}/(Nn)!$.

> **Read this as:** Agreement of independent recurrences is a useful check precisely because their bookkeeping is different. Neither permits silently changing the factorial convention.

The checker compares both recurrence routes and the determinant, then checks the parameter-addition identity symbolically. A deliberately incorrect ordinary-binomial substitution is rejected.

PLATE IV.12 / LOGARITHMIC DIFFERENTIATION

Compress the ODE into a tangent

Chapter IV: Proposition 8.2, Corollary 8.4, Theorem 8.5.

The transfer tangent is $T_N = -D_N'/D_N$. It compresses the linear differential equation into a nonlinear scalar identity. This division is allowed only on the zero-free set of the denominator.

LINEAR EQUATION	LOGARITHMIC DERIVATIVE
$D_2'' = -D_2$	$T_2' = 1 + T_2^2$
$D_3''' = -D_3$	$T_3'' - 3T_3T_3' + T_3^3 = 1$

$$T_N = -D_N'/D_N \quad \text{only where } D_N \neq 0$$

$$T_4(z) = \frac{z^3}{3!} + 34\frac{z^7}{7!} + \cdots$$

The coefficients retain the reduced logarithmic information:

$$T_N(z) = N\sum_{m\geq 1} \kappa_{N,m} z^{Nm-1}, \qquad T_N(n) = N(Nn+N-1)!\kappa_{N,n+1}.$$

For order four, $\kappa_{4,1} = 1/24$ and $\kappa_{4,2} = 17/10080$. These give $T_4(0) = 1$ and $T_4(1) = 34$, explaining the last line of the plate.

A nonlinear equation with a precise origin

If $D = e^g$ locally, then $g' = -T$. Differentiating e^g three times gives $D'''/D = -T'' + 3TT' - T^3$. Setting $D'''/D = -1$ yields the cubic Riccati identity shown above. No additional nonlinear model has been assumed. The reciprocal family also satisfies $(D_N^{-r})' = rT_N D_N^{-r}$ on a fixed-log domain. The tangent has a pole at each zero of D_N. Positive integer reciprocal powers also have poles there. General complex powers retain the stated branch convention.

> **Read this as:** The nonlinear tangent equation is exact where division is legal. It is not a global regular differential equation across the zeros.

The tests verify the tangent coefficient recurrence, the exact cubic ODE, and the symbolic Riccati reduction after clearing denominators. The order-one tangent is the separate constant function $T_1 = 1$.

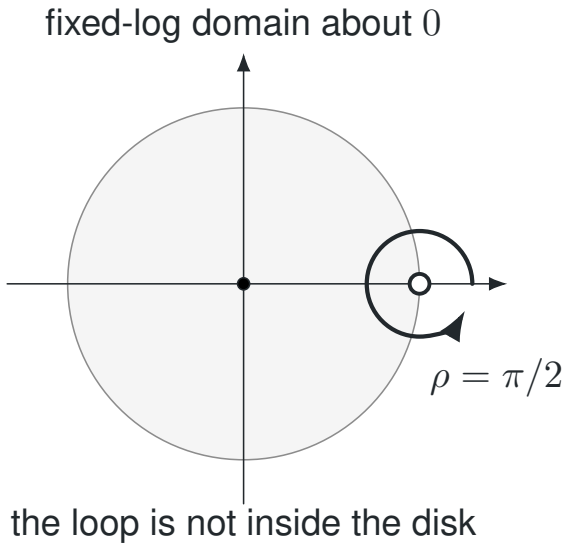


PLATE IV.13 / BRANCH BOOKKEEPING

A complex power needs a domain

Chapter IV: Section 2, Definition 7.1, Corollary 8.4.

A formal unit series has a formal logarithm at the origin. To interpret that germ analytically, choose a simply connected zero-free region containing 0 and normalize the logarithm to vanish there.

$$D_N(z)^{-r} = \exp(-rL(z)), \qquad e^{L(z)} = D_N(z), \quad L(0) = 0.$$

$$D(z) \sim D'(\rho)(z-\rho)$$

$$\log D \longmapsto \log D + 2\pi i$$

$$D^{-r} \longmapsto e^{-2\pi i r} D^{-r}$$

$$r = 1/2 : \ -1 \qquad r \in \mathbb{Z} : \ 1$$

For $D_2 = \cos z$, the open disk $|z| < \pi/2$ is an admissible domain. A small loop around the simple zero $\rho = \pi/2$ is not contained in that disk. Analytic continuation around the zero changes the local logarithm by $2\pi i$, and the power by $e^{-2\pi i r}$.

Three different kinds of statement

A *formal* identity compares coefficients at the origin. A *holomorphic* identity for complex powers uses a common specified logarithm. A positive *integer* reciprocal power is globally meromorphic and needs no branch choice. These scopes cannot be exchanged without a further argument. For example, $D^{-r}D^{-s} = D^{-(r+s)}$ is immediate using one fixed logarithm. Combining values built from unrelated branches can introduce additional phase factors.

> **Read this as:** The branch choice is mathematical data. It is not a plotting convention that can be removed by drawing a cleaner curve.

The domain picture is schematic. The phase change comes from the local simple-zero model and winding number, not from a sampled loop. Later nearest-pole asymptotics retain positive integral reciprocal order.

PLATE IV.14 / NORMALIZED SECTIONS

Three similar reciprocals differ

Chapter IV: Definition 9.1, Theorem 9.2, Example 9.11.

The signed denominator and the normalized unsigned sections produce different reciprocal families. In order two,

$$D_2^{-1} = \sec z, \qquad C_{2,0} = \operatorname{sech} z, \qquad C_{2,1} = z/\sinh z.$$

Their first block-EGF coefficients make the difference visible.

function	1	$z^2/2!$	$z^4/4!$	$z^6/6!$
$\sec z$	1	1	5	61
$\operatorname{sech} z$	1	-1	5	-61
$z/\sinh z$	1	$-\frac{1}{3}$	$\frac{7}{15}$	$-\frac{31}{21}$

$$E_{2,1}(z) = \sinh z = z\Phi_{2,1}(z^2), \qquad C_{2,1}(0) = 1$$

Remove the forced zero before taking a reciprocal

The section $E_{N,j}$ begins with $z^j/j!$. Define

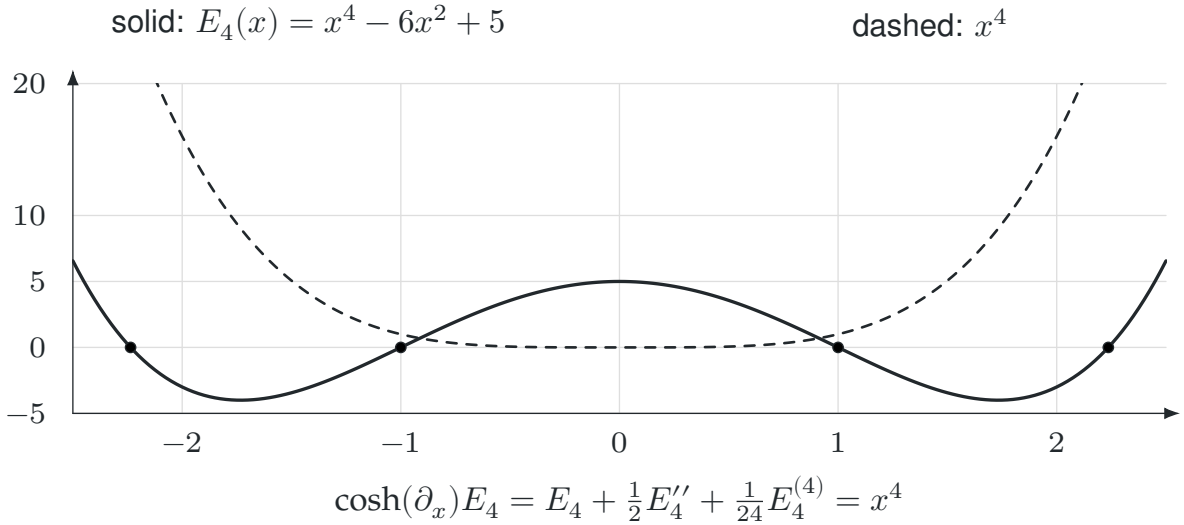
$$E_{N,j}(z) = \frac{z^j}{j!}\Phi_{N,j}(z^N), \qquad \Phi_{N,j}(0) = 1.$$

Then $C_{N,j}(z) = 1/\Phi_{N,j}(z^N)$ has value 1 at the origin. For $j > 0$, the notation $(z^j/j!)/E_{N,j}(z)$ means this removable continuation. It does not mean evaluating an undefined $0/0$ expression. For $N = 2, j = 1$, the first nontrivial coefficient is $-1/3$ in front of $z^2/2!$, equivalently $-z^2/6$. Dropping the numerator z would instead produce the pole of $1/\sinh z$.

> **Read this as:** A minus sign in the denominator series and removal of an initial zero are different operations. Their reciprocal coefficients should not be interchanged.

All entries in the table are exact rationals computed from independent triangular inverses. The table explicitly uses block-EGF columns. Ordinary coefficients are obtained by dividing by the displayed factorials.

PLATE IV.15 / APPELL POLYNOMIALS



An infinite symbol acts finitely

Chapter IV: Theorem 9.6, Theorem 9.8, Proposition 9.9.

For $C_{2,0}(z) = \operatorname{sech} z$, define $E_m(x)$ by $\operatorname{sech} z\, e^{xz} = \sum E_m(x) z^m/m!$. The formal differential-operator formula is

$$E_m(x) = \operatorname{sech}(\partial_x) x^m.$$

Although the symbol is an infinite series, derivatives above degree m vanish.

$$\cosh(\partial_x) E_4 = E_4 + \tfrac{1}{2} E_4'' + \tfrac{1}{24} E_4^{(4)} = x^4$$

For $m = 4$, only three terms survive:

$$\left(1 - \frac{\partial_x^2}{2!} + 5\frac{\partial_x^4}{4!}\right) x^4 = x^4 - 6x^2 + 5.$$

The four real roots of this polynomial are $\pm 1, \pm\sqrt{5}$. They are not the zeros of the original analytic denominator. The plot distinguishes the input polynomial and its transformed output.

An inverse operation, not a truncation error

Applying $\cosh(\partial_x)$ returns x^4 exactly. The general inverse uses the reciprocal formal symbol. The lowering and translation identities are

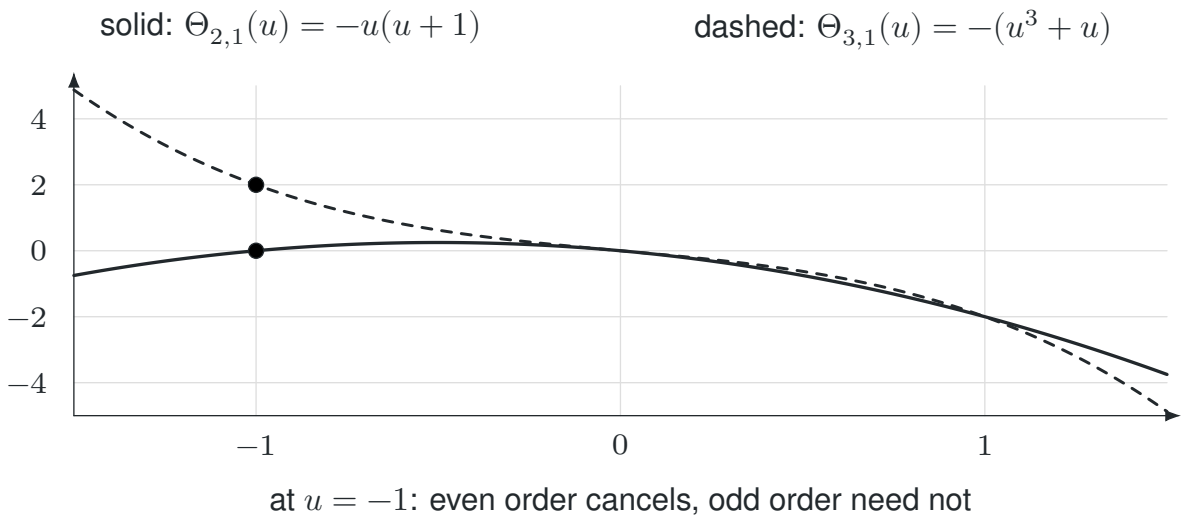
$$E_m' = m E_{m-1}, \qquad E_m(x+y) = \sum_{q=0}^{m} \binom{m}{q} E_q(x) y^{m-q}.$$

Both follow from the generating function. No operator-series convergence assumption on an infinite-dimensional function space is needed for this polynomial calculation.

> **Read this as:** Formal substitution into the derivative is safe here because every polynomial sees only finitely many derivatives. That is a domain statement.

The polynomial, its inverse image, and the Appell identities are checked symbolically through degree eight in four normalized-section families. The displayed curves are samples of exact polynomials.

PLATE IV.16 / THETA COUPLING



Scale and order enter differently

Chapter IV: Theorem 10.2, Proposition 10.3, Proposition 10.4.

Let $H_N(z) = E_{N,0}(z)$. The theta family uses the same parameter u twice, but in two different roles:

$$H_N(uz)^{-1} H_N(z)^{-u} = \sum_{n \geq 0} \Theta_{N,n}(u) \frac{z^{Nn}}{(Nn)!}.$$

Argument scaling contributes u^{Nm} at logarithmic block m. Reciprocal order contributes u.

Their combined logarithm has coefficient

$$(-1)^m \kappa_{N,m} \frac{u^{Nm} + u}{m}.$$

At the first block this gives $\Theta_{N,1}(u) = -(u^N + u)$. Every positive-index theta polynomial vanishes at $u = 0$. For even N, $H_N(-z) = H_N(z)$, so the defining product is also 1 at $u = -1$.

The odd-order boundary is visible

For $N = 3$, $\Theta_{3,1}(-1) = 2$, not zero. The factor $u + 1$ is not a uniform law across orders. In contrast,

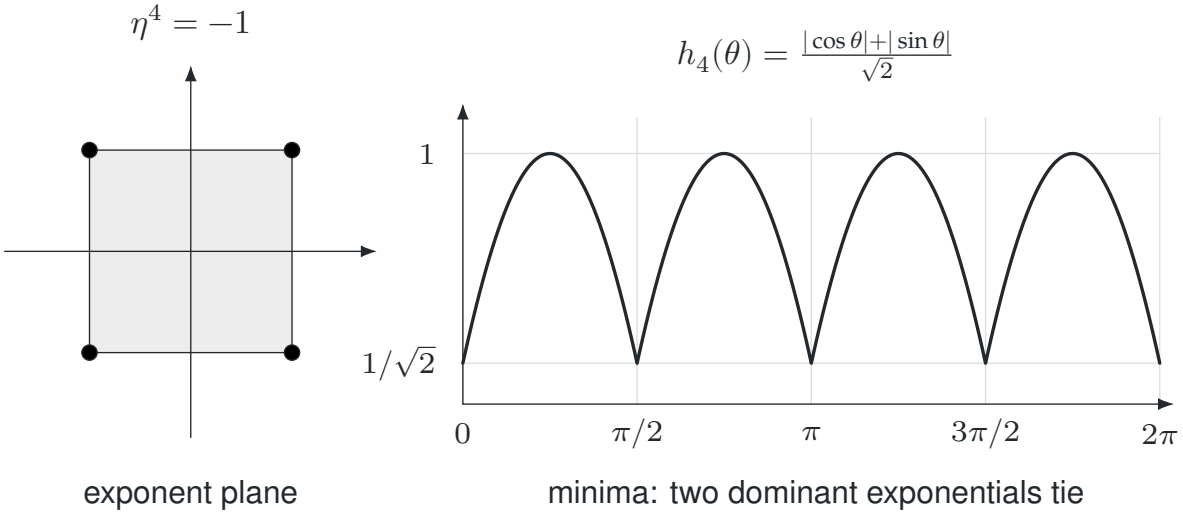
$$\Theta_{2,2}(u) = u(u+1)(5u^2 + u + 2).$$

The two guaranteed factors follow from the whole generating function, not from guessing the first few polynomial roots.

> **Read this as:** A common parameter does not make argument scaling and reciprocal order interchangeable. Their powers must be tracked separately.

The exact checker compares theta convolution with its logarithmic Newton recurrence through block index four. The odd-order factor claim is explicitly rejected as an invalid control.

PLATE IV.17 / DOMINANT EXPONENTS



Growth comes from a polygon

Chapter IV: Definition 11.3, Theorem 11.4.

Write the signed denominator as a finite exponential sum:

$$D_N(z) = \frac{1}{N} \sum_{\eta^N=-1} e^{\eta z}.$$

For $z = re^{i\theta}$, the size of one exponential is $e^{r\Re(\eta e^{i\theta})}$. The maximal projection determines the directional exponential growth.

The indicator is

$$h_N(\theta) = \max_{0 \le k < N} \cos\left(\theta + \frac{(2k+1)\pi}{N}\right).$$

Away from a tie direction, one exponential dominates all the others by a uniform positive projection gap on compact angular sets. For sufficiently large radius, smaller terms cannot cancel it. Those sectors are eventually zero-free.

Why zeros remain possible on a growing ray

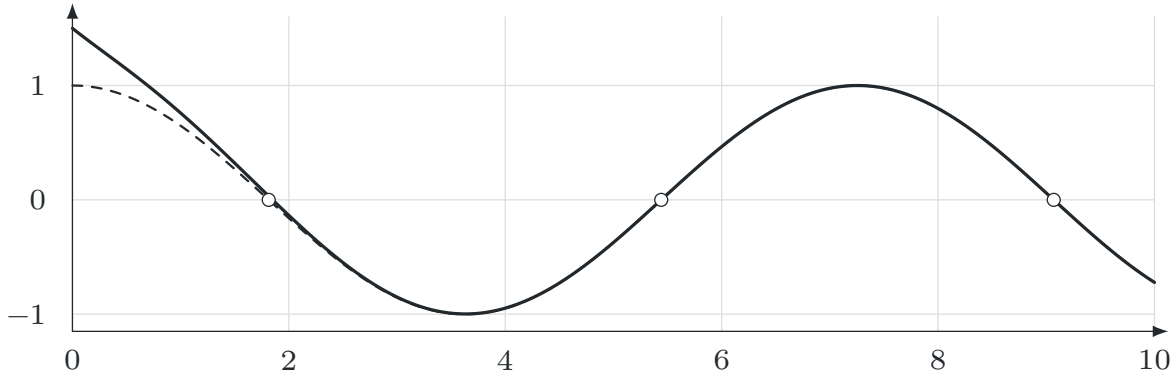
At a tie, two adjacent exponents have the same real projection. Their complex phases can be opposite. Their sum can therefore vanish even though each term is exponentially large. The minima in the order-four indicator plot occur precisely at the tie directions $\theta = k\pi/2$. The indicator uses a limsup in radius. It does not assert that $r^{-1}\log|D_N(re^{i\theta})|$ has an ordinary limit through the zeros on a tie ray.

> **Read this as:** The polygon predicts where large cancellation is possible. It does not, by itself, enumerate zeros or prove their simplicity.

The order-four polygon and support-function formula are explicit. The curve is a sampled display of that formula. Eventual localization and uniqueness require the separate zero-analysis arguments.

PLATE IV.18 / THE CUBIC MODEL

Two large terms nearly cancel



Chapter IV: Lemma 11.5, Theorem 11.7, Corollary 11.9.

For real t, order three has the exact formula

$$D_3(t) = \frac{e^{-t} + 2e^{t/2}\cos(\sqrt{3}t/2)}{3}.$$

Divide by the nonzero factor $2e^{t/2}/3$. The resulting equation separates the dominant cosine from the small third exponential.

$$\tfrac{3}{2}e^{-t/2}D_3(t) = \cos(\sqrt{3}t/2) + \tfrac{1}{2}e^{-3t/2}$$

solid: full expression; dashed: two-term model; circles: model zeros

Ignoring the last term gives model zeros

$$t_m = \frac{2\pi}{\sqrt{3}}(m + 1/2).$$

At t_m, the full normalized expression equals $\frac{1}{2}e^{-3t_m/2} > 0$, so t_m is not an exact zero. Linearizing the cosine at that point predicts

$$\delta_m^{(1)} = \frac{(-1)^m}{\sqrt{3}}e^{-3t_m/2}.$$

The alternating slope explains why the true zero is to the right of the first model zero, then to the left of the second, and so on in the eventual regime.

Symmetry needs uniqueness

Real coefficients alone allow nonreal conjugate pairs. The manuscript first proves that a near-model disk contains exactly one zero. Conjugation preserves that disk, so the unique zero must equal its conjugate. This additional uniqueness step, not the symmetry alone, places it exactly on the ray.

> **Read this as:** The correction is caused by a real, nonzero remainder. A good cosine approximation does not make its model zeros exact.

The curves are sampled analytic expressions. The next page independently certifies four narrow real-zero intervals rather than trusting the plotted crossing or the floating-point root finder.

PLATE IV.19 / EXACT RATIONAL BRACKETS

A root estimate becomes a certificate

Chapter IV: Theorem 11.7, Theorem 11.8, Corollary 11.9.

The root finder is used only to suggest intervals. Each displayed interval is accepted by exact rational arithmetic: opposite endpoint signs prove existence, and an interval bound for D_3' excludes zero throughout the interval, proving uniqueness inside it.

	certified lower endpoint	$\tau_m - t_m$	$\delta_m/\delta_m^{(1)} - 1$
$m = 0$	1.84981279919014347629	$+3.60134 \times 10^{-2}$	-5.243×10^{-2}
$m = 1$	5.44123335502366335540	-1.64738×10^{-4}	$+2.471 \times 10^{-4}$
$m = 2$	9.06899753487157765805	$+7.13700 \times 10^{-7}$	-1.071×10^{-6}
$m = 3$	12.69659554654675729440	-3.09277×10^{-9}	$+4.639 \times 10^{-9}$

Each upper endpoint is the displayed lower endpoint plus 10^{-20}.

Root intervals: exact rational certificates. Displacement columns: numerical diagnostics.

How the certificate works

Evaluate the Taylor polynomial

$$S_{90}(t) = \sum_{n=0}^{90} \frac{(-1)^n t^{3n}}{(3n)!}$$

at the two rational endpoints. From the next term onward, magnitudes decrease, because their successive ratio is

$$\frac{t^3}{(3n+1)(3n+2)(3n+3)} < 1$$

there. The alternating-series remainder is bounded by the first omitted term. A separate outward interval evaluation of the differentiated polynomial, plus its tail bound, certifies the derivative sign. The first bracket is

$$1.84981279919014347629 < \tau_0 < 1.84981279919014347630.$$

Its displacement differs from the leading asymptotic prediction by about five percent. The later examples have much smaller relative discrepancies, as the plate records.

> **Read this as:** A small residual is not a root certificate. Endpoint signs plus a derivative bound give a checkable local existence-and-uniqueness statement.

Four certified intervals do not establish that no other real or complex zeros exist. The displacement columns are high-precision diagnostics, not a finite verification of a global big-O theorem. All rational enclosures are included in the checks file.

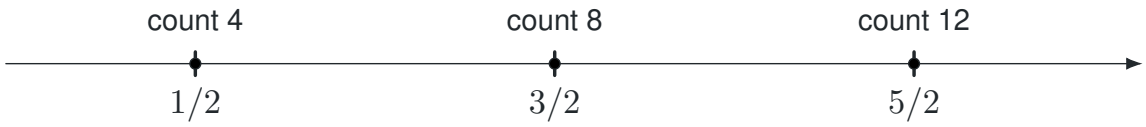


PLATE IV.20 / EXACT FOURTH-ORDER STRINGS

Counting changes under the power map

Chapter IV: Example 11.12, Theorem 11.14.

Order four gives a case with no asymptotic displacement at all. In normalized coordinates the positive radial locations are $u = m + 1/2$, while the reduced-zero locations are $v = (m + 1/2)^4$.

$$u = |z|/(\sqrt{2}\pi)$$

$$v = |w|/(4\pi^4)$$

$$n_{D_4}(\sqrt{2}\pi u) = 4\lfloor u + 1/2 \rfloor, \quad n_{\Delta_4}(4\pi^4 v) = \lfloor v^{1/4} + 1/2 \rfloor$$

The two rows describe the same zero orbits. The upper row counts four zeros each time a new radius is reached. The lower row counts one reduced zero each time its fourth-power location is reached. Both formulas include zeros on the boundary of the disk.

Separate radius conversion from orbit multiplicity

In unscaled variables the general relation is

$$n_{D_N}(R^{1/N}) = N n_{\Delta_N}(R).$$

There are two operations here: replace the radius by its Nth root and divide the count by N. Forgetting either operation changes the leading constant. For this family the asymptotics are

$$n_{D_N}(R) = \frac{N \sin(\pi/N)}{\pi} R + O(1), \qquad n_{\Delta_N}(R) = \frac{\sin(\pi/N)}{\pi} R^{1/N} + O(1).$$

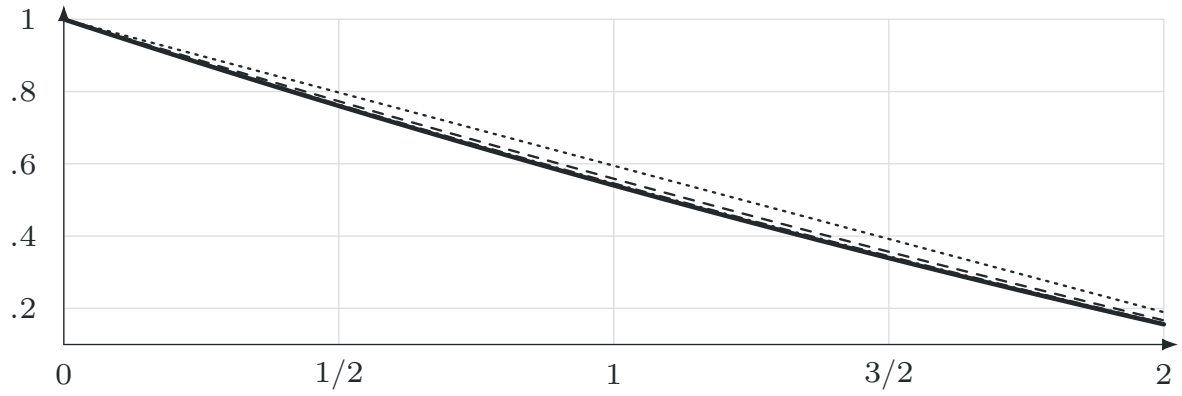
The different powers agree with the entire-function orders 1 and $1/N$.

> **Read this as:** The reduced function has fewer repeated zeros and a different radius scale. Its counting law is not obtained by dividing a same-radius count alone.

The exact order-four staircase formulas are tested at rational radii including jump points. The large-zero theorem for general N permits finitely many exceptions. These exact order-four identities do not justify discarding that boundary elsewhere.

PLATE IV.21 / CANONICAL PRODUCT

A product and an operator share zeros



Chapter IV: Theorem 12.1, Theorem 12.2.

For $N \geq 2$, the reduced entire function has order $1/N < 1$. Its multiplicity-sensitive genus-zero product is

$$\Delta_N(w) = \prod_{\lambda \in \Lambda_N} (1 - w/\lambda).$$

Putting $K_N e_\lambda = \lambda^{-1} e_\lambda$ on $\ell^2(\Lambda_N)$ gives the corresponding diagonal Fredholm determinant. Repeated zeros require repeated diagonal entries.

$$\Delta_2(w) = \cos\sqrt{w}, \qquad P_L(w) = \textstyle\prod_{m=0}^{L-1}(1 - w/\lambda_m)$$

thick: entire function; dotted $L = 1$; dashed $L = 3$; dash-dot $L = 10$

Finite compression is an approximation

For $N = 2$, $\lambda_m = \pi^2(m + 1/2)^2$. The finite determinant P_L is exactly the displayed finite product, but it is not exactly Δ_2. For $0 \leq w \leq 1$ and $L \geq 1$, an elementary tail estimate gives

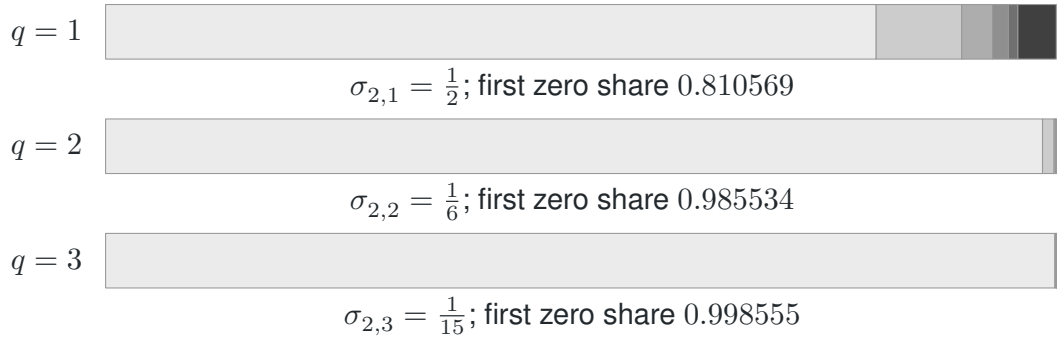
$$0 \leq 1 - \frac{\Delta_2(w)}{P_L(w)} \leq w \sum_{m \geq L} \lambda_m^{-1} \leq \frac{1}{9(L - 1/2)}.$$

The last bound uses $\pi > 3$ and integral comparison. Thus truncation has an explicit error mechanism.

> **Read this as:** The infinite product is justified by the analytic theorem. Finite determinants provide controlled approximations, not substitutes for that theorem.

The exact finite determinant test includes a repeated eigenvalue and rejects deduplication. The curves use known cosine zeros. Order one is excluded: $\Delta_1(w) = e^{-w}$ has no zeros, so its empty product would be 1, not the function.

PLATE IV.22 / ZERO POWER SUMS



Finite coefficients give infinite moments

Chapter IV: Theorem 12.6, Corollary 12.7, Corollary 12.9, Corollary 12.10.

Taking the logarithm of the canonical product identifies

$$\kappa_{N,q} = \sigma_{N,q} := \sum_{\lambda \in \Lambda_N} \lambda^{-q} = \operatorname{Tr}(K_N^q), \qquad q \geq 1.$$

The same exact numbers can be computed from finitely many denominator coefficients by Newton's recurrence. No numerical zero list is needed for that calculation.

five finite contributions plus the remaining tail. Higher moments emphasize the nearest zero

For order two,

$$\sigma_{2,1} = \frac{1}{2}, \quad \sigma_{2,2} = \frac{1}{6}, \quad \sigma_{2,3} = \frac{1}{15}, \quad \sigma_{2,4} = \frac{17}{630}.$$

The plate shows how successive inverse powers emphasize the nearest zero. Its shaded pieces are contributions from the first five positive reduced zeros, followed by the remaining tail. The total in each row is the exact rational moment.

The tangent is a sum of poles

Logarithmic differentiation also gives

$$T_N(z) = N z^{N-1} \sum_{\lambda \in \Lambda_N} \frac{1}{\lambda - z^N}$$

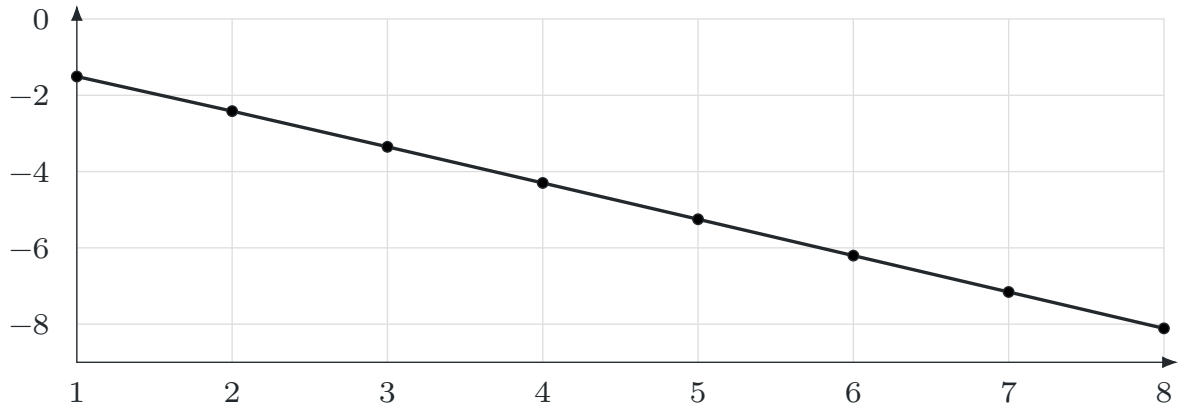
away from poles. Summability of $|\lambda|^{-1}$ permits the locally uniform partial-fraction expansion without added regularizing terms.

> **Read this as:** A global analytic product theorem connects the infinite zero sum to a finite algebraic recurrence. The recurrence alone does not prove the product theorem.

Displayed moments are checked against formal logarithm coefficients and exact order-two/order-four zeta values. Bar widths are numerical shares. General power sums use λ^{-q}, not $|\lambda|^{-q}$ when exceptional nonpositive zeros are present.

PLATE IV.23 / SINGULARITY ANALYSIS

Nearest poles set coefficient growth



Chapter IV: Theorem 13.1, Corollary 13.2, Corollary 13.3, Corollary 13.4.

For $1/\cos z$, the nearest poles are $\rho = \pm\pi/2$. They contribute equally to even-degree coefficients. Including both poles gives

$$P_{2,n}(1) \sim 2(2n)! \left(\frac{2}{\pi}\right)^{2n+1}.$$

The factor two is orbit multiplicity, not an adjustable fitted constant.

$$\log_{10}(1 - R_n), \quad R_n = \frac{P_{2,n}(1)}{2(2n)!(2/\pi)^{2n+1}}$$

Each ratio is enclosed with a rational Machin-formula bound for π.

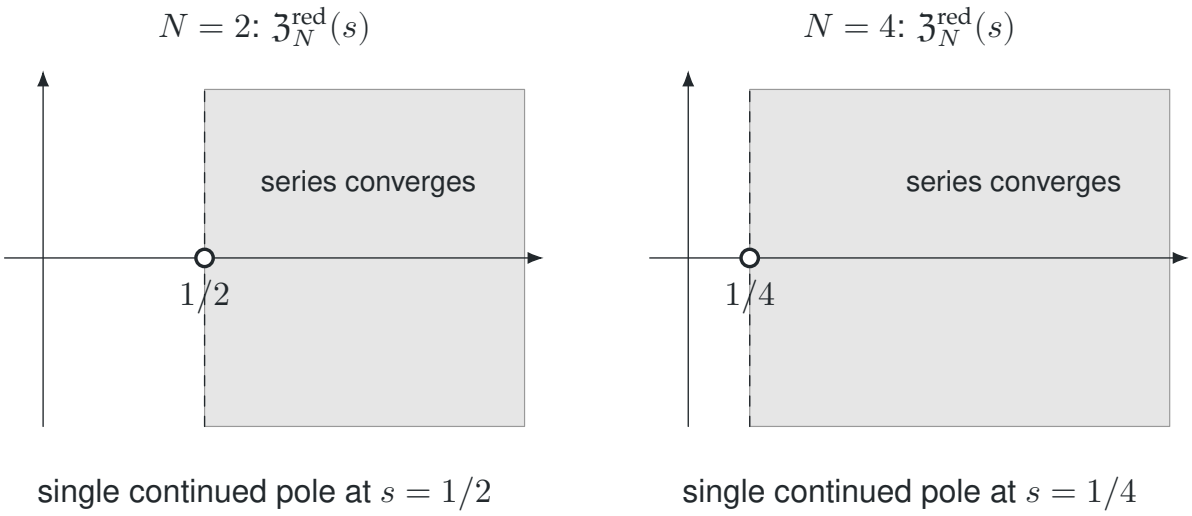
A finite quantitative check

For $n = 1, \ldots, 8$, the exact integer coefficients and a rational enclosure for π bound the ratio R_n strictly between zero and one. In this tested range, $1 - R_n < 3^{-(2n+1)}$. The plot displays the logarithm of the enclosed error, not an independently asserted all-n bound.

Higher reciprocal powers need more Laurent data

For positive integral order r, a simple denominator zero becomes a pole of order r. The highest Laurent term contributes a factor $\binom{m+r-1}{r-1}$, but lower Laurent terms still contribute on the same exponential scale. Subtracting *all* principal parts is what leaves a holomorphic remainder controlled by the next zero radius.

> **Read this as:** Nearest-zero geometry explains factorial-times-exponential growth. Multiplicity, reciprocal order, and lower principal parts determine its precise normalization.



The ratio certificates use a rational Machin-formula enclosure for π. The inherited general theorem retains simple nearest zeros, a gap to the next modulus, and positive integral reciprocal order. The plot does not remove those hypotheses.

PLATE IV.24 / ZERO ZETA FUNCTIONS

Convergence is not continuation

Chapter IV: Theorem 14.2, Theorem 14.3, Corollary 14.4.

Reduced zeros grow like m^N. Their absolute zero-zeta series therefore has a half-plane of absolute convergence $\Re s > 1/N$. The absolute zero zeta in the original variable instead requires $\Re s > 1$.

For $N = 2$ and $N = 4$, the lattices are exact:

$$\mathfrak{Z}_2^{\mathrm{red}}(s) = \pi^{-2s}\zeta(2s, 1/2), \qquad \mathfrak{Z}_4^{\mathrm{red}}(s) = (\sqrt{2}\pi)^{-4s}\zeta(4s, 1/2).$$

Each identity first holds where its defining series converges. The right side supplies its meromorphic continuation. There is a single pole, at $1/2$ or $1/4$, with residue $1/(2\pi)$ or $1/(4\sqrt{2}\pi)$ respectively.

The factor N matters twice

For every order in the paper,

$$\mathfrak{Z}_N^{\mathrm{abs}}(s) = N\mathfrak{Z}_N^{\mathrm{red}}(s/N).$$

For general N, exponentially accurate zero locations leave an entire correction to the Hurwitz model. A finite exceptional zero set also contributes entire terms. This reasoning establishes continuation, not a zeta functional equation.

> **Read this as:** An analytic continuation can exist at points where the original infinite sum diverges. It must not be evaluated there by naively summing that series.

The shaded regions show convergence, and the open circles mark poles of the continued functions. They are not zeros of the zeta functions. Branch-dependent orbit zetas and derivative-weighted zetas retain their separately stated conventions.

PLATE IV.25 / COEFFICIENT AND ZERO WORKED MODEL

One closed calculation: the number 69

Chapter IV: Corollary 7.7, Example 11.12, Theorem 12.6.

Use $N = 4$ throughout this page. Its denominator, its exact zero lattice, and the reciprocal recurrences provide two routes to the same coefficient. All symbols in the plate refer to this one order.

denominator	$1 - w/24 + w^2/40320 + \cdots$
negative logarithm	$w/24 + (17/20160)w^2 + \cdots$
zero moments	$\sigma_1 = 1/24, \quad \sigma_2 = 17/10080$
reciprocal	$1 + w/24 + 69w^2/40320 + \cdots$
tangent	$z^3/3! + 34z^7/7! + \cdots$

$$69 = 8!\,\frac{\sigma_1^2+\sigma_2}{2}, \qquad 34 = 4 \cdot 7!\,\sigma_2$$

Route one: invert the denominator

The w^2 coefficient of Δ_4^{-1} is

$$\frac{1}{24^2} - \frac{1}{8!} = \frac{69}{8!}.$$

Thus $P_{4,2}(1) = 69$. Keeping r variable gives $P_{4,2}(r) = 35r^2 + 34r$.

Route two: use the zero moments

The exact reduced zeros are $4\pi^4(m + 1/2)^4$. Their first two power sums are $\sigma_1 = 1/24$ and $\sigma_2 = 17/10080$. The Bell/Newton identity gives the same reciprocal coefficient $(\sigma_1^2 + \sigma_2)/2$. The tangent independently reads off the second moment as $4 \cdot 7!\sigma_2 = 34$. This links coefficients, geometry, and derivatives without a fitted parameter or an inferred zero list.

> **Read this as:** The content is the agreement of precisely normalized descriptions. A matching small example illustrates the general bridges. It is not a proof of all their analytic hypotheses.

Every rational value and polynomial identity on this page is checked exactly. The infinite zero-sum interpretation uses the inherited canonical-product theorem and the exact order-four zero formula.

PLATE IV.26 / FORMAL AND COMPUTATIONAL BOUNDARIES

What is evidence, and for what?

Chapter IV: Section 15, Section 16.

These twenty-six plates develop the mathematical models accompanying Chapter IV. Their references connect each example to the chapter's statements. The formal companion records the separate verification contracts and evidence scope.

Evidence layer	What it supports
Recorded formal audit	All 118 production modules compiled in the recorded audit. Separate kernel replay and manuscript correspondence checks cover the 68 scoped results. Exact counts, hypotheses, and controls appear in the Lean guide.
Recorded exact checks	All 1,008 rational algebra assertions and fifteen finite transfer-derivative polynomial identities passed. Fifteen deliberate corruptions were rejected. These are bounded checks.
Exact certificates	The retained visual run records 147 checks, five rejected controls, and four rational zero brackets of width 10^{-20}. The brackets certify local existence and uniqueness. The symbolic suites were hash-validated, not rerun in the recorded audit.
Numerical visualization	Sampled analytic curves, finite products, moment shares, and displacement diagnostics have the roles stated on their pages. They are not exact global zero censuses.
Figure provenance	The source records preserve all twenty-four editable TikZ figures. Plate IV.13 retains its reviewed label adjustment.
Editorial preservation	Assembly does not regenerate figures. The original worked formulas, model code, checker, and vector sources are preserved. Locators refer to Chapter IV.

Boundaries that remain in force

The general family has eventual positivity and simplicity of its reduced zeros, not an assertion that every reduced zero is positive and simple. The paper leaves universal simplicity, positivity of every reduced zero, full displacement expansions, and a zeta functional equation open. The exact order-two and order-four models do not settle those questions for every order. Imported standard fact 11.1 stays outside the 68-result contract. Fixed logarithms, zero-free domains, multiplicities, and the hypotheses of nearest-pole asymptotics remain explicit. No historical priority is inferred from successful computation or formal verification.

Replay the worked layer

Run `python build.py` in this editable guide folder to compile the PDF in an isolated temporary directory. The separate model checker is `checks/verify_examples.py`. The plate generator is `source/generate_graphics.py`. They require the listed Python dependencies. Run those mathematical tools in a temporary copy to preserve the delivered evidence.

> **Read this as:** A proof, a finite exact test, a root enclosure, and a sampled curve answer different questions. Keeping their scopes explicit makes the pictures useful mathematical evidence.

The source package preserves the formal sources, proofreading record, verification audit, exact certificates, and rebuild instructions. PDF assembly remains separate from mathematical verification.

CHAPTER V

Multiresolution Signal Calculus

Exact coordinates, singular packets, and stable reconstruction

The analytic constructions give way to signal representations and reconstruction.

Signal models move through filters, packet trees and reconstruction maps. Exact coordinates and singular packets distinguish representation from approximation and recovery.

IN THIS CHAPTER

Mathematical text 383

Visual studies 467

Formal companion 1936

Sources and references 2675

Scope

Separated-jump results require the stated model, gap and grid assumptions. Stable edge-packet recovery and the broader approximation class remain open.

The next chapter asks how transfers evolve in time and how eliminated states contribute memory.

How to use this volume

Part I. The twenty-result formal core develops exact polyphase reconstruction, filter transfers, Hilbert packet operators, finite adaptive trees, edge error bounds, and Smith coordinates.

Part II. The complete extended development treats lattice coordinates, stable banks, singular packets, separated jump recovery, geometric error bounds, and multiscale localization.

Visual atlas. Forty worked plates close the volume. The separate visual guide provides the same examples, and the Lean guide gives the precise formal contract.

Reading this chapter

This chapter develops signal calculus in two complementary parts. Part I gives twenty results on exact coordinates, filtering, adaptive selection and packet error. Part II develops lattice coordinates, stable banks, singular packets and separated jump recovery, with E-prefixed section numbers. The two parts share constructions but use them under different hypotheses.

For a first reading, follow Part I Sections 1–7. These sections establish the coordinate maps, filter transfers, exact reconstruction, and the separation of packet error from smooth approximation error. Section 11 develops finite adaptive selection. Sections 13–14 give the cyclic Smith realization. Continue with Part II Sections E2–E6 for lattice and stability generalizations, E7–E11 for singular packets and recovery, and E12–E14 for nonlinear and Cayley coordinates. Each visual plate identifies the corresponding manuscript result.

The formal companion maps all twenty Part I results to 225 supporting Lean theorem targets across 23 proof modules. Part II has ordinary written proofs and is outside that twenty-result formal map. Exact examples and numerical studies have their own stated scopes. The formal companion and source records distinguish kernel verification, finite checks and numerical replay.

The two broad edge recovery conjectures remain open. Part II proves recovery for a declared one-dimensional separated jump class under its sampling, contrast, and noise assumptions. These results do not supply universal image segmentation or infinite-tree consistency. Numerical illustrations keep the finite interpretation stated in their captions.

Part I: The formal core

Coordinates first, decisions second

A residue decomposition changes the coordinates of a signal without changing its information. Filtering then acts between those coordinates. Approximation enters when an operator compresses a component or when a decision discards coefficients. The formal core follows these operations in that order.

Overview

This chapter develops the signal realization of the projector-resolved seed calculus. The impulse δ_0 is taken as a primitive signal seed and its shift orbit supplies the address system. Residue projectors split a sequence into exact polyphase channels, nested divisibility gives exact refinement, and every finite impulse-response operator becomes a matrix of packet transfers. The standard perfect-reconstruction condition for a filter bank is therefore an analysis–synthesis identity in the common operator language of the series. Haar analysis and every finite-depth wavelet-packet transform are treated on complex ℓ^2, together with concrete finite-signal models and a predict–update lifting step. The edge problem is separated into two statements. When a discontinuity packet is known and retained exactly, approximation error is exactly the approximation error of the remaining smooth packet. No spectral approximation of the jump is performed. When the packet is estimated, a symmetric-difference bound isolates mask error, amplitude error, and smooth-background error. Numerical studies compare global Fourier truncation, exact known-packet reconstruction, and a deliberately narrow positive-contrast estimator in one and two dimensions, including curved boundaries, corners, and multiple amplitudes. The same cyclic phase action is then placed on the Smith reflection disk. Its pullback through the Cayley transform is a Möbius action on impedance, and the two-phase case is precisely impedance–admittance inversion. Nonlinear coefficient products obey cyclic packet convolution. The accompanying formal development gives a Lean formalization of all twenty theorem-like statements under the hypotheses stated below: 225 supporting theorem targets in 23 modules. Eighteen regenerated figures, machine-readable numerical results, the 33-test original companion suite, and 36 additional exact-model and verifier tests accompany the chapter. Exact signal theorems, limited numerical estimators, classical constructions, and open recovery problems are kept distinct throughout.

Scope and claim boundary

The chapter proves exact polyphase reconstruction, exact finite filter-transfer identities, perfect reconstruction for the stated filter banks, the conditional known-edge theorem, mask and amplitude perturbation bounds, nonlinear residue-convolution laws, and the Smith-coordinate phase action. It does not claim that every discontinuity can be detected automatically, that every form of Gibbs ringing has been eliminated, or that the supplied two-class estimator is a universal segmentation method. The estimator is included as one reproducible finite example. For every finite packet refinement tree, the chapter proves existence of a globally optimal complete pruning, an exact dynamic-programming selector for additive costs, and a deterministic margin-stability certificate. Wavelets, filter banks, the Cayley transform, and the classical Smith grid are treated as classical inputs organized in the common seed–packet–refinement language.

Verification convention. "Lean-checked" refers to the explicitly scoped theorem statements and their supporting declarations, accepted by the pinned Lean kernel. It does not certify the English text automatically, the floating-point Python implementation, physical modeling choices, or the two conjectures. The manuscript-to-declaration correspondence has been reviewed manually. Section D records it result by result. Numerical replay has a separate record and does not enlarge the formal theorem scope.

1 The signal realization of the seed calculus

Let $\ell^2(\mathbb{Z};\mathbb{C})$, abbreviated $\ell^2(\mathbb{Z})$, be the Hilbert space of square-summable complex discrete signals. The inner product is conjugate-linear in its first argument. A superscript $*$ on a bounded operator denotes its Hilbert adjoint. Write δ_n for the unit impulse at address n and let the bilateral shift be

$$(Sx)[n] = x[n-1].$$

Then

$$S^n\delta_0 = \delta_n.$$

The primitive signal seed is therefore $s = \delta_0$, the address operators are the shift words S^n, and the completion is the ℓ^2 norm.

Theorem 1.1 (Impulse seed theorem). *The closed shift-generated hull of δ_0 is all of $\ell^2(\mathbb{Z})$:*

$$\boxed{\overline{\operatorname{span}\{S^n\delta_0 : n \in \mathbb{Z}\}}^{\ell^2} = \ell^2(\mathbb{Z}).}$$

Every finitely supported signal has the exact finite expression

$$x = \sum_{n\in\mathbb{Z}} x[n]S^n\delta_0.$$

Proof. The shift orbit is the standard orthonormal basis $\{\delta_n\}_{n\in\mathbb{Z}}$. For $x \in \ell^2$, the finite truncations

$$x_F = \sum_{n\in F} x[n]\delta_n, \qquad F \subset \mathbb{Z} \text{ finite},$$

satisfy $\|x - x_F\|_2^2 = \sum_{n\notin F} |x[n]|^2 \to 0$ as the finite sets exhaust $\mathbb{Z}$. Thus the unordered Hilbert-space sum $\sum_n x[n]\delta_n$ converges to x, and the finite-support statement is exact. The shift is a surjective isometry because $n \mapsto n-1$ is a bijection of $\mathbb{Z}$, with inverse shift $n \mapsto n+1$. This proves the closed-span assertion. □

This realization fixes the language used below:

$$\text{impulse seed} \longrightarrow \text{shift address} \longrightarrow \text{packet projection} \longrightarrow \text{filter transfer}$$
$$\longrightarrow \text{refinement} \longrightarrow \text{reconstruction}.$$

Remark 1.2 (Several completions). The same algebraic seed description applies to finite sequences, ℓ^1, ℓ^2, periodic sequences, tempered distributions, and multidimensional lattices. The topology decides which infinite reconstructions are legitimate. Finite-dimensional experiments in this chapter use ordinary Euclidean norms. Theorem statements specify the ambient norm when it matters.

2 Residue projectors and exact polyphase coordinates

A packet has two useful representations

The masked packet keeps its original sample addresses and sets the other phases to zero. The decimated channel stores only the retained addresses, now indexed by the coarse coordinate. They carry the same values, but their domains differ. Refinement sums belong on the original lattice. Interleaving converts the channels back to that lattice.

Fix an integer $N \geq 1$. For $0 \leq r < N$, define

$$(P_{N,r}x)[n] = \mathbf{1}_{n \equiv r \,(\mathrm{mod}\, N)} x[n].$$

The corresponding decimated channel is

$$x_r[q] = x[Nq + r].$$

Theorem 2.1 (Polyphase projector theorem)**.** *The maps $P_{N,r}$ are bounded orthogonal projectors on ℓ^2, with operator norm at most one, and satisfy*

$$P_{N,r}P_{N,s} = \delta_{rs}P_{N,r}, \qquad \sum_{r=0}^{N-1} P_{N,r} = I.$$

Consequently,

$$\boxed{x = \sum_{r=0}^{N-1} P_{N,r}x}$$

with no approximation.

Proof. Each integer belongs to exactly one residue class modulo N. Multiplying the two indicator functions gives zero for distinct classes and the same indicator for equal classes. Summing all residue indicators gives one at every address. Moreover,

$$\|P_{N,r}x\|_2^2 = \sum_{n \equiv r \,(\mathrm{mod}\, N)} |x[n]|^2 \leq \|x\|_2^2, \qquad \langle P_{N,r}x, y\rangle = \langle x, P_{N,r}y\rangle.$$

The mask is real-valued, so the inner-product identity follows term by term. Hence each projector is self-adjoint, and the ranges of different residue projectors are orthogonal. □

Define the analysis and synthesis maps

$$\mathcal{A}_N x = (x_0, \dots, x_{N-1}), \qquad \mathcal{S}_N(x_0, \dots, x_{N-1})[Nq + r] = x_r[q].$$

Corollary 2.2 (Analysis–synthesis identity)**.**

$$\boxed{\mathcal{S}_N\mathcal{A}_N = I.}$$

On the product of the channel spaces one also has $\mathcal{A}_N\mathcal{S}_N = I$. Equip this finite product with the Hilbert norm

$$\|(x_0, \dots, x_{N-1})\|_{\mathrm{ch}}^2 = \sum_{r=0}^{N-1} \|x_r\|_2^2.$$

Then $\mathcal{A}_N$ is a linear isometric equivalence and

$$\|x\|_2^2 = \sum_{r=0}^{N-1} \|x_r\|_2^2.$$

Proof. Euclidean division gives a unique pair (r, q) with $0 \le r < N$ and $n = Nq + r$, including negative n. The address maps $n \mapsto (n \bmod N, n \operatorname{div} N)$ and $(r, q) \mapsto Nq + r$ are inverse. Analysis and synthesis are reindexing by this bijection. Reindexing the nonnegative sum $\sum_n |x[n]|^2$ proves the norm identity and shows that both maps preserve square summability. In Lean the target is $\ell^2(\{0, \dots, N-1\} \times \mathbb{Z})$, which realizes exactly this Hilbert norm. □

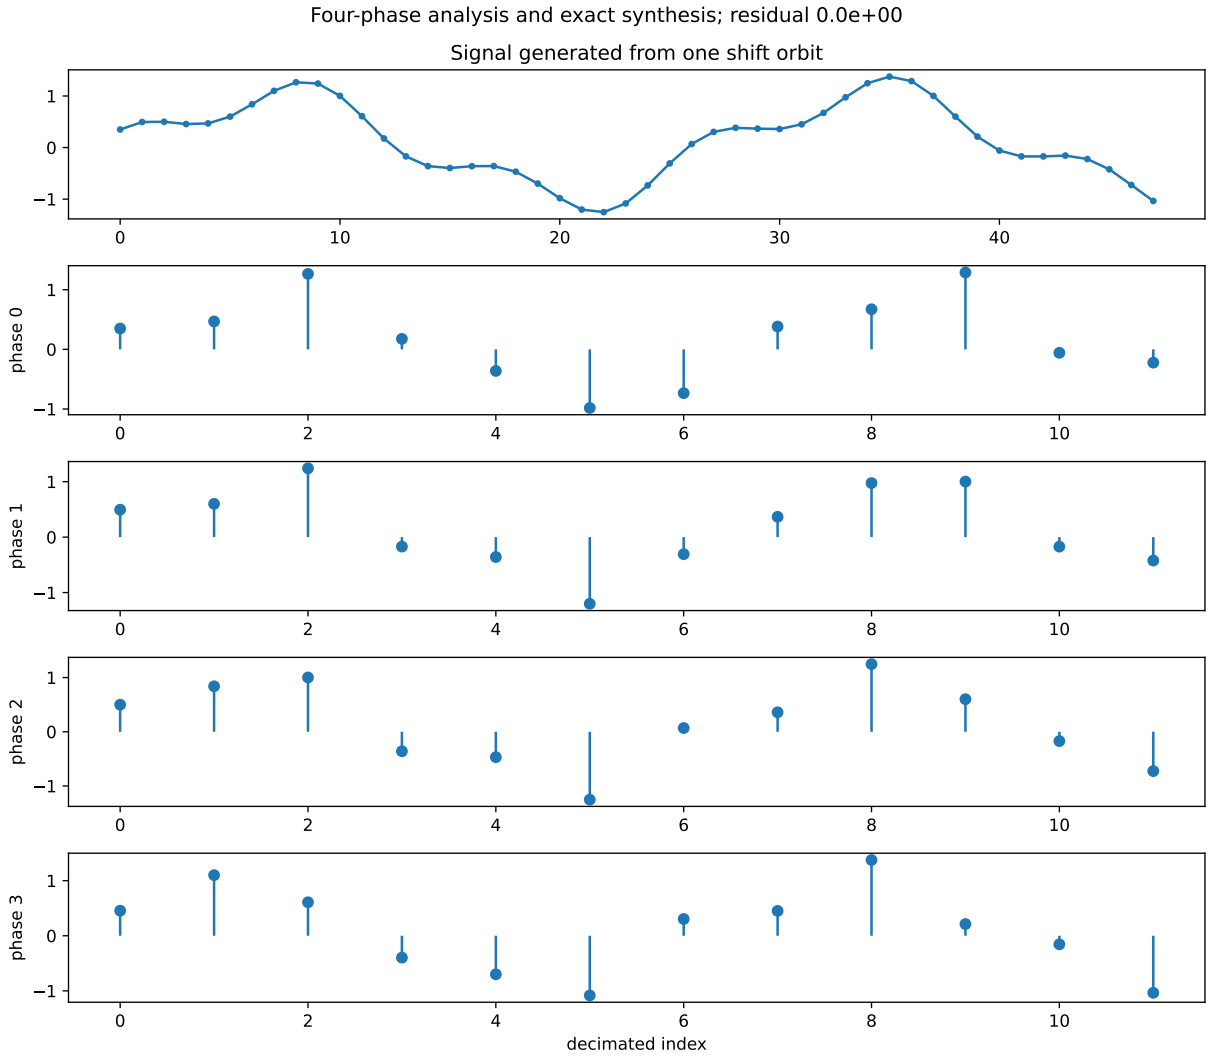


Figure 1. Four-phase analysis of a finite signal. The channels are decimated coordinate packets. Interleaving them gives the original signal exactly.

2.1 Nested refinement

Suppose $N, M \geq 1$ and $N \mid M$. Every coarse phase has a disjoint family of fine descendants:

$$\mathrm{Child}_M(N, r) = \{s : 0 \leq s < M,\ s \equiv r \pmod{N}\}.$$

Theorem 2.3 (Exact nested refinement). *For $N, M \geq 1$ and $N \mid M$,*

$$\boxed{P_{N,r} = \sum_{\substack{0 \leq s < M \\ s \equiv r \,(\mathrm{mod}\, N)}} P_{M,s}.}$$

Proof. An integer n satisfies $n \equiv r \pmod{N}$ exactly when its unique residue $s = n \bmod M$ lies among the listed descendants. The fine indicators are disjoint, so their sum is the coarse indicator. □

This identity is the signal form of the refinement law introduced in Chapter II. It is not merely a denser sampling rule. The coarse masked packet, represented on the original integer lattice, is exactly the sum of its fine masked descendants. Decimated channels at different moduli must first be placed in these common coordinates before being added.

3 Linear time-invariant operators as transfer matrices

Let h be a finite impulse response and

$$y = h * x, \qquad y[n] = \sum_{q \in \mathbb{Z}} h[q]x[n-q].$$

Resolve both input and output into N phases. For output phase k and input phase s, define the transfer kernel

$$\boxed{h_{ks}[m] = h[Nm + k - s].}$$

Out-of-range taps are understood to be zero.

Theorem 3.1 (Exact FIR polyphase transfer law). *The output channels satisfy*

$$\boxed{y_k[n] = \sum_{s=0}^{N-1} \sum_{m \in \mathbb{Z}} h_{ks}[m] x_s[n-m].}$$

For the numerical channel transform, take $z \in \mathbb{C} \setminus \{0\}$ and assume

$$\sum_{n \in \mathbb{Z}} |x_s[n] z^{-n}| < \infty \quad (0 \leq s < N).$$

Define $X_s(z) = \sum_n x_s[n] z^{-n}$. The output series then also converge absolutely, and

$$\boldsymbol{Y}(z) = \boldsymbol{H}^{(N)}(z)\boldsymbol{X}(z), \qquad H^{(N)}_{ks}(z) = \sum_m h[Nm + k - s] z^{-m}.$$

Proof. Evaluate y at address $Nn + k$ and partition every input index by its residue s:

$$\begin{aligned} y[Nn + k] &= \sum_{q} h[q]x[Nn + k - q] \\ &= \sum_{s=0}^{N-1} \sum_{m} h[Nm + k - s]x[N(n - m) + s]. \end{aligned}$$

For a fixed output phase k, the change of tap address $q = Nm + k - s$ is a bijection between $\mathbb{Z}$ and the pairs (s, m) with $0 \le s < N$: choose $s \equiv k - q \pmod N$ and then $m = (q - k + s)/N$. Thus this is a reindexing of the finite filter support, valid for every bilateral input sequence, without a convergence assumption on x.

The last factor is $x_s[n-m]$, giving the time-domain formula. Under the additional transform hypothesis, each delayed channel has transform

$$\sum_{n} x_s[n - m]z^{-n} = z^{-m} \sum_{j} x_s[j]z^{-j}.$$

Absolute summability permits this bijective reindexing, and only finitely many delayed channels are combined. Taking their finite linear combination gives the matrix formula. The time-domain theorem therefore remains valid even when no numerical bilateral transform exists. □

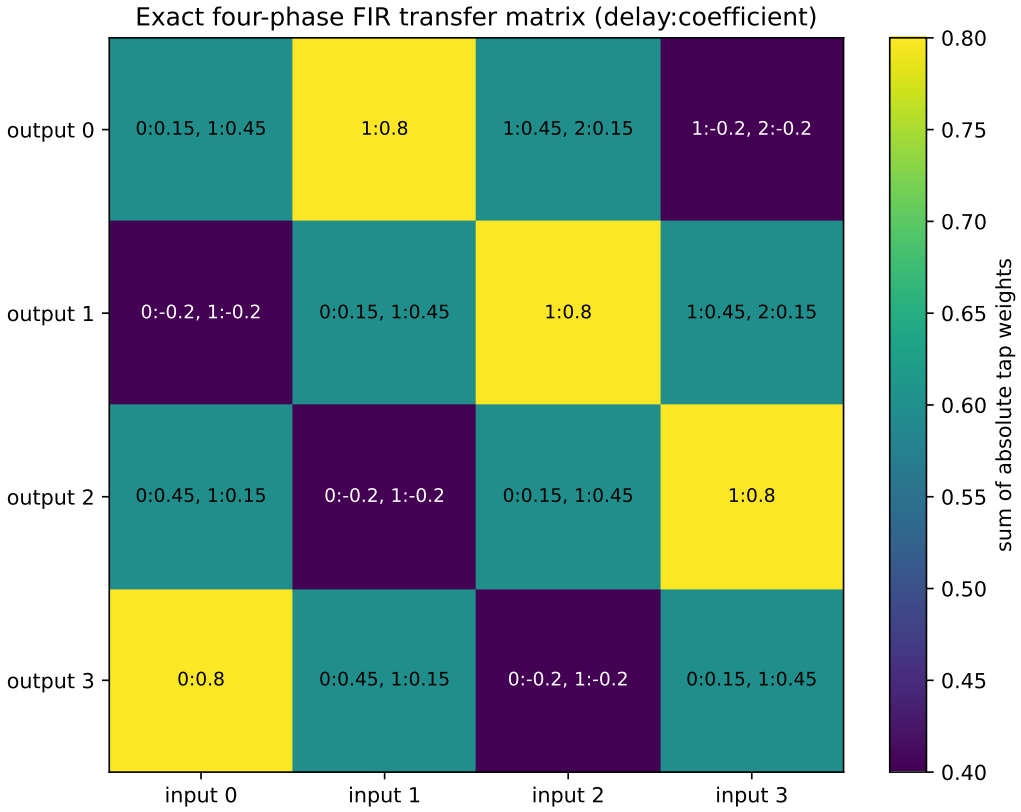

Figure 2. The exact transfer matrix for a seven-tap FIR filter in four phases. Every cell records the delays and coefficients carrying one input packet into one output packet.

Remark 3.2 (Operator-block form). If H denotes convolution by h, the same identity is

$$H = \sum_{k,s} P_{N,k} H P_{N,s}.$$

Thus the familiar polyphase matrix is exactly the transfer-block matrix of the seed calculus.

4 Analysis banks, synthesis banks, and perfect reconstruction

Read the delay in the coordinate system used

A step in one decimated channel crosses a full block of original samples. A one-sample shift also permutes the residue labels. At two phases, these operations have different matrices. The following calculation keeps the original sample delay visible instead of hiding it in a channel convention.

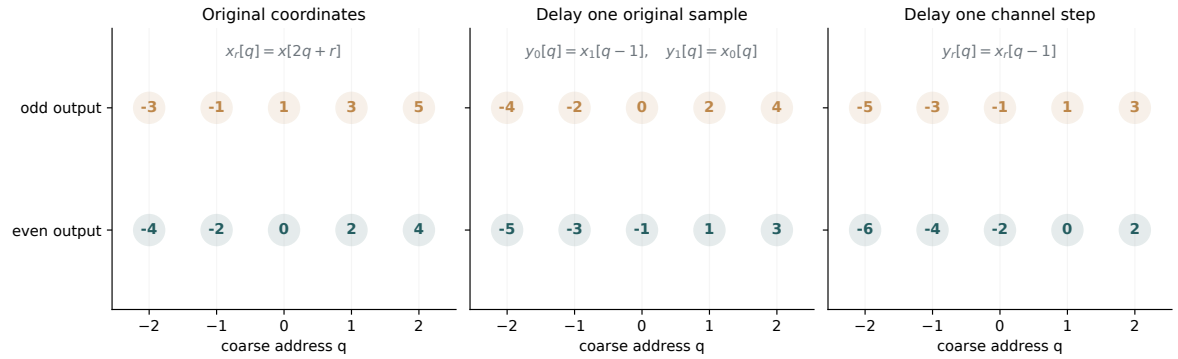

Figure 3. Exact address comparison for a two-phase split. A delay of one original sample sends the odd channel into the even channel with a coarse delay, and the even channel into the odd channel without a coarse delay. A one-step channel delay moves both original residues by two samples. All plotted values are integer sample addresses.

Work with finite impulse-response banks. Let $\mathcal{L} = \mathbb{C}[z, z^{-1}]$ be the Laurent-polynomial algebra, with the monomial z^{-m} acting on a bilateral sequence by $x[n] \mapsto x[n-m]$. Let $\boldsymbol{E} \in \mathrm{Mat}_{N\times N}(\mathcal{L})$ and $\boldsymbol{R} \in \mathrm{Mat}_{N\times N}(\mathcal{L})$ be analysis and synthesis matrices. Their composition acts on all bilateral channel sequences by finite convolutions. At a nonzero z where the input transforms are absolutely convergent, this gives

$$\widehat{\boldsymbol{X}}(z) = \boldsymbol{R}(z)\boldsymbol{E}(z)\boldsymbol{X}(z).$$

Theorem 4.1 (Perfect-reconstruction criterion). *For $d \in \mathbb{Z}$, such a bank reconstructs every input up to a delay of d* channel indices *exactly when the following Laurent-polynomial identity holds:*

$$\boxed{\boldsymbol{R}(z)\boldsymbol{E}(z) = z^{-d} I_N.}$$

If the right side is $cz^{-d}I_N$ with $c \neq 0$, reconstruction holds up to gain c and channel delay d. After interleaving, this is a delay of Nd original samples. A negative delay denotes an advance.

Proof. Finite convolution represents Laurent-polynomial multiplication: composing shifts adds their delays, and distributivity handles finite sums. Thus the matrix identity implies the asserted action.

Conversely, let $\boldsymbol{B} = \boldsymbol{R}\boldsymbol{E} - cz^{-d}I_N$ and suppose its action vanishes on every channel sequence. Insert an impulse at channel s, address zero, with every other channel zero. Output channel k reads the coefficients of the Laurent polynomial B_{ks} at all addresses. All of these coefficients vanish, so $B_{ks} = 0$ for every k, s. The representation is faithful, proving necessity as a polynomial identity rather than merely equality at one evaluation point. The displayed unit-gain case is $c = 1$. □

Original-sample delay. For an arbitrary original-sample delay $D \in \mathbb{Z}$, the output phase k has

$$y_k[n] = x_{r_k}[n + q_k], \qquad r_k = (k - D) \bmod N, \qquad q_k = (k - D) \operatorname{div} N.$$

Its channel matrix has the sole nonzero entry z^{q_k} in row k, column r_k. In particular, a one-sample delay at $N = 2$ has matrix

$$\begin{pmatrix} 0 & z^{-1} \\ 1 & 0 \end{pmatrix},$$

whereas $z^{-1}I_2$ delays the original signal by two samples. The general address identity is valid for negative sample addresses as well.

4.1 The Haar bank

The Haar analysis matrix is

$$\boldsymbol{E}_{\mathrm{H}} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

It is orthogonal, so $\boldsymbol{R}_{\mathrm{H}} = \boldsymbol{E}_{\mathrm{H}}^{\mathsf{T}}$ and

$$\boldsymbol{R}_{\mathrm{H}}\boldsymbol{E}_{\mathrm{H}} = I_2.$$

The channels are

$$a[n] = \frac{x[2n] + x[2n+1]}{\sqrt{2}}, \qquad d[n] = \frac{x[2n] - x[2n+1]}{\sqrt{2}}.$$

Corollary 4.2 (Haar energy identity)**.**

$$\boxed{\|x\|_2^2 = \|a\|_2^2 + \|d\|_2^2.}$$

Proof. For any $u, v \in \mathbb{C}$, the parallelogram identity gives

$$\left|\frac{u+v}{\sqrt{2}}\right|^2 + \left|\frac{u-v}{\sqrt{2}}\right|^2 = |u|^2 + |v|^2.$$

Apply this to $u = x[2n]$, $v = x[2n+1]$ and sum over $n \in \mathbb{Z}$. Each summand is nonnegative. The right side is $\|x\|_2^2$ by the two-channel address equivalence. This also proves that the literal low and detail channels belong to ℓ^2. The real Haar matrix is unitary over $\mathbb{C}$, so the finite-signal statement is the same calculation with a finite sum. □

4.2 Predict–update lifting

Split x into even and odd channels e, o. Define

$$d = o - e, \qquad s = e + \frac{1}{2}d.$$

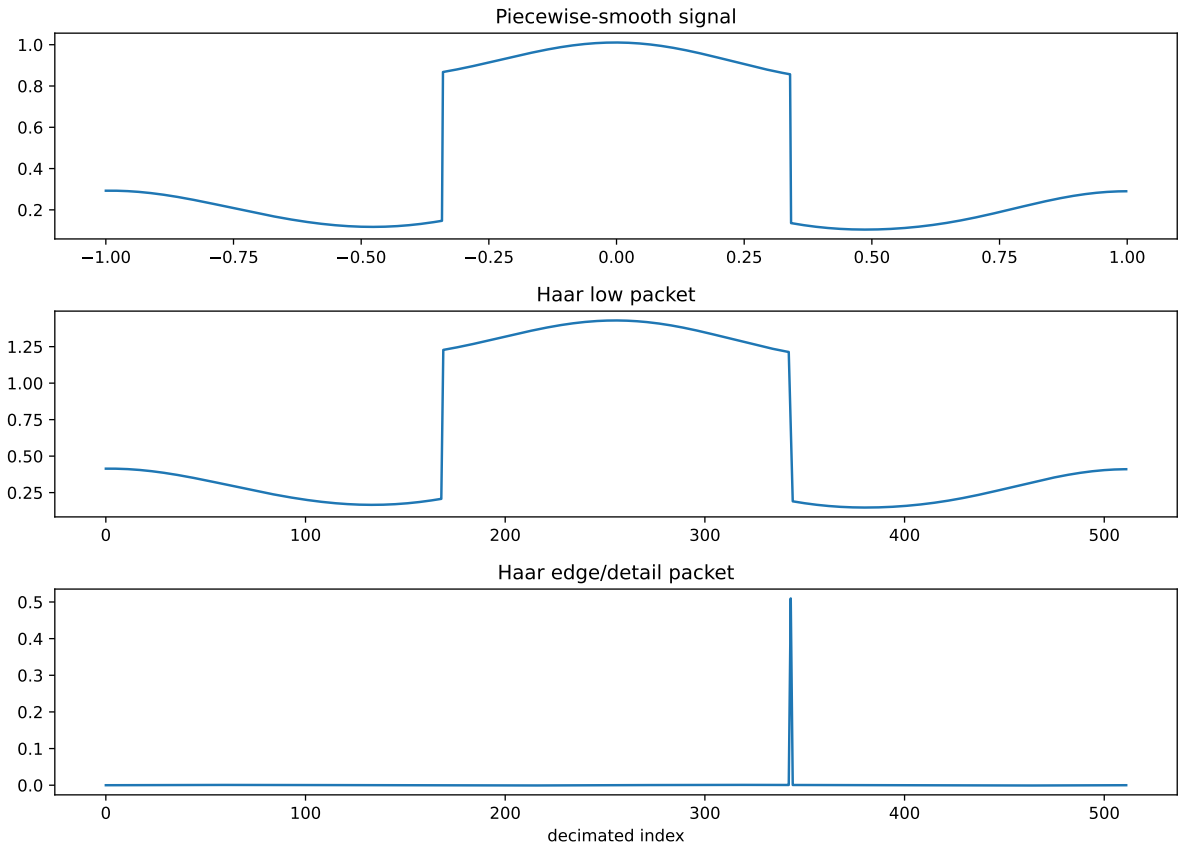

Figure 4. A piecewise-smooth signal and its first Haar low/detail packets. The low channel records local averages. The detail channel records adjacent-sample differences, including pairs that cross a jump.

The inverse is

$$e = s - \frac{1}{2}d, \qquad o = d + e.$$

Theorem 4.3 (Exact lifting reconstruction). *The predict–update map $(e, o) \mapsto (s, d)$ is invertible with determinant one and the displayed inverse. Consequently the associated finite transform reconstructs every even-length signal exactly.*

Proof. The forward matrix is

$$\begin{pmatrix} s \\ d \end{pmatrix} = \begin{pmatrix} 1/2 & 1/2 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} e \\ o \end{pmatrix},$$

whose determinant is one. Direct substitution gives the inverse formulas. □

5 Wavelet packets as addressed refinements

On $\ell^2(\mathbb{Z}; \mathbb{C})$, apply the Haar analysis to both children at each stage. For a finite input, assume its length is divisible by 2^ℓ when a depth-ℓ transform is used. A binary word $\alpha \in \{0, 1\}^\ell$ addresses a depth-ℓ packet, denoted $W_{\ell,\alpha}x$. Appending 0 or 1 selects the low or high child.

Theorem 5.1 (Wavelet-packet reconstruction and energy). *At every finite depth ℓ,*

$$\boxed{x = \sum_{\alpha \in \{0,1\}^\ell} W_{\ell,\alpha}^* W_{\ell,\alpha} x,}$$

and

$$\boxed{\|x\|_2^2 = \sum_{\alpha \in \{0,1\}^\ell} \|W_{\ell,\alpha} x\|_2^2.}$$

Proof. Write H_0, H_1 for the literal low and detail operators. The preceding energy identity implies $\|H_b x\|_2 \le \|x\|_2$, so both have bounded Hilbert adjoints. At depth zero the only packet operator is the identity. If the energy identity holds at depth ℓ, apply the one-level identity to each $W_{\ell,\alpha}x$ and sum. This proves it at depth $\ell + 1$.

Set $A = \sum_\alpha W_{\ell,\alpha}^* W_{\ell,\alpha}$. This is a finite sum of bounded operators. The energy result says $\langle x, Ax\rangle = \langle x, x\rangle$ for every x. Complex polarization, applied also to $x + y$ and $x + \mathrm{i}y$, gives $\langle y, (A - I)x\rangle = 0$ for all x, y, hence $A = I$. Applying the operator identity to x proves synthesis. This argument uses the actual Hilbert adjoints of the decimation operators, not a separately postulated inverse symbol. □

Classical Input 5.2 (Wavelet boundary). The existence and perfect-reconstruction theory of wavelets and filter banks are classical. Their role here is structural: they provide a fully developed realization in which seed generation, packet addressing, refinement, transfer blocks, and exact synthesis can all be read literally in the common operator language.

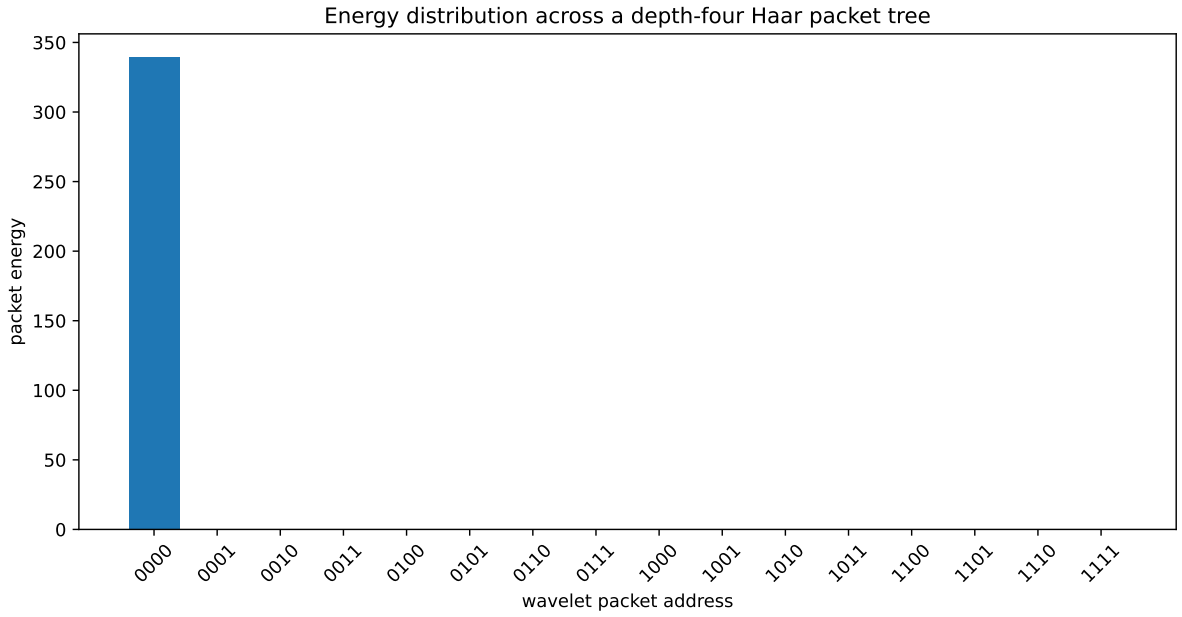

Figure 5. Energy of the sixteen depth-four Haar packet addresses for the test signal. The packet address is an operator word in the common seed grammar.

6 Known edge packets and spectral reconstruction

Retention changes the approximation target

The retained packet is supplied as part of the model. It passes through synthesis exactly. The approximation operator acts on the smooth remainder, so its error can be studied without forcing a global smooth basis to reproduce the jump. Finding that packet from observations is a separate recovery problem.

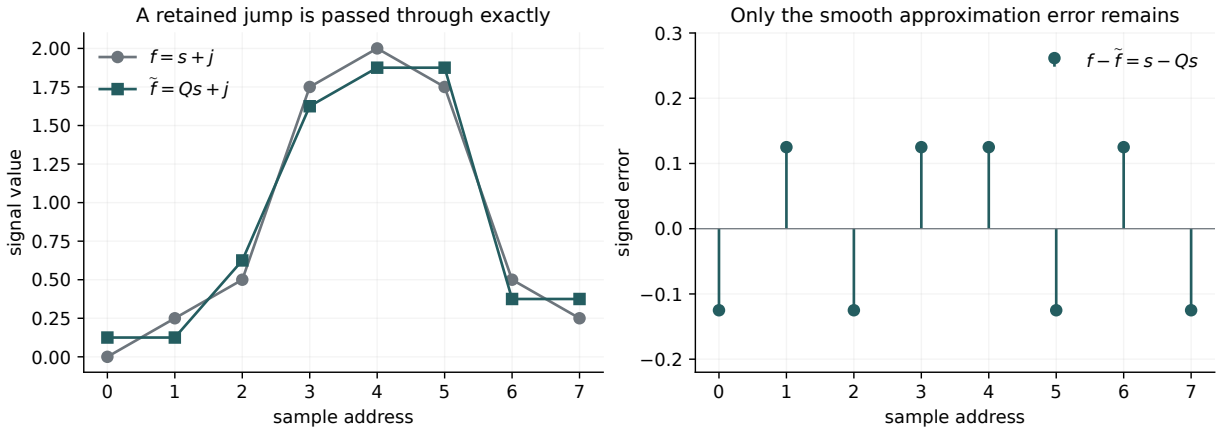

Figure 6. An exact rational eight-coordinate example of retained packet cancellation. The supplied jump packet is kept, while the linear operator averages adjacent pairs in the smooth component. The two error vectors agree coordinate by coordinate. This model illustrates cancellation and does not test packet detection or a Fourier convergence rate.

The central distinction is between approximating a jump globally and retaining it as its own packet. Let

$$f = s + j$$

where s belongs to a smooth approximation class and j is a known discontinuity packet. Let Q_m be any approximation operator applied only to s, and define

$$\tilde{f}_m = Q_m s + j.$$

Theorem 6.1 (Exact known-edge theorem)**.** *For every norm for which the expressions are defined,*

$$\boxed{f - \tilde{f}_m = s - Q_m s, \qquad \|f - \tilde{f}_m\| = \|s - Q_m s\|.}$$

No approximation of j occurs.

Proof. Subtract:

$$f - \tilde{f}_m = (s + j) - (Q_m s + j) = s - Q_m s.$$

Taking the norm gives the second identity. □

Corollary 6.2 (Several exact edge packets)**.** *If*

$$f = s + \sum_{q=1}^{M} j_q$$

and every j_q is retained exactly, then

$$\left\| f - \left(Q_m s + \sum_{q} j_q \right) \right\| = \|s - Q_m s\|.$$

Curved edges, corners, and different jump amplitudes do not alter the identity.

Proof. The finite sum $j = \sum_{q=1}^{M} j_q$ is a single retained packet. Applying the preceding cancellation identity gives the result. The empty family $M = 0$ is included with sum zero. □

Boundary 6.3 (What the theorem does and does not say). The theorem explains why global ringing caused by spectrally approximating a known jump is absent from the reconstructed jump packet. It does not discover the packet. If the packet is wrong, its error is reconstructed exactly as well. Nor does the theorem prevent unrelated truncation errors in the smooth packet, domain-boundary errors, noise, or model mismatch.

7 Mask, amplitude, and smooth-background error

Let (X, Σ, μ) be a measure space, with measurable masks $\Omega, \widehat{\Omega} \subseteq X$ and scalar amplitudes $a, \hat{a} \in \mathbb{C}$ (real amplitudes are a special case). Suppose a scalar jump packet is

$$j = a\mathbf{1}_{\Omega},$$

and an estimated packet is

$$\hat{j} = \hat{a}\mathbf{1}_{\widehat{\Omega}}.$$

Theorem 7.1 (Packet perturbation bound). *For $1 \le p < \infty$, interpreted first as an inequality of extended L^p seminorms,*

$$\boxed{\|j - \hat{j}\|_{L^p} \le |a - \hat{a}|\,\mu(\Omega)^{1/p} + |\hat{a}|\,\mu(\Omega \triangle \widehat{\Omega})^{1/p}.}$$

If $\mu(\Omega)$ and $\mu(\Omega \triangle \widehat{\Omega})$ are finite, all terms in this displayed jump bound are finite and it is an ordinary real-valued L^p inequality. For the pointwise supremum, and consequently also the essential L^∞ seminorm,

$$\|j - \hat{j}\|_\infty \le |a - \hat{a}| + |\hat{a}|\,\mathbf{1}_{\Omega \triangle \widehat{\Omega} \neq \emptyset}.$$

Proof. Write

$$a\mathbf{1}_\Omega - \hat{a}\mathbf{1}_{\widehat{\Omega}} = (a - \hat{a})\mathbf{1}_\Omega + \hat{a}(\mathbf{1}_\Omega - \mathbf{1}_{\widehat{\Omega}}).$$

Apply the triangle inequality and use

$$\|\mathbf{1}_\Omega - \mathbf{1}_{\widehat{\Omega}}\|_{L^p} = \mu(\Omega \triangle \widehat{\Omega})^{1/p}.$$

For the supremum estimate, $|\mathbf{1}_\Omega - \mathbf{1}_{\widehat{\Omega}}| \le 1$ pointwise, and this function vanishes everywhere when the symmetric difference is empty. The same pointwise bound also bounds the essential supremum. Nonempty null symmetric differences need not contribute to the essential norm. The stated bound remains valid in that case and need not be sharp. Measurability justifies the L^p triangle inequality and the indicator norm formula. □

If $s, \hat{s}$ are measurable smooth-background models, the same triangle inequality gives, for finite p,

$$\boxed{\|f - (\hat{s} + \hat{j})\|_p \le \|s - \hat{s}\|_p + |a - \hat{a}|\mu(\Omega)^{1/p} + |\hat{a}|\mu(\Omega \triangle \widehat{\Omega})^{1/p}.}$$

This is the correct separation of errors. Detection error is not hidden inside a generic reconstruction score.

Conjecture 7.2 (Stable edge-packet recovery)**.** For specified piecewise-smooth classes, contrast bounds, separation conditions, and noise models, there should exist a multiscale packet estimator whose symmetric-difference error and amplitude error converge at rates controlled independently of the smooth approximation rate. A theorem of this kind would turn the conditional known-edge result into a stable data-driven reconstruction theorem. No universal version is asserted here.

8 One-dimensional numerical study

The one-dimensional signal contains a smooth non-bandlimited background and a positive rectangular packet. Three reconstructions are compared:

(i) global Fourier truncation of the complete signal;

(ii) Fourier truncation of the known smooth packet plus the exact jump packet;

(iii) a two-class estimated packet followed by harmonic background filling, spectral smoothing, and jump-amplitude estimation.

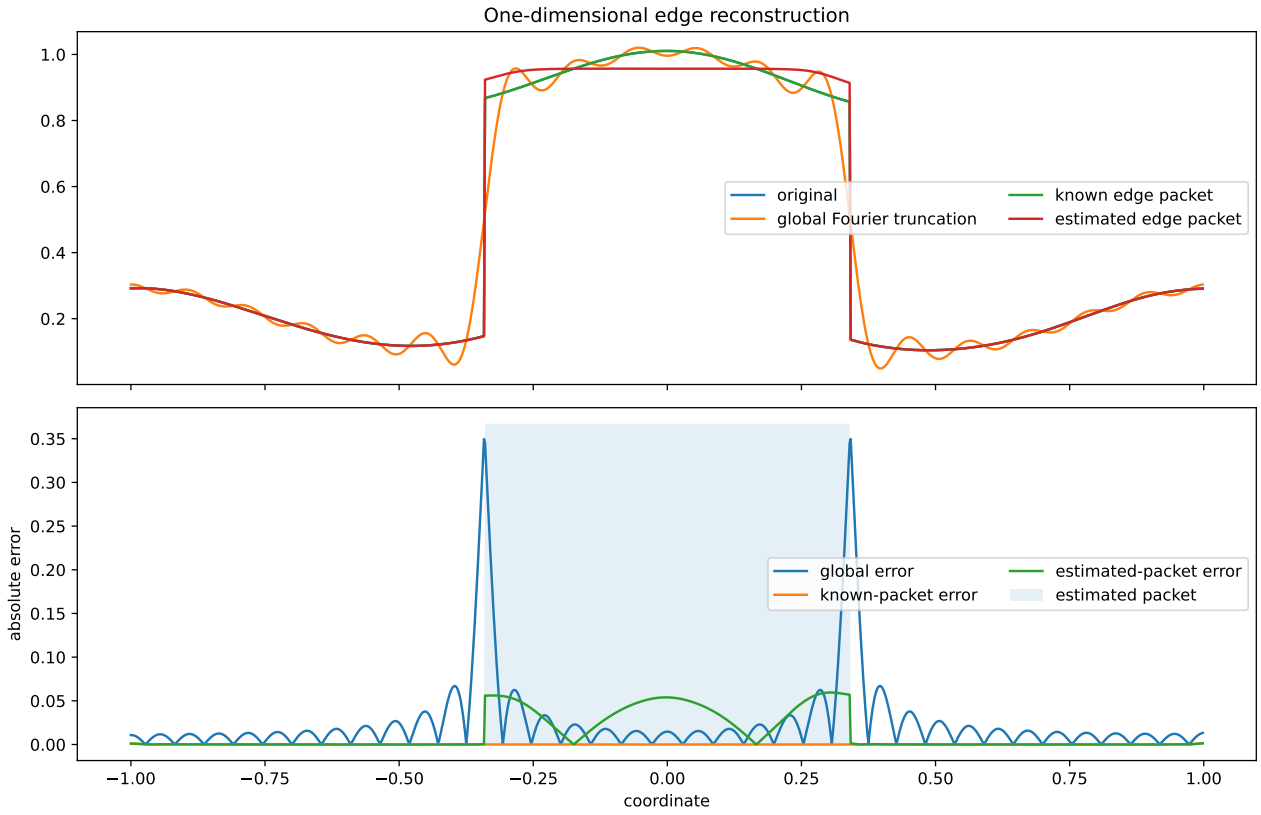

Figure 7. One-dimensional reconstruction and absolute error. The known packet removes the edge from the global spectral approximation. The estimated packet is visibly better than the global reconstruction in this limited test but retains smooth-background estimation error.

Numerical Certificate 8.1 (One-dimensional errors). For 1024 samples on $[-1, 1)$ and Fourier cutoff $m = 18$, the retained frequency indices are $-18, \dots, 18$: 37 bins including the zero-frequency bin. The measured values were

method	RMSE	maximum absolute error
global Fourier truncation	5.4023×10^{-2}	3.4968×10^{-1}
known edge packet	1.3692×10^{-4}	1.4503×10^{-3}
estimated edge packet	2.4029×10^{-2}	5.9530×10^{-2}

The simple estimator recovered the binary mask exactly in this deliberately separated two-class example. That result is a property of this test, not a universal guarantee.

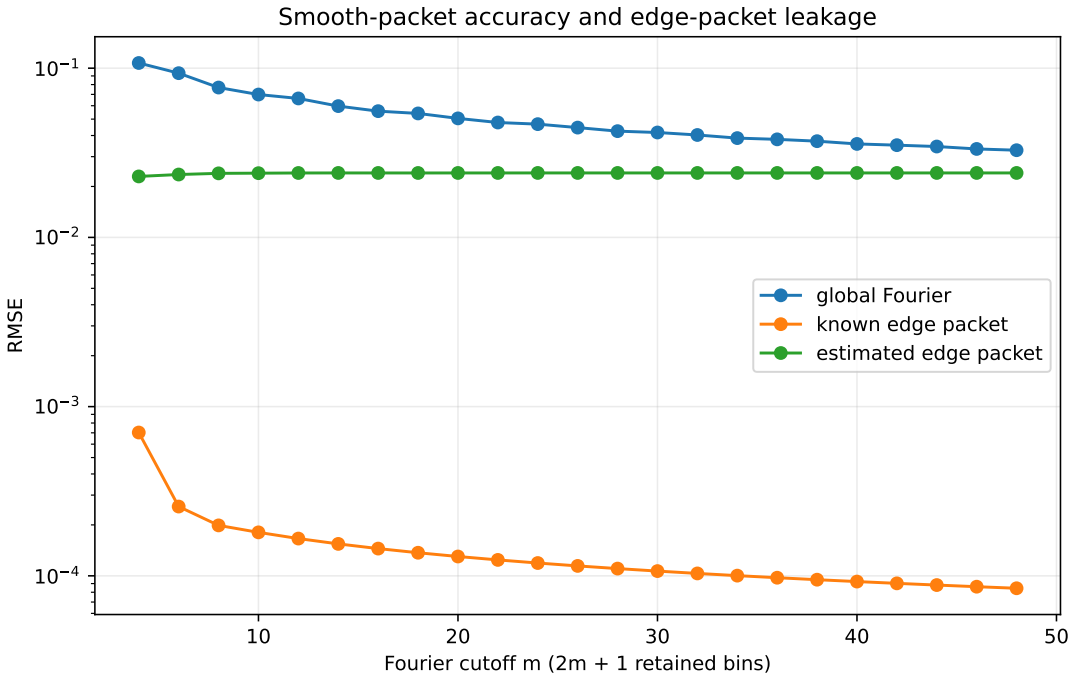

Figure 8. Error as spectral resolution increases. The known packet follows only the smooth approximation error. The estimated reconstruction reaches a floor determined by background and amplitude estimation.

9 Two-dimensional edge packets

The first image consists of a smooth background and one sharp disk. The same three logical levels must remain separate:

(a) the exact theorem using the known decomposition;

(b) a limited estimator designed for a positive-contrast two-class packet;

(c) the open problem of recovering arbitrary edge packets under noise and model ambiguity.

Numerical Certificate 9.1 (Two-dimensional errors). For the 192×192 disk experiment, a square Fourier mask retains indices $|k_x|, |k_y| \leq 16$, or $33^2 = 1089$ bins. The reported errors are

method	full-image RMSE	boundary-band RMSE
global Fourier truncation	3.7643×10^{-2}	1.8541×10^{-1}
known edge packet	6.4752×10^{-5}	1.2709×10^{-5}
estimated edge packet	3.4043×10^{-3}	8.8834×10^{-3}

The mask intersection-over-union was one in this positive-contrast synthetic case. The amplitude was estimated rather than inserted from the generating model.

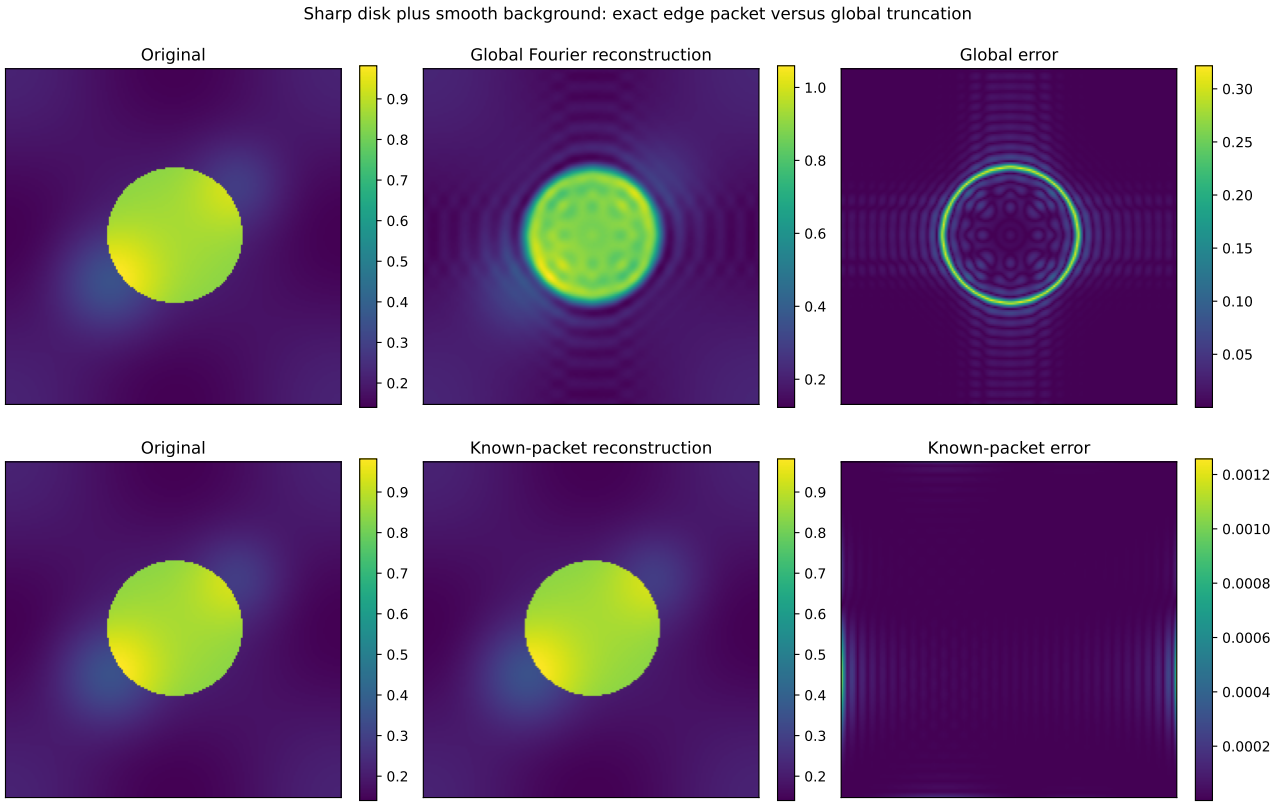

Figure 9. A sharp disk on a smooth background. Global Fourier truncation produces a bright boundary halo and oscillatory interior and exterior error. Retaining the exact edge packet leaves only the smooth-background approximation error.

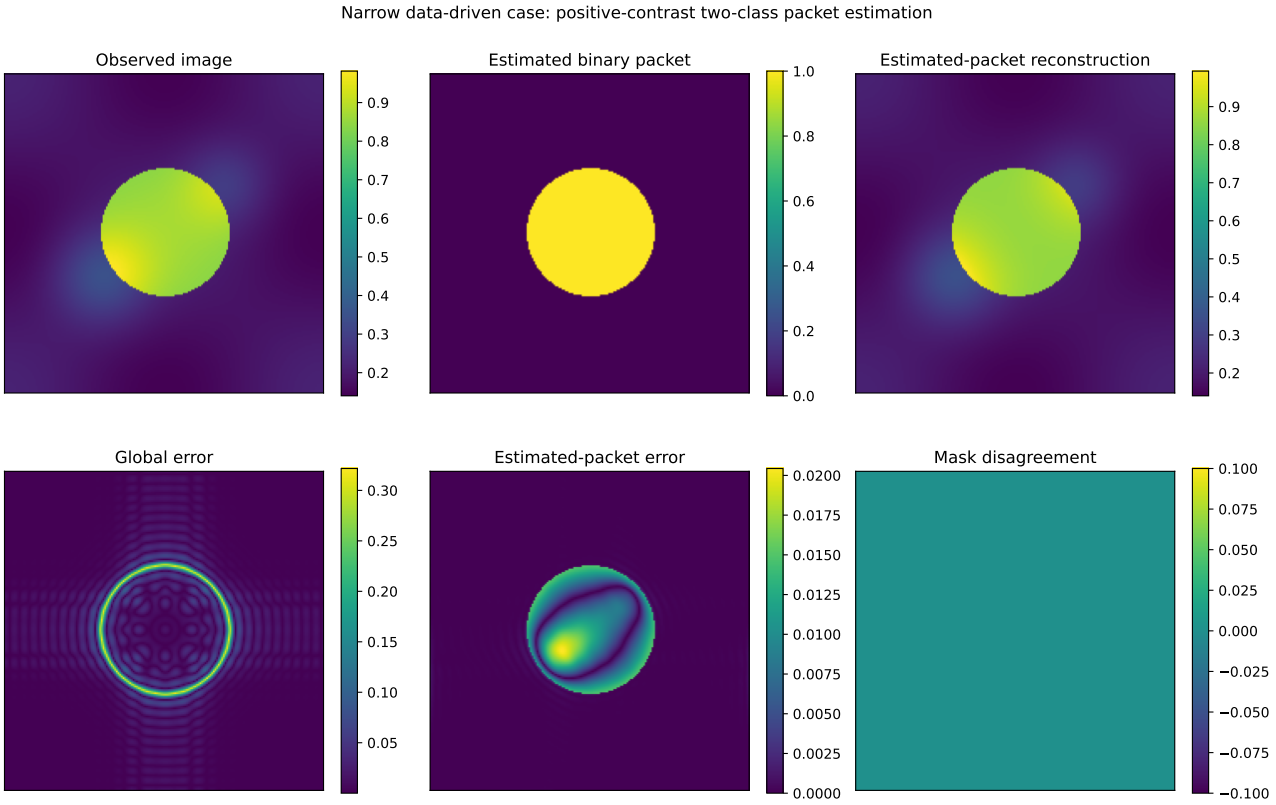

Figure 10. The limited data-driven experiment. The observed image alone is thresholded into two intensity classes, cleaned topologically, harmonically filled, spectrally smoothed, and recombined with an estimated jump.

9.1 Curves, corners, and multiple amplitudes

The exact theorem does not depend on the shape of the known edge packet. The next experiment contains a disk, a square, and a diamond with different jump amplitudes.

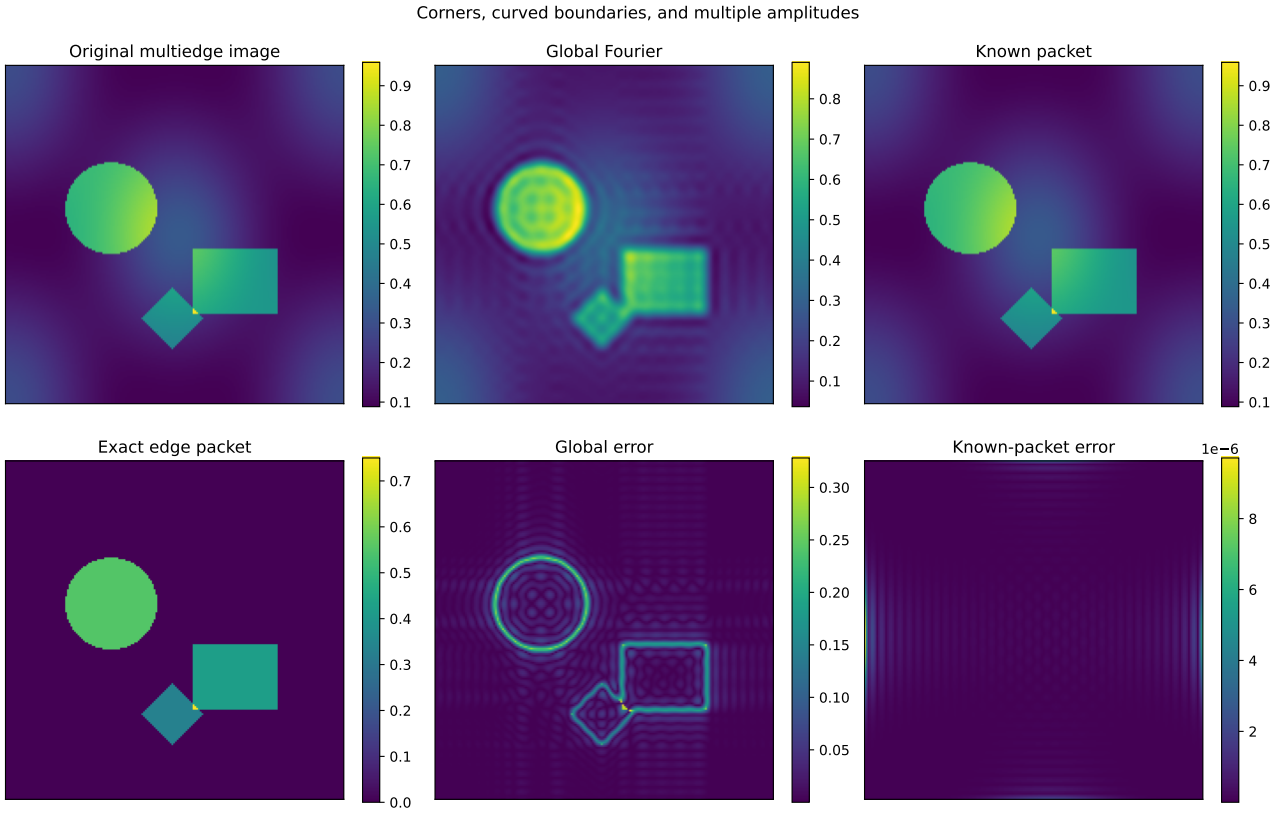

Figure 11. Known-packet stress test with curved boundaries, corners, overlap, and different jump amplitudes. The exact packet is not a binary mask multiplied by one amplitude. It is the complete piecewise packet.

Numerical Certificate 9.2 (Multiedge errors). The global reconstruction had RMSE 3.3740×10^{-2} and maximum error 3.2807×10^{-1}. The known-packet reconstruction had only the remaining smooth-background error. The experiment checks the finite implementation of the theorem for a composite packet. It is not a data-driven multiregion segmentation result.

10 Sparse wavelet packets and global Fourier modes

A sharp edge is spatially local but spectrally global. Wavelets often provide a more economical coordinate system once enough localized coefficients are retained. To keep the comparison explicit, the numerical study subtracts the signal mean, keeps the largest coefficients in a fixed depth-five Haar packet basis, and compares them with the same number of largest-magnitude discrete Fourier coefficients. These are coefficient-count budgets, not equal bit-storage budgets. The Fourier reconstruction uses the real part of the inverse transform. For the five reported budgets, the selected nonzero-frequency bins occur in conjugate pairs, so this operation removes only floating-point imaginary residuals.

Boundary 10.1 (Basis selection). This table compares two fixed finite coordinate systems for one signal. It does not prove that Haar packets are optimal, that Fourier is inferior on smooth or oscillatory data, or

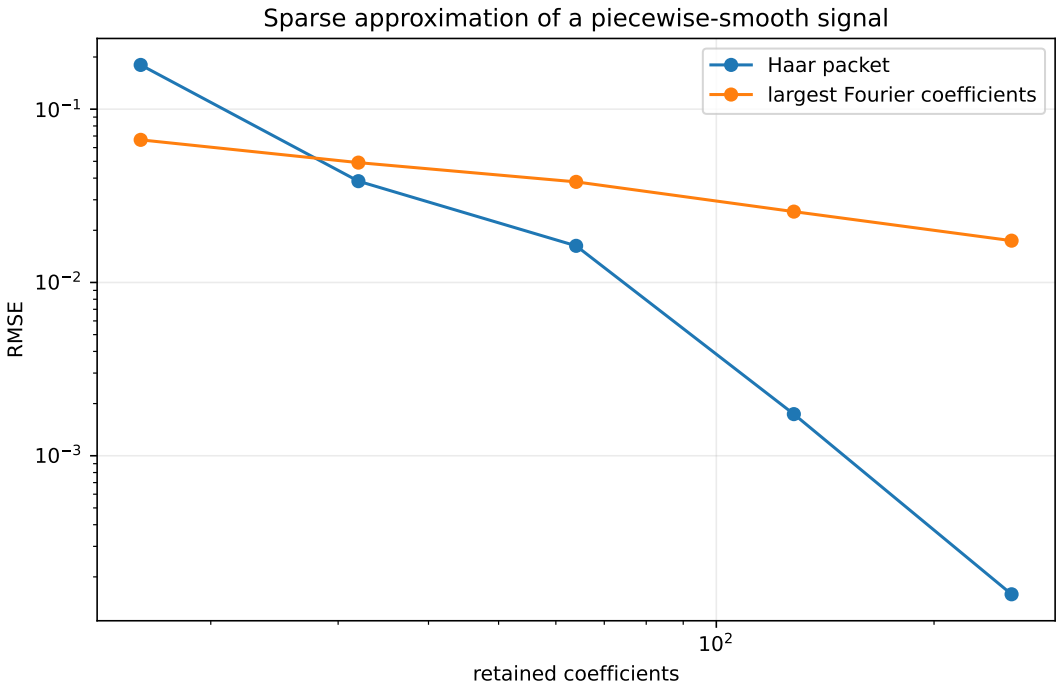

Figure 12. Sparse approximation of the test signal. With very few coefficients the global Fourier basis is initially better. After the edge packets are resolved, the Haar packet error decays much faster in this example.

Table 1. Sparse approximation errors for the one-dimensional test signal.

retained coefficients	Haar packet RMSE	Fourier RMSE
16	1.7999×10^{-1}	6.6522×10^{-2}
32	3.8414×10^{-2}	4.9153×10^{-2}
64	1.6267×10^{-2}	3.8056×10^{-2}
128	1.7387×10^{-3}	2.5631×10^{-2}
256	1.5870×10^{-4}	1.7424×10^{-2}

that a single packet tree is best for every edge geometry. The seed calculus records both systems with the same analysis, transfer, refinement, and synthesis maps.

11 Finite adaptive packet trees

Three levels of a finite tree decision

First choose a complete pruning, so every terminal path is represented once and synthesis remains exact. Then assign a finite objective to those feasible choices. Additivity permits the local dynamic recursion. Finally, a positive cost gap protects the selected pruning against a declared perturbation envelope. Each step uses a different hypothesis.

The preceding sparse comparison used one fixed depth-five packet basis. A refinement tree permits a stronger choice: different branches may stop at different depths while the selected packets still form one complete coordinate system.

Definition 11.1 (Complete packet pruning)**.** Let $\mathcal{T}$ be a finite rooted refinement tree. Every node v carries a projector P_v, the root satisfies $P_\emptyset = I$, and every internal node satisfies

$$P_v = \sum_{u \in \mathrm{ch}(v)} P_u, \qquad P_u P_w = 0 \quad (u \neq w \text{ in } \mathrm{ch}(v)).$$

A set Λ of nodes is a complete pruning if it is an antichain and every root-to-terminal path meets Λ exactly once.

Theorem 11.2 (Exact synthesis from every complete pruning)**.** *For every complete pruning Λ,*

$$\boxed{\sum_{v \in \Lambda} P_v = I,} \qquad \boxed{x = \sum_{v \in \Lambda} P_v x.}$$

Thus changing the selected tree changes the coordinates but does not introduce reconstruction error.

Proof. Starting from the root identity $P_\emptyset = I$, replace every unselected internal node by the exact sum of its children. If a complete pruning contains the root it contains no other node. Otherwise its restriction to each child subtree is itself a complete pruning: every terminal path through that child must be met exactly once. Induction on the finite tree therefore justifies the substitution and its termination precisely at Λ. Child subtrees have distinct node addresses, so their selected-node sets form a disjoint union. The sum identity uses only root identity and parent-to-child conservation. Sibling orthogonality gives the additional interpretation as nonoverlapping projector packets. Applying the resulting identity to x gives the synthesis formula. □

Let y denote the observed data. For a complete pruning Λ, consider any finite criterion

$$J_y(\Lambda) = R_y(\Lambda) + \eta L_y(\Lambda) + \tau K(\Lambda),$$

where R_y is a representation cost, L_y is a cross-packet leakage cost, and K is a tree-complexity penalty. Here R_y, L_y, K take finite real values, and η, τ are fixed real weights (usually nonnegative in applications). No additivity is needed for the first theorem.

Theorem 11.3 (Finite globally optimal stable selector)**.** *Let $\mathfrak{P}(\mathcal{T})$ be the finite set of complete prunings of $\mathcal{T}$.*

(i) A global minimizer

$$\Lambda_y^* \in \operatorname*{argmin}_{\Lambda \in \mathfrak{P}(\mathcal{T})} J_y(\Lambda)$$

always exists.

(ii) If the minimizer is unique and at least one competing pruning exists, its gap

$$\Gamma_y = \min_{\Lambda \neq \Lambda_y^*} \left(J_y(\Lambda) - J_y(\Lambda_y^*)\right)$$

is attained and strictly positive. If the pruning set is a singleton, its only element minimizes every criterion. No real-valued minimum over an empty competitor set is introduced.

(iii) In the case with competitors, if new data y' satisfy

$$\sup_{\Lambda \in \mathfrak{P}(\mathcal{T})} |J_{y'}(\Lambda) - J_y(\Lambda)| < \frac{\Gamma_y}{2},$$

then $\Lambda_{y'}^* = \Lambda_y^*$.

(iv) Every selected minimizer preserves the exact synthesis identity of the preceding theorem.

Proof. The root-only pruning exists, and every pruning is a subset of the finite node set, so the feasible set is nonempty and finite. Thus the minimum is attained. If competitors exist, their finitely many differences from a unique optimum are strictly positive, so their minimum is positive and is achieved by a competitor. In the singleton case there is no alternative selector under any objective change. In the remaining case, for any competing pruning $\Lambda \neq \Lambda_y^*$,

$$\begin{aligned} J_{y'}(\Lambda) - J_{y'}(\Lambda_y^*) &\geq J_y(\Lambda) - J_y(\Lambda_y^*) - 2 \sup_{\Xi} |J_{y'}(\Xi) - J_y(\Xi)| \\ &> \Gamma_y - \Gamma_y = 0. \end{aligned}$$

Hence the same pruning remains uniquely optimal. Exact synthesis depends only on completeness of the pruning, not on the cost used to select it. □

For tree-local costs, the optimum can be found without enumerating all prunings.

Theorem 11.4 (Dynamic-programming best packet basis)**.** *Suppose*

$$J_y(\Lambda) = \sum_{v \in \Lambda} c_v(y).$$

For a node v, define recursively

$$V_y(v) = \begin{cases} c_v(y), & v \text{ terminal}, \\ \min\left\{ c_v(y), \sum_{u \in \mathrm{ch}(v)} V_y(u) \right\}, & v \text{ internal}. \end{cases}$$

Stop at v when $c_v(y) \le \sum_u V_y(u)$, including equality, and refine otherwise. This deterministic rule produces a globally optimal complete pruning. With the node costs supplied and child values cached, the evaluator uses one comparison per internal node, one visit per node, and at most $|\mathcal{T}| - 1$ additions. Its arithmetic-and-visit count is therefore at most $3|\mathcal{T}|$. This is a unit-cost statement about the specified evaluator. It excludes evaluation of the local costs, bit complexity of scalar arithmetic, and materialization or sorting of packet-address strings.

Proof. Proceed upward from the terminal nodes. Every complete pruning below an internal node v has exactly two possible forms: it either stops at v, with cost $c_v(y)$, or it refines and is the union of complete child prunings, whose minimum total cost is the sum of the already computed child minima. The recursion therefore gives the exact minimum on every subtree, in particular at the root. This characterization also proves both directions of the correspondence between recursive cuts and complete covering antichains, for arbitrary positive finite branching, including unary branches. Summing cached child values charges at most one addition per child edge. A finite rooted tree has $|\mathcal{T}| - 1$ such edges. The number of internal nodes is at most $|\mathcal{T}|$, which gives the stated work bound. Ties do not affect optimality, but the stop-on-ties rule makes the selected pruning unambiguous. □

Corollary 11.5 (Local perturbation certificate)**.** *Assume*

$$|c_v(y') - c_v(y)| \le \varepsilon_v.$$

Define

$$E(v) = \begin{cases} \varepsilon_v, & v \text{ terminal}, \\ \max\left\{ \varepsilon_v, \sum_{u \in \mathrm{ch}(v)} E(u) \right\}, & v \text{ internal}. \end{cases}$$

For the complete prunings $\mathfrak{P}_v$ below v, the envelope is exactly

$$E(v) = \max_{\Lambda \in \mathfrak{P}_v} \sum_{a \in \Lambda} \varepsilon_a.$$

The maximum is attained. Every complete-pruning cost changes by at most $E(\emptyset)$, and the two globally optimal values differ by at most this quantity. Consequently, for a unique optimum with competitors,

$$\boxed{\Gamma_y > 2E(\emptyset)}$$

is a deterministic certificate that the globally optimal pruning is unchanged. A singleton pruning set is stable without a gap condition. Assume the random node costs and the joint local-error event are measurable. If a noise model supplies all *local bounds simultaneously on one event of probability at least $1 - \delta$, and the displayed strict-gap condition holds, the same selector is recovered with probability at least $1 - \delta$. Individual nodewise probabilities alone do not give this joint confidence without an additional argument, such as a union bound.*

Proof. For any pruning of the subtree rooted at v, either v itself is selected, producing perturbation at most ε_v, or the pruning is the disjoint union of child prunings, producing perturbation at most the sum of the child envelopes. The same decomposition applied to the nonnegative weights ε_a proves equality with the maximum weight: at each node choose either the stop option or a maximizing pruning in each child, whichever gives the larger total. Finiteness ensures these choices attain their maxima. Evaluating each cost at a minimizer of the other cost bounds the difference of the two optimal values by the uniform envelope. The selector statement follows from the strict-gap theorem. The finite deterministic comparisons defining the selector make its preservation event measurable when the random node costs are measurable. The joint local-error event is contained in the selector-preservation event, so monotonicity of probability proves the probabilistic assertion. □

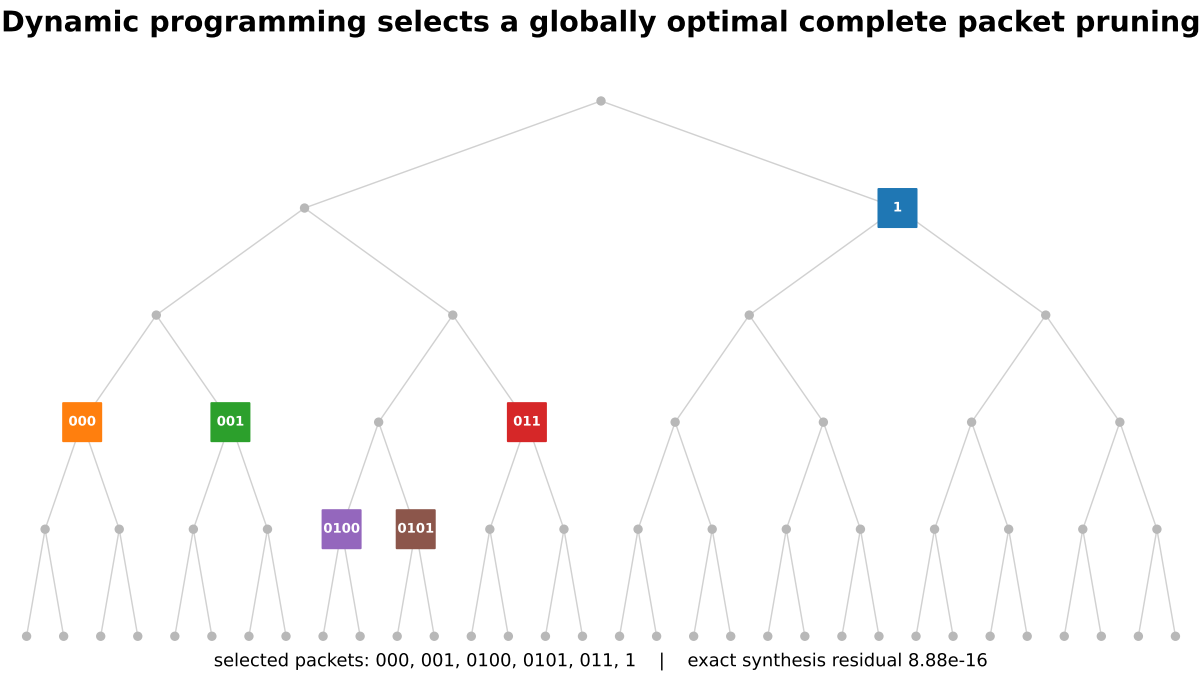

Figure 13. A globally optimal mixed-depth Haar packet pruning. The selected antichain covers the full tree, so its synthesis is exact even though different branches stop at different depths.

Numerical Certificate 11.6 (Adaptive-tree optimum). For the depth-five example, the complete binary tree has $458{,}330$ admissible prunings. Dynamic programming and exhaustive enumeration returned the same minimum with residual 0. The selected pruning was

$$\{000, 001, 0100, 0101, 011, 1\},$$

and mixed-depth synthesis reconstructed the signal with maximum residual 8.88×10^{-16}. The optimum gap was 3.1909×10^{-4}, while twice the declared perturbation envelope was 6.4×10^{-5}, so the finite selector is certified stable.

Boundary 11.7 (Finite versus asymptotic selection). The theorem resolves the finite adaptive-tree existence, exact-synthesis, global-optimality, and margin-stability problem. It does not by itself prove minimax rates, statistical consistency on an infinite tree, or a universal choice of representation and leakage costs for every signal class.

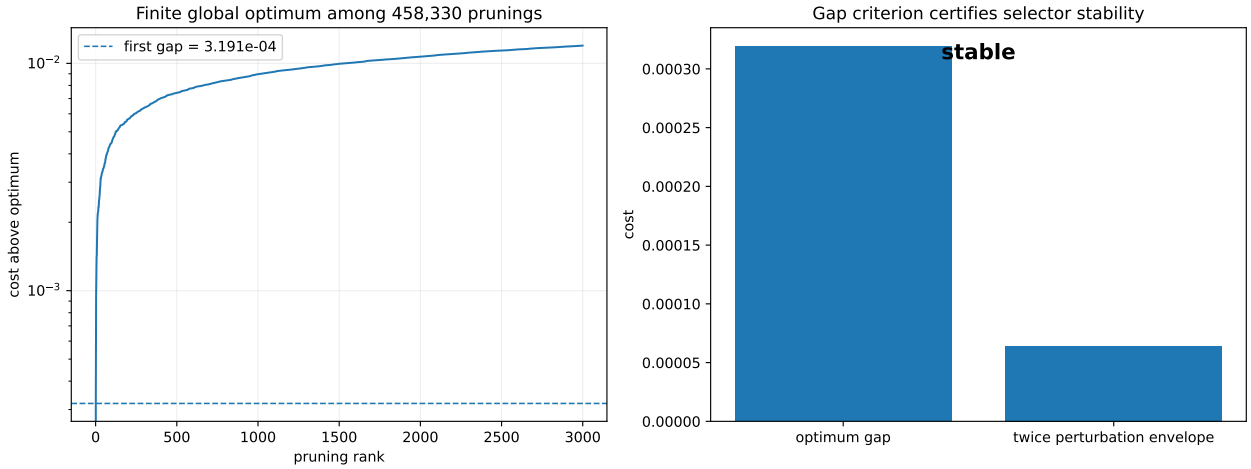

Figure 14. The dynamic-programming optimum agrees with exhaustive enumeration. A positive gap larger than twice the declared perturbation envelope certifies that the selected tree is stable.

12 Nonlinear signal packets

Linear time invariance is not required for exact packet coordinates. Let A and B be formal power series over a commutative coefficient ring (in particular $\mathbb{C}$). Set

$$A(z) = \sum_{n \geq 0} a_n z^n, \qquad A_i = P_{N,i} A.$$

All phase indices range from 0 to $N - 1$. For another representation $B(z)$, multiplication gives a nonlinear or bilinear interaction.

Theorem 12.1 (Cyclic product law)**.**

$$\boxed{P_{N,k}(AB) = \sum_{i+j \equiv k \,(\mathrm{mod}\, N)} A_i B_j.}$$

For $q \in \mathbb{N}$, the qth-power identity is

$$P_{N,k}(A^q) = \sum_{i_1 + \cdots + i_q \equiv k} A_{i_1} \cdots A_{i_q}.$$

Proof. Every coefficient in $A_i B_j$ has degree congruent to $i + j$ modulo N. At any fixed degree n, the Cauchy coefficient sum is finite. Sorting these terms by the residues of their two indices gives the first identity coefficient by coefficient. For the power identity, use induction on q and the finite product law. At $q = 0$, the index set contains the single empty tuple, its product is 1, and its residue sum is 0. Hence the right side is 1 for $k = 0$ and 0 otherwise, as required. No convergence is needed for these formal identities. For analytic power series, the same identities hold wherever the series are absolutely convergent and their Cauchy products may be evaluated. □

For a finite nonlinear shift operator

$$F(x)[n] = x[n] + \alpha x[n] x[n-1],$$

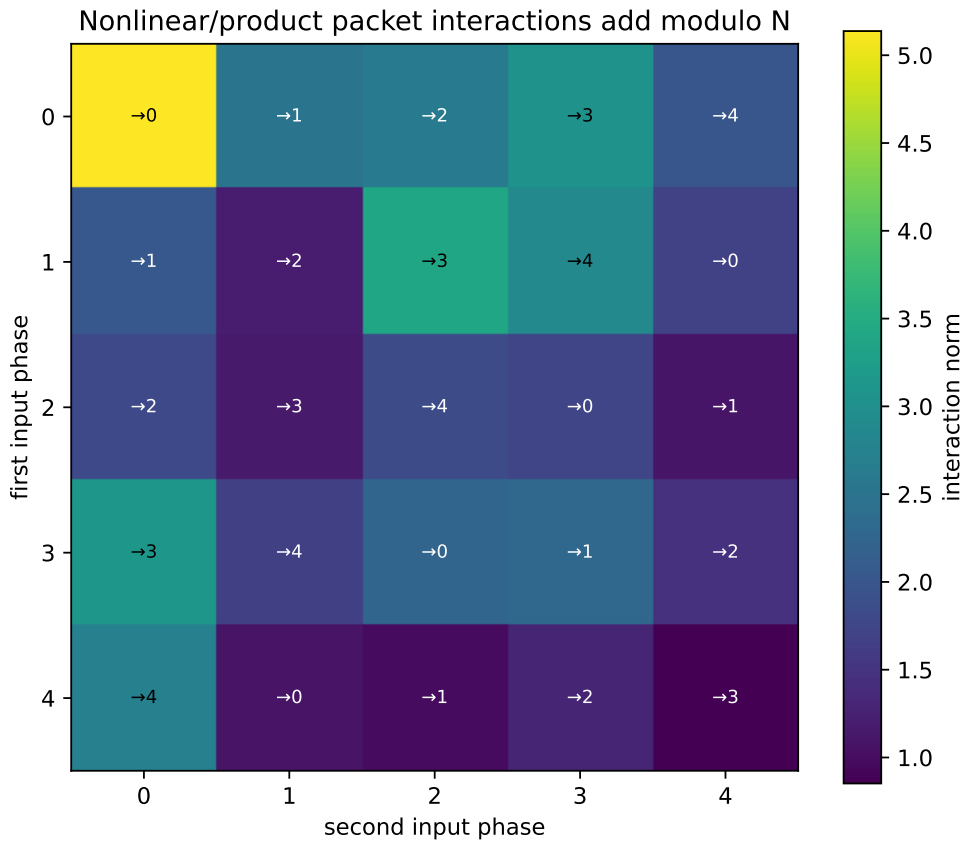

Figure 15. Norms of pairwise product interactions for five residue phases. The label in each cell gives the output phase $(i + j) \bmod 5$.

the exact packet coordinates are simply

$$F_r((x_s)_s) = P_{N,r} F\left(\sum_s P_{N,s} x\right).$$

Analysis followed by this packet system and synthesis reproduces the direct nonlinear output exactly. The numerical residual in the companion implementation was zero to machine representation.

13 Smith coordinates as cyclic signal coordinates

Let $Z_0 > 0$ be a reference impedance and

$$z = \frac{Z}{Z_0} = r + \mathrm{i}x.$$

The reflection coefficient is

$$\boxed{\Gamma = \frac{z-1}{z+1}, \qquad z = \frac{1+\Gamma}{1-\Gamma}.}$$

Classical Input 13.1 (Cayley geometry). The map sends the finite passive half-plane $r \geq 0$ onto the closed unit disk with $\Gamma = 1$ omitted. Adjoining the point at infinity in impedance adds that missing boundary point. The open right half-plane maps conformally onto the open disk. Constant resistance and reactance become the familiar Smith circles. This conformal geometry is classical and is not replaced by polyphase refinement.

Writing $\Gamma = u + \mathrm{i}v$, the grid equations are

$$\left(u - \frac{r}{1+r}\right)^2 + v^2 = \frac{1}{(1+r)^2},$$

and, for $x \neq 0$,

$$(u-1)^2 + \left(v - \frac{1}{x}\right)^2 = \frac{1}{x^2}.$$

Fix

$$\omega_N = e^{2\pi \mathrm{i}/N}$$

and rotate the reflection coefficient by

$$R_{N,k}(\Gamma) = \omega_N^k \Gamma.$$

Theorem 13.2 (Polyphase Möbius action). *Regard normalized impedance as the projective line $\mathbb{P}^1(\mathbb{C}) = \mathbb{C} \cup \{\infty\}$. For $N \geq 1$, the pullback is a globally defined projective action. In the finite chart, wherever the denominator is nonzero, it is*

$$\boxed{T_{N,k}(z) = \frac{(1+\omega_N^k)z + (1-\omega_N^k)}{(1-\omega_N^k)z + (1+\omega_N^k)}.}$$

As maps on $\mathbb{P}^1(\mathbb{C})$ it satisfies

$$T_{N,k} \circ T_{N,\ell} = T_{N,k+\ell \,(\mathrm{mod}\, N)}.$$

Proof. Let $C(z) = (z-1)/(z+1)$. Then

$$T_{N,k} = C^{-1} \circ R_{N,k} \circ C.$$

For a division-free construction, represent a point by a nonzero pair $[u : v]$, identifying $[cu : cv] = [u : v]$ for $c \neq 0$. With $w = \omega_N^k$, use the matrix

$$A(w) = \frac{1}{2}\begin{pmatrix} 1+w & 1-w \\ 1-w & 1+w \end{pmatrix}.$$

It has determinant $w \neq 0$, preserves nonzero pairs, and commutes with rescaling, so it induces a projective map. Direct multiplication gives $A(w)A(w') = A(ww')$ and $A(1) = I$. Since $\omega_N^N = 1$, this proves the cyclic composition law modulo N. The Cayley coordinate of $[u : v]$ is $[u - v : u + v]$, and applying $A(w)$ changes this pair to $[w(u-v) : u+v]$. This proves the conjugacy also at poles. For $[z : 1]$, taking the coordinate ratio gives the displayed finite-chart formula. □

Corollary 13.3 (Impedance–admittance is the two-phase split)**.** *For $N = 2$ and finite $z \neq 0$,*

$$\boxed{T_{2,1}(z) = z^{-1}.}$$

On the full projective line it exchanges 0 and ∞. Thus a half-turn of the reflection disk exchanges normalized impedance and admittance.

Proof. $\omega_2 = \exp(\pi \mathrm{i}) = -1$, so $A(\omega_2)[u : v] = [v : u]$. The finite ratio is $1/z$ when $z \neq 0$. The coordinate swap also gives $[0 : 1] \leftrightarrow [1 : 0]$. No ordinary division by zero is used to represent infinity. □

13.1 Radial seeds and physical phase

For $0 \leq \rho < 1$ and angle θ,

$$\Gamma = \rho e^{\mathrm{i}\theta}$$

gives

$$z(\rho, \theta) = \frac{1 + \rho e^{\mathrm{i}\theta}}{1 - \rho e^{\mathrm{i}\theta}},$$

with

$$r(\rho, \theta) = \frac{1 - \rho^2}{1 - 2\rho\cos\theta + \rho^2}, \qquad x(\rho, \theta) = \frac{2\rho \sin\theta}{1 - 2\rho\cos\theta + \rho^2}.$$

A fixed ρ is a constant-mismatch circle. Refining N increases angular resolution without changing ρ.

For a lossless transmission line,

$$\Gamma_{\text{in}} = \Gamma_L e^{-2\mathrm{i}\beta\ell}.$$

One N-phase step corresponds to a line-length increment $\lambda/(2N)$, up to the chosen orientation convention. Hence the phase address has a direct electrical interpretation.

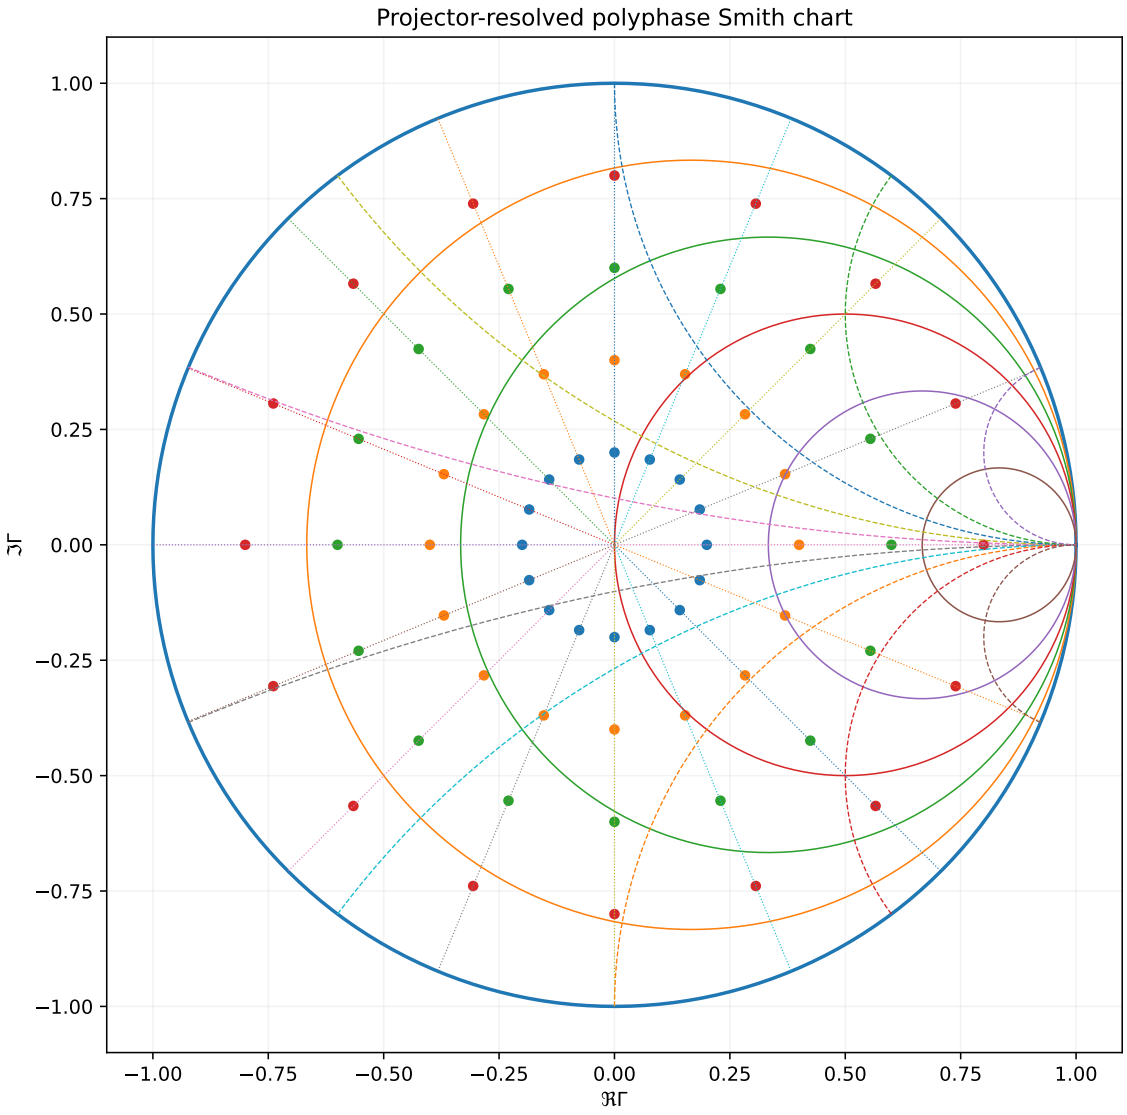

Figure 16. The classical Smith grid equipped with sixteen exact phase rays and four radial seed orbits. The Cayley transform creates the chart. The projector calculus supplies the nested cyclic coordinate system.

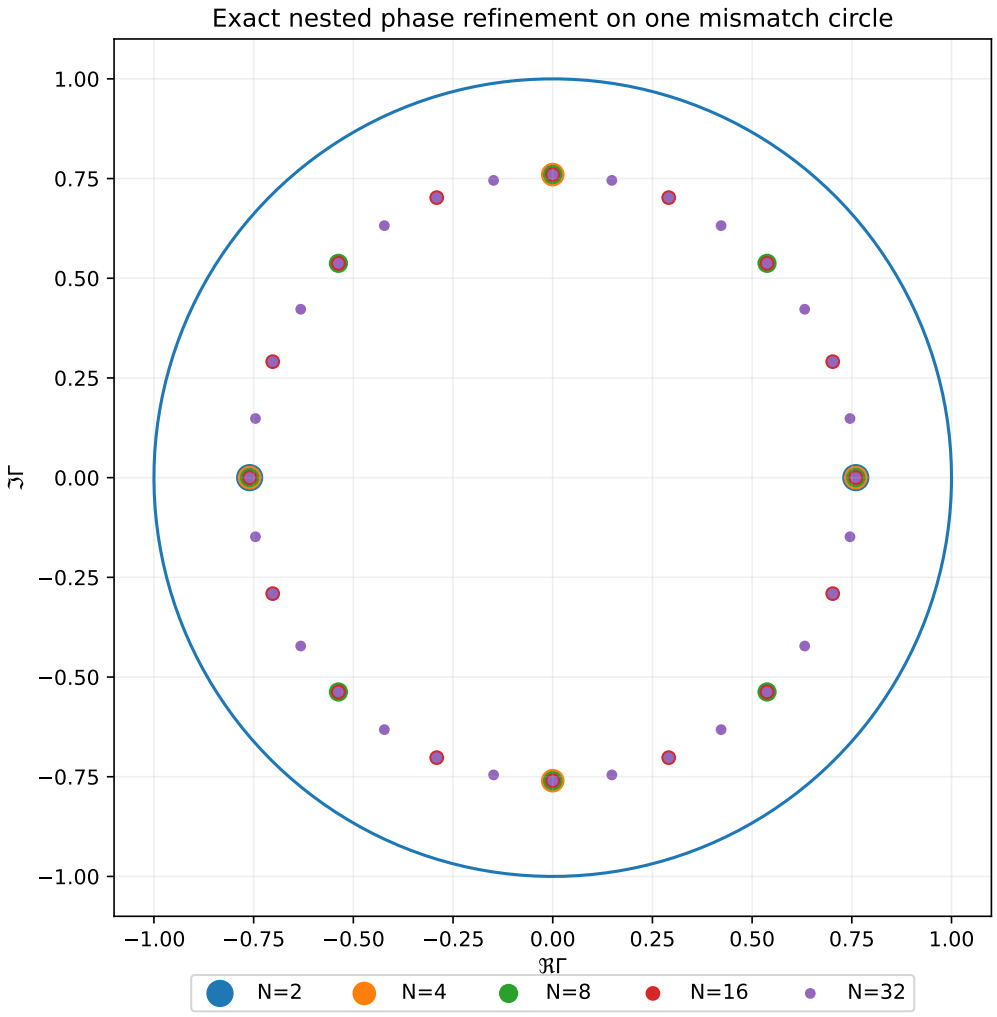

Figure 17. The same reflection circle at phase orders $2, 4, 8, 16, 32$. Each coarse phase ray appears in every finer grid whose order is a multiple of its order. The exact residue-projector refinement law concerns coefficient packets, not sums of impedance points.

14 Dyadic–odd phase factorization and boundary weighting

Write

$$N = 2^s M, \qquad M \text{ odd}.$$

The cyclic index splits by the Chinese remainder theorem:

$$\mathbb{Z}/N\mathbb{Z} \cong \mathbb{Z}/2^s\mathbb{Z} \times \mathbb{Z}/M\mathbb{Z}.$$

Proposition 14.1 (Dyadic–odd packet factorization)**.** *After identifying the residue labels by the Chinese remainder map, the phase projector factors as*

$$\boxed{P_{N,j} = P_{2^s,j_2} P_{M,j_o}.}$$

Proof. The two congruence conditions are independent because 2^s and M are coprime. Their indicator functions multiply to the indicator of the unique residue class modulo N satisfying both. □

The first dyadic step is exceptional in Smith coordinates because it is the inversion $z \mapsto z^{-1}$. Higher dyadic levels refine the open/short duality into quarter-, eighth-, and finer phase sectors.

Away from its pole $\Gamma = 1$, the inverse Cayley map has derivative

$$\frac{dz}{d\Gamma} = \frac{2}{(1-\Gamma)^2},$$

while normalized admittance has derivative proportional to $(1+\Gamma)^{-2}$. Away from $\Gamma = \pm 1$, this motivates the symmetric sensitivity

$$\boxed{w_{\text{Smith}}(\Gamma) = \frac{1}{|1-\Gamma|^2} + \frac{1}{|1+\Gamma|^2}.}$$

Boundary 14.2 (Weighted refinement). The sensitivity formula follows directly from the exact coordinate derivatives. Using it to choose an optimal adaptive grid, interpolation rule, or measurement design is a separate numerical problem. The illustration displays the weight but does not prove optimality.

15 Boundary-localized error and claim control

The strongest visual distinction between global Fourier reconstruction and exact packet retention is seen in a band around the discontinuity.

Conjecture 15.1 (Edge-packet approximation class)**.** There should exist natural function spaces in which a signal is represented as

$$f = s + \sum_q a_q \mathbf{1}_{\Omega_q},$$

with separate norms for smooth approximation, boundary geometry, packet amplitude, and packet identification. A projector-resolved approximation theory on such spaces should yield rates that do not mix smooth truncation error with discontinuity-location error.

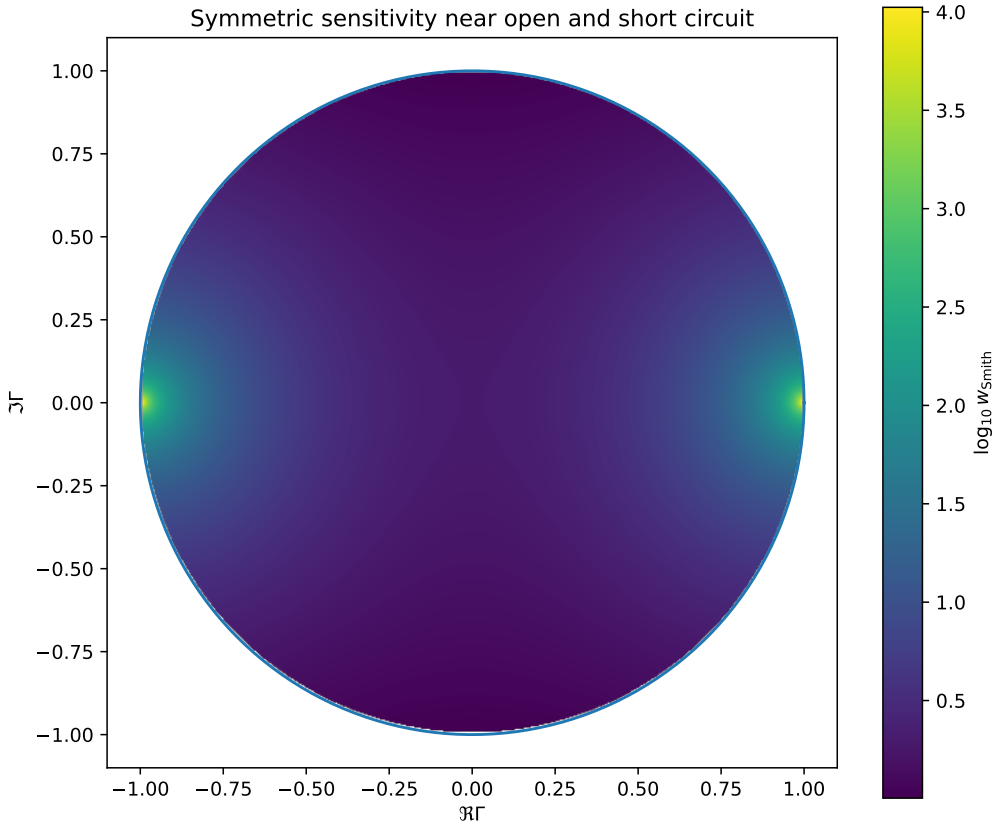

Figure 18. The proposed symmetric refinement weight becomes large near the open- and short-circuit boundary points. It is a condition-based adaptive coordinate, not an asserted optimal sampling law.

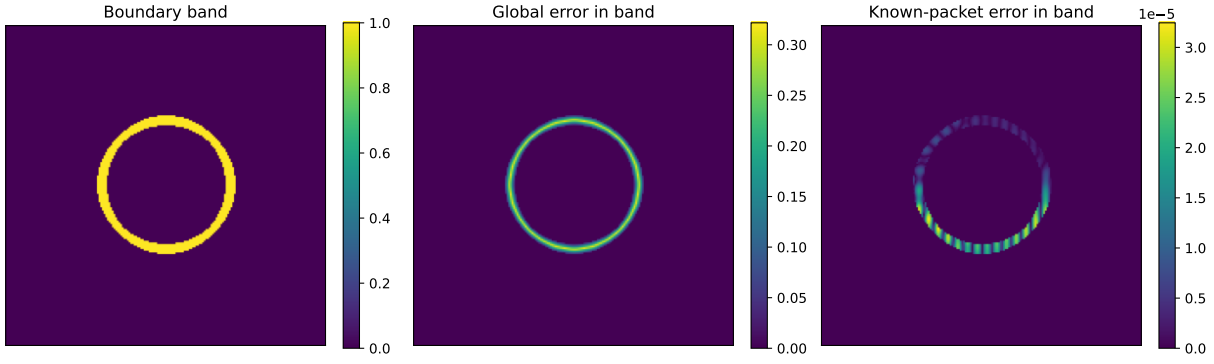

Figure 19. Error restricted to a narrow boundary band. Global truncation concentrates large error on the jump. The known-packet reconstruction has only the small smooth-packet error in the same band.

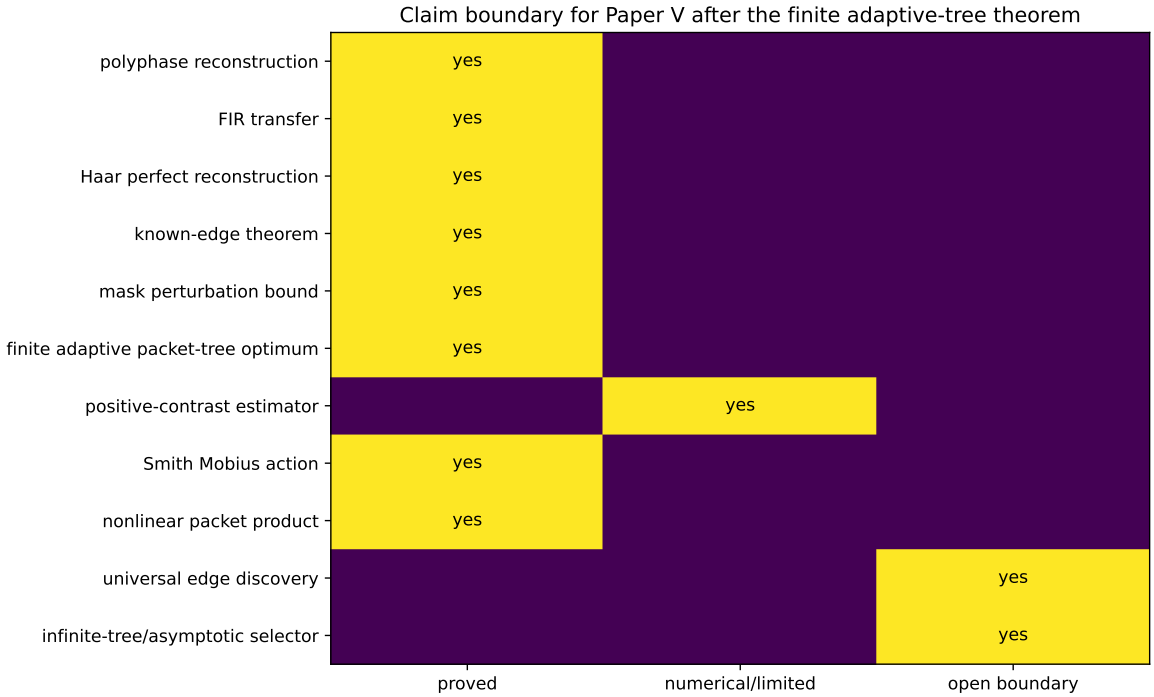

Figure 20. Proof and claim boundary. Finite adaptive-tree selection is proved. The remaining open rows concern universal recovery and infinite-tree or asymptotic selection.

16 Implementation and reproducibility

The companion package is organized by mathematical layer:

Table 2. Numerical companion modules.

module	implemented content
`polyphase.py`	residue projectors, analysis/synthesis, refinement, exact FIR transfer kernels, polyphase convolution
`filterbanks.py`	Haar analysis/synthesis, complete Haar packet trees, energy accounting, predict–update lifting
`adaptive.py`	complete-pruning enumeration, exact mixed-depth synthesis, dynamic-programming optimization, and stability certificates
`edges.py`	one- and two-dimensional Fourier truncation, known-packet reconstruction, narrow two-class estimators, harmonic filling, error metrics
`smith.py`	Cayley coordinates, cyclic Möbius action, Smith circles, sensitivity weight, coefficient projectors
`nonlinear.py`	coefficient packets, cyclic product convolution, nonlinear shifted packet reconstruction
`experiments.py`	all machine-readable numerical certificates and tabular summaries
`visuals.py`	the eighteen figure pairs used in the chapter

The recorded companion run reports that its 33 tests passed, and all 18 figure pairs and numerical tables were regenerated. The Lean package contributes 20 independent exact-model tests and 16 tests of the verifier itself. These account for another

36 passing tests. The exact-model suites count 305,933 assertions. These counts are separate from the 225 Lean theorem targets.

All numerical computations are CPU-based. Floating-point residuals measure finite implementations and may vary at rounding level with the scientific libraries. The universal mathematical statements are supported by the Lean proofs. The Python modules are not compiled or verified by Lean. The adaptive-tree certificate uses floating-point costs and an exhaustive finite comparison, so its displayed gap is numerical evidence rather than an interval-arithmetic proof about those computed costs. Appendix D explains the verification boundary.

Numerical Certificate 16.1 (Finite numerical residuals). The largest recorded residuals were

identity	residual
polyphase reconstruction	0
nested refinement	0
polyphase convolution	4.44×10^{-16}
Haar reconstruction	8.88×10^{-16}
wavelet-packet reconstruction	2.22×10^{-15}
adaptive-tree optimum versus exhaustive search	0
adaptive mixed-depth synthesis	8.88×10^{-16}
lifting reconstruction	4.44×10^{-16}
Smith rotation conjugacy	3.34×10^{-16}
Smith impedance–admittance duality	0
nonlinear product-packet reconstruction	1.33×10^{-15}
nonlinear shifted-filter reconstruction	0

The Haar and wavelet energy residuals were 5.68×10^{-14} and 2.27×10^{-13}, respectively.

17 Conclusions

The signal realization makes the seed, address, packet, transfer, refinement, and synthesis operations concrete. The objects and laws can be read directly:

$$\begin{aligned}
\text{seed} &= \delta_0, \\
\text{address} &= S^n, \\
\text{packet} &= P_{N,r}x, \\
\text{transfer} &= P_{N,k}HP_{N,s}, \\
\text{refinement} &= P_{N,r} = \sum_{s \succ r} P_{M,s}, \\
\text{synthesis} &= \sum_{r} P_{N,r}x, \\
\text{nonlinearity} &= P_{N,r}F\left(\sum_{s} P_{N,s}x\right).
\end{aligned}$$

Filter banks, wavelet packets, adaptive complete prunings, edge packets, and Smith coordinates inhabit the same operator grammar, but their claims differ. Polyphase and filter-bank identities are exact.

Wavelet perfect reconstruction is exact. The known-edge theorem is exact conditional on the decomposition. Estimated-edge performance depends on a detection model. The Smith chart remains the classical Cayley geometry equipped with an exact cyclic refinement algebra. Keeping those distinctions explicit is part of the calculus, not an editorial afterthought.

Chapter VI turns from discrete signal transfer to semigroups, resolvents, conditioning, stochastic evolution, fractional powers, and PDE kernels.

A Algorithm statements

A.1 Exact polyphase filtering

Given x, h, and N:

1. Form $x_s[n] = x[Nn + s]$ for $0 \le s < N$.
2. Form every transfer kernel $h_{ks}[m] = h[Nm + k - s]$.
3. Compute
$$y_k[n] = \sum_s \sum_m h_{ks}[m] x_s[n - m].$$
4. Interleave the y_k channels.

The algorithm is algebraically identical to direct convolution. Its purpose is to expose independent and interacting packets for block computation and refinement.

A.2 Conditional known-edge reconstruction

Given a decomposition $f = s + j$:

1. Apply the selected smooth approximation Q_m to s only.
2. Retain j exactly.
3. Return $Q_m s + j$.

The error certificate is $\|s - Q_m s\|$.

A.3 Limited positive-contrast estimator

The included finite estimator does the following:

1. Split the observed values into two classes by an Otsu threshold.
2. Keep coherent connected components and fill holes.
3. Harmonically fill the selected packet to estimate the missing background.
4. Smooth the filled background spectrally.
5. Estimate one packet amplitude by a robust median residual.

6. Recombine the estimated smooth and edge packets.

This procedure is useful for the supplied separated synthetic case. It assumes a positive-contrast two-class packet and is not promoted to a general edge theorem.

B Numerical record

Table 3. Main edge-study measurements.

case	global RMSE	known-packet RMSE	estimated RMSE
1D rectangular packet	5.4023×10^{-2}	1.3692×10^{-4}	2.4029×10^{-2}
2D disk packet	3.7643×10^{-2}	6.4752×10^{-5}	3.4043×10^{-3}
2D multiedge packet	3.3740×10^{-2}	known composite packet only	

Table 4. Main software artifacts.

artifact	purpose
`results/numerical_results.json`	complete machine-readable certificate record
`tables/numerical_summary.csv`	flat summary of errors and residuals
`tables/sparse_representation.csv`	wavelet/Fourier coefficient study
`tests/`	automated finite identity and estimator tests
`figures/`	PNG and vector-PDF figure pairs
`VERIFY_PAPER.py`	combined manuscript, numerical, and Lean checks

C Notation crosswalk

Table 5. Notation crosswalk.

common symbol	**signal realization**	**interpretation**
s	δ_0	primitive signal seed
A_n	S^n	address operator
$P_{N,r}$	residue mask	phase packet projector
T_{ks}	$P_{N,k} H P_{N,s}$	input-to-output phase transfer
E, R	analysis and synthesis matrices	coordinate conversion and reconstruction
$W(\gamma)$	filter or path weight	refinement or implementation cost
$\Delta(F)$	coarse/fine signal defect	aliasing, leakage, or estimator inconsistency
$\mathrm{Hol}(\gamma)$	closed phase transfer	cycle consistency in a network
Γ	reflection coefficient	Smith-disk coordinate

D Formalization and reproducibility record

D.1 What has been checked

The preserved Part I manuscript has twenty theorem-like statements: Theorems, Propositions, and Corollaries, counted together. The Lean project contains 225 explicit supporting theorem targets in 23 proof modules. All twenty statements have an explicit scope row and principal declaration targets. The retained compiler record documents a successful build and axiom audit with warnings treated as errors. The formal companion identifies its source, toolchain, and reproduction procedure. The audit inspected all 827 declarations in the project namespace, including definitions and automatically generated declarations. The latter is an implementation census, not a count of 827 mathematical theorems.

The accepted axiom dependencies are `propext`, `Classical.choice`, and `Quot.sound`. No admitted proof or additional project axiom is permitted. The verifier checks the imported modules, registered theorem inventory, dependency pins, source hashes, and coverage of the twenty-row scope contract. Its successful status is `LEAN_CHECKS_PASS`. The correspondence between a mathematical sentence in this PDF and its Lean type is a manual mathematical review, not an automated semantic-equivalence test.

The mathematical text integrates the checked hypotheses and conclusions. Editorial changes do not increase the Lean theorem count. Eleven foundational formal-power-series proofs in `CyclicSeries` are adaptations of Chapter IV and are identified as such in the provenance record.

D.2 Result-by-result correspondence

The following table summarizes the reviewed statement boundary. Full qualified declaration names, source locations, and supplementary targets appear in `MANUSCRIPT_TARGET_MAP.md` and the machine-readable scope contract. Every row below has supporting kernel-checked declarations. Numerical certificates, classical-input paragraphs, remarks, and conjectures are not additional theorem rows.

Table 6. The twenty manuscript results and their Lean statement scopes.

Result	Principal modules	Checked mathematical content
1.1	HilbertPackets	Complex ℓ^2 impulse expansion, finite-support identity, unitary shifts, and closed shift-generated span.
2.1	HilbertPackets	Bounded self-adjoint residue projectors, pairwise annihilation, completeness, and orthogonal ranges.
2.2	IntegerPolyphase; HilbertPackets	Signed quotient/remainder coordinates, both inverse identities, and the joint Hilbert norm of the channels.
2.3	HilbertPackets	Literal bounded-projector refinement for positive divisible moduli.
3.1	FIRTransfer; ZTransform	Finite-support tap reindexing for all bilateral inputs; numerical channel transforms under weighted absolute summability.
4.1	FilterBank; FiniteTransforms	Finite Laurent/FIR bank composition, faithful action on sequences, gain-delay reconstruction criterion, and the Nd original-sample delay.
4.2	HaarChannels; HaarHilbert	Literal even/odd input samples, normalized complex low/detail channels, and ℓ^2 energy equality.
4.3	Lifting; FiniteTransforms	Predict/update inverse maps, determinant one, and both flat finite-signal inverse identities.

Result	Principal modules	Checked mathematical content
5.1	WaveletPackets	Every finite depth of literal Haar packet operators, energy equality, and reconstruction using actual Hilbert adjoints.
6.1	KnownEdge	Exact cancellation of one retained packet, and equality of approximation errors.
6.2	KnownEdge	Finite families of retained packets, with no geometry assumption on the packets.
7.1	MaskPerturbation	Measurable-mask symmetric-difference norm, extended finite-p error bound, pointwise and essential supremum bounds, and smooth-background error.
11.2	CompletePrunings; PruningSums	Recursive cuts correspond to complete covering antichains; literal finite node sums preserve synthesis.
11.3	PruningSums	Finite arbitrary-objective minimization, attained positive gap with competitors, strict stability, and the singleton case.
11.4	FiniteAdaptive; PruningAlgorithm	Deterministic stop-on-ties selector, global optimum, arbitrary positive finite branching, and the stated unit-operation count.
11.5	PruningSums; PruningAlgorithm	Attained maximum error envelope, optimal-value perturbation, strict-gap selector stability, and probability transfer from a joint event.
12.1	CyclicSeries	Formal Cauchy-product residue convolution and the finite-tuple power identity, including the empty product at exponent zero.
13.2	SmithAction; SmithCyclic	Nonzero homogeneous pairs modulo scaling, Cayley conjugacy, the actual exponential phase, and cyclic composition on the projective line.
13.3	SmithCyclic	Two-phase coordinate swap, $0 \leftrightarrow \infty$, and finite impedance inversion when $z \neq 0$.
14.1	CRT	Signed integer residue-mask factorization for coprime moduli, including the dyadic–odd case.

The remaining foundational modules `Packets`, `FiniteSelection`, and `BinaryAdaptive` provide generic coordinate, finite-minimum, and binary-tree lemmas used or retained alongside the concrete constructions. The Hilbert target is the square-summable space on a product of indices. It is not the supremum-norm function space that Lean would otherwise assign to an unqualified finite family of channels.

D.3 Three bridges that matter for the statement

Finite filters and numerical transforms. The filter-bank proof is an algebraic theorem about finite Laurent-polynomial kernels acting faithfully on bilateral sequences. Equality at a single complex value of z would be insufficient to prove a polynomial identity. The impulse argument avoids that error. The separate transform theorem proves the finite-filter action agrees with evaluation wherever the weighted input series converge absolutely. An arbitrary bilateral ℓ^2 sequence need not have an absolutely convergent numerical z-transform. The all-sequence time-domain theorem makes no such assumption.

Recursive trees and set-valued prunings. The formal tree permits any positive finite arity at an internal node, including arity one. A node has a position in the tree, so equal data labels on distinct nodes do not identify the nodes. A recursive cut is either a stop or a collection of child cuts. Its equivalence

with a covering antichain is proved in both directions. The cost, envelope, and operator sums are then shown to equal actual finite sums over the selected node set. This connects the recursive optimizer to the manuscript's set-valued definition instead of assuming that connection.

Hilbert operators and finite experiments. The coordinate maps, literal Haar channels, and packet operators are constructed on complex ℓ^2. Square summability and boundedness are established before adjoints are used. The finite Python experiments separately check indexing, reconstruction, and energy at finite lengths. They illustrate these operators but are not the objects executed by the Lean kernel. Likewise, the Python Smith routine evaluates only finite charts. The Lean projective construction supplies the pole-safe universal statement.

D.4 Recorded checks and numerical conventions

Check family	Accepted count
Original numerical companion tests	33
Independent exact-model tests	20
Verifier positive and negative controls	16
Total tests in these three families	69
Exact assertions inside the independent model suites	305,933
Registered Lean theorem targets	225
Lean proof modules	23
Regenerated figure pairs	18

The recorded numerical comparison states that all scalar entries in the recovered numerical-results JSON reproduced exactly in its environment. This includes the 458,330-pruning depth-five comparison, its selected six-node pruning, the optimum gap, and the reconstruction residuals. The five Fourier sparseapproximation budgets were also checked for conjugate-pair closure. The figures and tables use the regenerated data. This exact replay of the stored floating-point numbers is stronger than a visual similarity check, but it is not a promise of bitwise equality on every platform.

For the one-dimensional low-pass experiment, "cutoff 18" means 37 signed frequency bins, not 18 retained coefficients. The disk experiment uses a square 33×33 frequency mask, not a radial cutoff. The sparse comparison uses largest-coefficient budgets instead of either low-pass convention. The full-image and boundary-band RMSEs are normalized by the number of samples in the respective comparison set. The supplied inpainting routines perform a fixed finite number of periodic neighbor-averaging iterations. The term "harmonic filling" describes that iteration, not a separately proved exact continuum Dirichlet solver.

The independent exact-model suite checks signed polyphase/FIR addresses, exact lifting and normalized Haar arithmetic, mask bounds, and exhaustive finite-tree objectives. Its tree census includes all 626 ordered rooted tree shapes with one through eight nodes and 129,958 node subsets. These finite checks can catch implementation or convention errors. They are not substitutes for the universal Lean proofs. The verifier controls exercise failure paths, including incomplete scope contracts and unregistered proof targets. Mandatory verification conditions use explicit exceptions rather than Python assertions, so optimized Python cannot silently remove them.

D.6 What remains open

All twenty scoped theorem-like statements have reviewed, accepted formal counterparts. The two edge-recovery conjectures remain open research directions. No universal segmentation theorem, infinite-tree consistency result, minimax rate, or optimal Smith sampling theorem is inferred from the finite results. Classical Smith-grid and transmission-line formulas provide application context. Those contextual assertions are not additional Lean-certified theorem rows.

> The formal scope consists of the twenty Part I results. Supporting declarations, reused results and proofs in the broader written development have distinct roles.

Part II: Extended mathematical development

Multiresolution Signal Calculus, Singular Packets, and Stable Reconstruction

This part preserves the complete standalone mathematical branch, with the explicit audit repairs recorded in the accompanying source ledger. Its sixty-three proofs are prose proofs. No additional Lean coverage is asserted. Section and result numbers carry the prefix E to distinguish this scope from Part I.

Overview

Signals on a lattice admit exact coordinates indexed by the residue classes of every finite index sublattice. Convolution becomes a matrix of packet transfers, while filter banks and packet trees become exact changes of coordinates. We develop this structure on sequence spaces, prove quantitative stability for imperfect and perturbed banks, and give an exact dynamic recursion for adaptive packet trees. A singular signal is written as a smooth component plus step or truncated power packets that record jumps in the signal and its derivatives. Retaining the correct packets leaves only the smooth approximation error. Estimated packets are governed by exact formulas involving value error, region overlap, boundary displacement, and the norm of the smooth approximation operator. The main recovery result treats separated jumps sampled on a uniform grid. An explicit contrast gap gives exact recovery of every jump cell, grid scale location accuracy, amplitude control, and finite norm consistency. Probability bounds cover sub-Gaussian noise and repeated measurements. Haar coefficients, two shifted grids, and annihilating differences give complementary localization results. The final sections treat Gibbs oscillation, nonlinear residue interactions, numerical illustrations, and cyclic Cayley coordinates.

E1 Introduction

Polyphase decompositions, filter banks, lifting schemes, and wavelet packets are standard parts of multirate signal processing and harmonic analysis. Their classical development is described in [CR83, Vai93, VK95, SN96, Dau92, Mal09]. These theories are often introduced through several parallel languages. Residue classes appear in polyphase analysis. Matrix symbols appear in filter banks. Trees appear in wavelet packets. Singularities are handled through a different approximation or detection method. The first aim of this part is to place these constructions in one exact coordinate system.

The second aim is to separate representation from recovery. If a signal has already been written as

$$f = s + j$$

with a smooth part s and a singular packet j, then

$$\tilde{f} = Qs + j$$

satisfies

$$f - \tilde{f} = s - Qs.$$

This identity is exact, but it does not discover j. A useful signal theory must therefore distinguish three errors. The first is the approximation error of the smooth component. The second is the error in the estimated singular packet. The third is the amplification caused by applying a reconstruction operator to that packet error. The middle sections of this part isolate all three terms.

The singular packets considered here range from indicator functions of regions to truncated powers

$$\frac{(t-\tau)_+^m}{m!}.$$

The latter encode jumps in derivatives of order m. They permit a piecewise smooth function to be reduced to a globally Sobolev remainder under explicit trace assumptions. This gives a precise version of the informal statement that a discontinuity should be represented directly rather than approximated by a global smooth basis.

The recovery theory begins with one-dimensional separated jumps. For bounded deterministic noise, thresholding adjacent sample contrasts recovers the exact grid cells containing the jumps whenever the jump size exceeds the combined smooth variation and noise by an explicit margin. The same proof gives location and amplitude bounds. A sub-Gaussian version follows from a union bound. Averaging repeated measurements reduces the required threshold in the expected way. Haar coefficients provide a second detection mechanism. Two grids shifted by half a cell guarantee that every jump is well placed in at least one grid, which removes the most elementary dyadic alignment failure.

The literature on singularity detection is much broader than the results proved here. Wavelet modulus maxima are developed in [MH92]. Best basis selection in packet libraries was introduced in [CW92]. Nonlinear approximation is surveyed in [DeV98]. Geometric image models, wedgelets, and curvelets appear in [Don99, CD04]. The present part does not replace those theories. Its narrower purpose is to give a common exact calculus in which coordinate reconstruction, adaptive basis selection, singular packet estimation, and smooth approximation remain logically separate.

This part is organized as follows. Appendices E2 and E3 develop lattice addresses and exact residue coordinates in any dimension. Appendices E4 and E5 express convolution and filter banks in those coordinates, including stability under imperfect reconstruction and filter perturbation. Appendix E6 treats arbitrary pruned packet trees and stability of the best basis decision. Appendices E7 and E8 introduce step and higher order singular packets, exact reconstruction identities, and error formulas. Appendices E9 and E10 prove deterministic and probabilistic recovery results. Appendices E11 and E12 treat Gibbs oscillation and nonlinear interactions. The final sections record finite numerical illustrations and a secondary cyclic Cayley realization.

Several conclusions are deliberately excluded. The chapter does not prove a universal image segmentation theorem. Exact recovery of separated jumps in one dimension does not imply stable recovery of arbitrary boundaries in higher dimensions. Retaining a correct singular packet does not remove noise or model error. An adaptive tree selected by an additive objective need not remain optimal when global hardware costs or cross-packet interactions are introduced. The Cayley coordinate section is a secondary conformal realization and is not used in the recovery theorems.

E1.1 Main results

The first result is an exact coordinate theorem. Let L be a finite index sublattice of $\mathbb{Z}^d$, and let R contain one representative from every coset. The analysis map

$$x \longmapsto (x_r)_{r\in R}, \qquad x_r(\ell) = x(r+\ell),$$

is an isometric isomorphism on every ℓ^p space. This statement includes the usual one-dimensional polyphase decomposition, but it also applies to arbitrary finite index lattice packets in several dimensions. If $L' \leq L$, the coarse packets split exactly into their fine descendants. A convolution operator becomes a matrix of convolution operators on L, with entries

$$h_{rs}(m) = h(r - s + m).$$

The matrix is therefore a coordinate representation of the original operator, not a reduced model.

The filter bank results distinguish exact reconstruction from quantitative near reconstruction. Exact recovery with delay d is the pointwise matrix identity

$$R(z)E(z) = z^{-d}I.$$

When this identity fails, the reconstruction error is controlled by the essential supremum of the delay compensated multiplier defect. If the filters themselves are perturbed, theorem E5.4 separates the analysis error, the synthesis error, and their product. The frame bound in theorem E5.7 shows that a lower singular value gap survives every sufficiently small perturbation. This makes the distinction between algebraic invertibility and stable numerical reconstruction explicit.

The packet tree results treat every admissible pruning, not only complete trees of a fixed depth. Unitary local splits give a unitary global transform. Local frame bounds propagate recursively in the nonunitary case. If the cost of a pruning is additive over retained nodes, then

$$F(v) = \min\left\{ c(v), \sum_{w \in \mathrm{child}(v)} F(w) \right\}$$

gives the exact optimal tree. The cost and the selected basis are stable when the node costs change by less than the gap separating the optimal pruning from its competitors.

The singular packet results begin with trace data. If a piecewise smooth function has a jump in its derivative of order m at τ_q, then the packet

$$\left[f^{(m)}\right]_{\tau_q} \frac{(t - \tau_q)_+^m}{m!}$$

removes exactly that trace jump. Subtracting all packets through order $r - 1$ leaves a global $W^{r,p}$ remainder. The packet coefficients are uniquely determined by the one-sided trace jumps. This gives a finite and explicit singular part for the class covered by theorem E7.2.

The reconstruction formula with an estimated packet is

$$f - \hat{f}_m = (I - Q_m)s + (I - Q_m)(j - \hat{j}).$$

This identity identifies the two terms that must be controlled. The exact packet formulas in appendix E8 then evaluate or bound $\|j - \hat{j}\|$ from amplitude error, region overlap, boundary displacement, and the order of a derivative jump. A value jump has location modulus $|\tau - \hat{\tau}|^{1/p}$ in finite L^p, while every positive order truncated power packet is Lipschitz in its location.

The principal recovery theorem uses adjacent sample contrasts. Let

$$b_h = Mh + 2\varepsilon$$

be the largest contrast that can be produced by a Lipschitz background and bounded noise in one grid cell. If

$$a_{\min} > 2b_h,$$

then every threshold between b_h and $a_{\min} - b_h$ detects exactly the cells containing jumps. The jump locations are recovered within $h/2$, and each amplitude error is at most b_h. The probability theorem replaces the deterministic noise term by

$$2\sigma\sqrt{\log(2n/\delta)}.$$

Two half shifted Haar grids provide a second recovery mechanism. Every point is at least one quarter of a cell away from the boundary of one of the grids, so the Haar coefficient gap can be made independent of dyadic alignment.

E1.2 Notation

The following symbols recur throughout this part.

symbol	meaning
$L \le \mathbb{Z}^d$	a finite index sublattice
R	a set of representatives for $\mathbb{Z}^d/L$
P_r	the coordinate projector onto the coset $r + L$
$\mathcal{A}_L, \mathcal{S}_L$	lattice analysis and interleaving synthesis
E, R	filter bank analysis and synthesis symbols
Q_m	a bounded linear approximation operator acting on the smooth part
$j, \hat{j}$	the true and estimated singular packets
H_τ	the step packet $\mathbf{1}_{[\tau,1]}$
$\phi_{m,\tau}$	the truncated power packet $(t-\tau)_+^m/m!$
h	the grid spacing in the recovery theorems

E2 Signal seeds and lattice addresses

Let $1 \le p \le \infty$. For a countable set G, write $\ell^p(G)$ for the usual complex sequence space. For an integer $d \ge 1$, when $G = \mathbb{Z}^d$, translation by $a \in \mathbb{Z}^d$ is

$$(T_a x)(n) = x(n-a).$$

Let δ_0 be the impulse at the origin.

Theorem E2.1 (Impulse generation). *For $1 \le p < \infty$,*

$$\overline{\operatorname{span}\{T_a\delta_0 : a \in \mathbb{Z}^d\}}^{\ell^p} = \ell^p(\mathbb{Z}^d).$$

The same statement holds in $c_0(\mathbb{Z}^d)$ with the supremum norm. In $\ell^\infty(\mathbb{Z}^d)$, the closed span of the translation orbit is exactly $c_0(\mathbb{Z}^d)$.

Proof. The translation orbit is the standard coordinate family $(\delta_a)_{a\in\mathbb{Z}^d}$. Its finite span is the space of finitely supported sequences. Finitely supported sequences are dense in ℓ^p for finite p and in c_0. Their closure in the supremum norm is c_0, which is a proper closed subspace of ℓ^∞. □

Remark E2.2. The distinction at $p = \infty$ is structural. The impulse generates every finitely supported signal algebraically, but it is not a topological cyclic seed for all bounded signals.

Proposition E2.3 (Finite periodic signals)**.** *Let $G = \mathbb{Z}^d/L$, where $L \leq \mathbb{Z}^d$ has finite index. The translation orbit of the impulse at the identity is a basis of $\mathbb{C}^G$. In particular, one impulse generates every signal on the finite periodic lattice.*

Proof. Translation sends the impulse at the identity to the impulse at each element of G. These impulses form the standard basis of $\mathbb{C}^G$. □

E3 Polyphase coordinates on finite index sublattices

Let $L \leq \mathbb{Z}^d$ be a sublattice of finite index q. Choose a set $R \subset \mathbb{Z}^d$ containing one representative from every coset in $\mathbb{Z}^d/L$. Thus

$$\mathbb{Z}^d = \bigsqcup_{r\in R} (r + L).$$

For $x : \mathbb{Z}^d \to \mathbb{C}$, its channel at r is the sequence on L

$$x_r(\ell) = x(r + \ell).$$

Definition E3.1 (Lattice packet)**.** For $r \in R$, define the coordinate projector

$$(P_r x)(n) = \mathbf{1}_{r+L}(n)x(n).$$

The family $(P_r)_{r\in R}$ is called the packet system associated with L and R.

For finite p, equip $\bigoplus_{r\in R} \ell^p(L)$ with

$$\|(u_r)\|^p = \sum_{r\in R} \|u_r\|_p^p.$$

For $p = \infty$, use the maximum norm.

Theorem E3.2 (Exact lattice polyphase decomposition)**.** *For every $1 \leq p \leq \infty$, the analysis map*

$$\mathcal{A}_L : \ell^p(\mathbb{Z}^d) \longrightarrow \bigoplus_{r\in R} \ell^p(L), \qquad \mathcal{A}_L x = (x_r)_{r\in R},$$

is an isometric isomorphism. Its inverse is the interleaving map

$$\mathcal{S}_L(u)(r + \ell) = u_r(\ell).$$

The projectors satisfy

$$P_r P_s = \delta_{rs} P_r, \qquad \sum_{r \in R} P_r = I.$$

Proof. Every address has a unique representation $r + \ell$. For finite p,

$$\|x\|_p^p = \sum_{r \in R} \sum_{\ell \in L} |x(r+\ell)|^p = \sum_{r \in R} \|x_r\|_p^p.$$

The corresponding supremum identity is immediate when $p = \infty$. Unique address representation proves that analysis and interleaving are inverse maps. The projector identities follow from the disjoint coset partition. □

Corollary E3.3 (One dimensional residue coordinates)**.** *For $L = N\mathbb{Z}$ and $R = \{0, \dots, N-1\}$,*

$$x_r(k) = x(Nk + r)$$

and

$$\ell^p(\mathbb{Z}) \cong \bigoplus_{r=0}^{N-1} \ell^p(\mathbb{Z})$$

isometrically.

Proof. Apply theorem E3.2 to the standard residue representatives. □

Proposition E3.4 (Translation covariance)**.** *Fix $a \in \mathbb{Z}^d$. For every $r \in R$, write uniquely*

$$r - a = r_a + \lambda_{a,r}, \qquad r_a \in R, \quad \lambda_{a,r} \in L.$$

Then

$$(\mathcal{A}_L T_a x)_r(\ell) = x_{r_a}(\ell + \lambda_{a,r}).$$

Thus a fine translation permutes the lattice packets and applies an internal translation on L.

Proof. Evaluate at $r + \ell$:

$$(T_a x)(r + \ell) = x(r + \ell - a) = x(r_a + \ell + \lambda_{a,r}).$$

This is the stated channel formula. □

E3.1 Refinement of sublattices

Let $L' \le L \le \mathbb{Z}^d$, with both indices finite. Choose representative systems R for $\mathbb{Z}^d/L$ and R' for $\mathbb{Z}^d/L'$. For $r \in R$, define

$$\mathrm{Child}(r) = \{s \in R' : s + L' \subset r + L\}.$$

Theorem E3.5 (Exact lattice refinement)**.** *For every coarse packet,*

$$P_r^L = \sum_{s \in \mathrm{Child}(r)} P_s^{L'}.$$

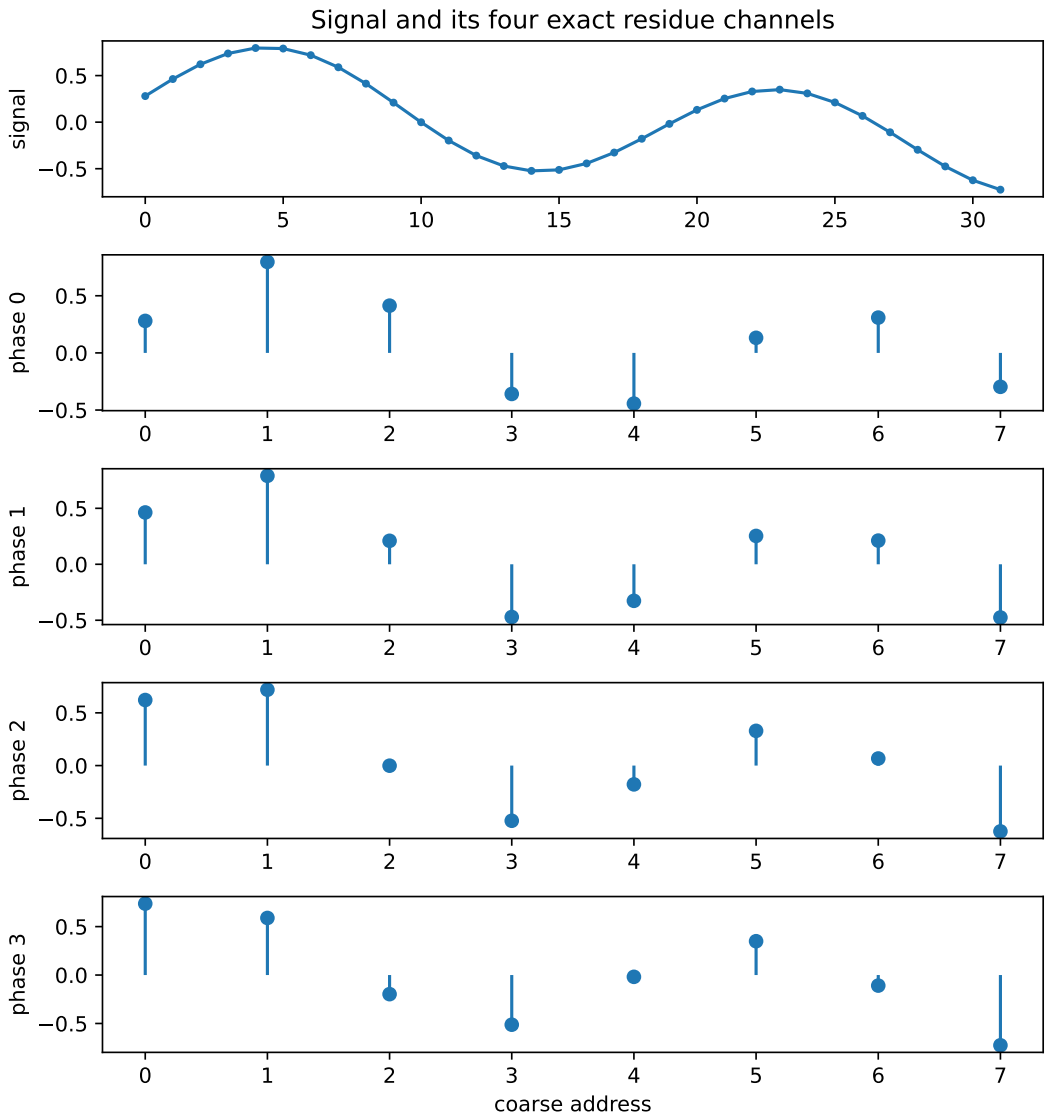

Figure E1. A signal and its four exact residue channels. Interleaving the channels returns the original samples without approximation.

The fine packets in the sum are pairwise disjoint. Refinement through several nested sublattices is transitive.

Proof. The coset $r + L$ is the disjoint union of the L' cosets contained in it. Multiplying by the corresponding indicator functions gives the projector identity. A nested partition of a coset is independent of whether the intermediate level is inserted, which proves transitivity. □

Example E3.6 (Rectangular image phases)**.** For

$$L = M\mathbb{Z} \times N\mathbb{Z} \subset \mathbb{Z}^2,$$

one may take

$$R = \{0, \dots, M-1\} \times \{0, \dots, N-1\}.$$

The analysis map separates an image into MN exact phases. Refining (M, N) to (M', N'), where $M \mid M'$ and $N \mid N'$, splits every coarse phase into

$$\frac{M'}{M}\,\frac{N'}{N}$$

fine phases.

E4 Convolution as a packet transfer matrix

Let $h \in \ell^1(\mathbb{Z}^d)$ and $x \in \ell^p(\mathbb{Z}^d)$, with $1 \le p \le \infty$, and define

$$(Hx)(n) = (h * x)(n) = \sum_{q \in \mathbb{Z}^d} h(q)x(n-q).$$

Young's inequality gives

$$\|Hx\|_p \le \|h\|_1 \|x\|_p$$

for every $1 \le p \le \infty$.

Definition E4.1 (Packet transfer kernel)**.** For output residue $r \in R$ and input residue $s \in R$, define a kernel on L by

$$h_{rs}(m) = h(r - s + m), \qquad m \in L.$$

Theorem E4.2 (Exact convolution transfer law)**.** *Let $y = h * x$. Then*

$$y_r(\ell) = \sum_{s \in R} \sum_{m \in L} h_{rs}(m)x_s(\ell - m).$$

Equivalently,

$$\mathcal{A}_L H \mathcal{A}_L^{-1} = (H_{rs})_{r,s \in R},$$

where H_{rs} is convolution on L by h_{rs}.

Proof. Evaluate the output at $r + \ell$. Write every input address as $s + \ell'$. The convolution offset is

$$(r + \ell) - (s + \ell') = (r - s) + (\ell - \ell').$$

Setting $m = \ell - \ell'$ gives the formula. □

Proposition E4.3 (Transfer norm control)**.** *For every output residue r,*

$$\sum_{s \in R} \|h_{rs}\|_{\ell^1(L)} = \|h\|_{\ell^1(\mathbb{Z}^d)}.$$

The packet transfer matrix acts on the polyphase direct sum with norm at most $\|h\|_1$ on every ℓ^p space.

Proof. For fixed r, every $q \in \mathbb{Z}^d$ has a unique representation $q = r - s + m$ with $s \in R$ and $m \in L$. This proves the equality of the absolute sums. The operator norm bound also follows by conjugating Young's inequality through the isometric analysis map. □

Proposition E4.4 (Composition of transfer matrices)**.** *If G and H are convolution operators with packet matrices (G_{rs}) and (H_{rs}), then the packet matrix of GH is*

$$(GH)_{rt} = \sum_{s \in R} G_{rs} H_{st}.$$

In one-dimensional transform notation, the corresponding matrix symbols multiply pointwise.

Proof. Conjugation by $\mathcal{A}_L$ preserves composition:

$$\mathcal{A}_L GH \mathcal{A}_L^{-1} = (\mathcal{A}_L G \mathcal{A}_L^{-1})(\mathcal{A}_L H \mathcal{A}_L^{-1}).$$

Reading the (r, t) block gives the formula. □

E4.1 The one-dimensional symbol

For $L = N\mathbb{Z}$ with $N \geq 1$, first take $|z| = 1$. The assumption $h \in \ell^1(\mathbb{Z})$ makes the following symbol series absolutely convergent. Define

$$H_{ks}(z) = \sum_{m \in \mathbb{Z}} h(Nm + k - s) z^{-m}.$$

For $x \in \ell^1(\mathbb{Z})$, the channel transforms converge absolutely on the unit circle and satisfy

$$\boldsymbol{Y}(z) = \boldsymbol{H}_N(z) \boldsymbol{X}(z).$$

For $x \in \ell^2(\mathbb{Z})$, the same identity holds almost everywhere in the L^2 Fourier sense. For finite impulse-response kernels it also holds at nonzero z wherever the input channel transforms are weighted absolutely summable. This is the classical polyphase matrix. It is the exact block matrix of the original convolution operator.

Corollary E4.5 (Finite impulse response closure)**.** *If h has finite support, every packet kernel h_{ks} has finite support. Matrix multiplication of polyphase symbols agrees with composition of the original finite impulse response operators.*

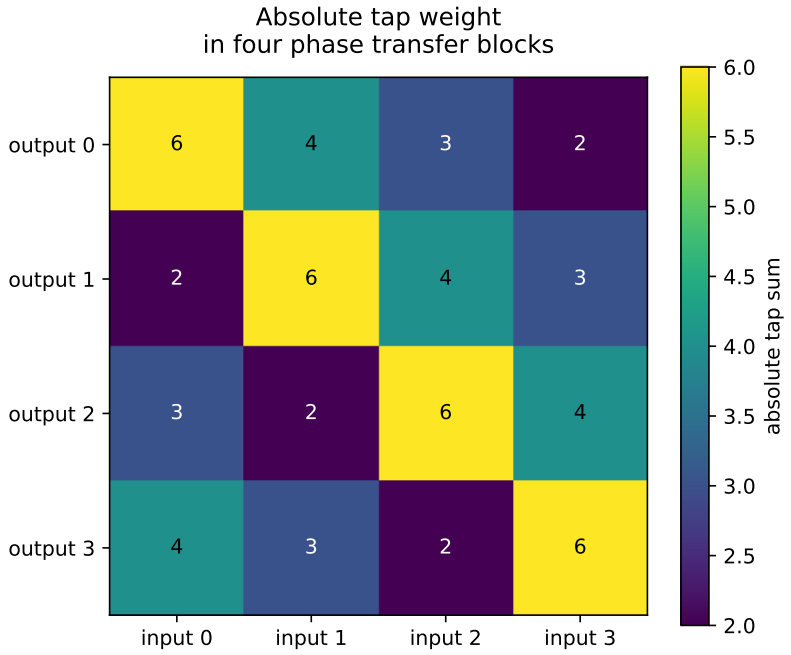

Figure E2. Absolute tap weight in the transfer blocks of the four phase operator in example E4.6.

Proof. Finite support is preserved by taking residue subsequences. The composition statement is proposition E4.4. □

Example E4.6 (A four phase finite impulse response operator)**.** Let

$$h(0) = 1, \quad h(1) = 2, \quad h(2) = 3, \quad h(3) = 4, \quad h(4) = 5,$$

with all other taps zero. For four residue channels, the transfer symbol is

$$\boldsymbol{H}_4(z) = \begin{pmatrix} 1 + 5z^{-1} & 4z^{-1} & 3z^{-1} & 2z^{-1} \\ 2 & 1 + 5z^{-1} & 4z^{-1} & 3z^{-1} \\ 3 & 2 & 1 + 5z^{-1} & 4z^{-1} \\ 4 & 3 & 2 & 1 + 5z^{-1} \end{pmatrix}.$$

The delay term records the tap that crosses a coarse cell boundary. No approximation is introduced by the matrix representation.

E5 Filter banks, frame bounds, and lifting

Throughout this section the banks act boundedly on the relevant polyphase ℓ^2 spaces. A finite channel analysis bank acts in Fourier coordinates by a matrix $E(z)$. A synthesis bank acts by a matrix $R(z)$. The matrices may be square or rectangular. Their entries are Laurent polynomials for finite filters and bounded measurable functions for general stable filters.

Theorem E5.1 (Perfect reconstruction criterion)**.** *Let $E(z)$ be an M by N analysis matrix and let $R(z)$ be an N by M synthesis matrix. The bank reconstructs every input with a delay of d coarse channel samples, equivalent to Nd original samples in the one-dimensional N-phase convention, exactly if and only if*

$$R(z)E(z) = z^{-d} I_N$$

for almost every point on the unit circle. A nonzero scalar factor gives exact reconstruction up to gain and delay.

Proof. The channel Fourier transform turns analysis followed by synthesis into multiplication by $R(z)E(z)$. If the matrix identity holds, inverse transformation gives the delayed input. Conversely, if every input is reconstructed with that delay, the difference matrix annihilates every vector valued Fourier datum and must vanish almost everywhere. □

Theorem E5.2 (Quantitative imperfect reconstruction)**.** *Define the delay compensated defect*

$$D(\mathrm{e}^{\mathrm{i}\omega}) = \mathrm{e}^{\mathrm{i}d\omega} R(\mathrm{e}^{\mathrm{i}\omega}) E(\mathrm{e}^{\mathrm{i}\omega}) - I_N.$$

If

$$\varepsilon_{\mathrm{rec}} = \operatorname*{ess\,sup}_{\omega} \|D(\mathrm{e}^{\mathrm{i}\omega})\|_{\mathrm{op}} < \infty,$$

then the delay compensated reconstruction $\tilde{x}$ satisfies

$$\|\widetilde{x} - x\|_2 \le \varepsilon_{\mathrm{rec}} \|x\|_2.$$

The constant is sharp as an operator norm.

Proof. In polyphase Fourier coordinates, the error is $D(\mathrm{e}^{\mathrm{i}\omega})\boldsymbol{X}(\mathrm{e}^{\mathrm{i}\omega})$. Pointwise multiplication and Plancherel's theorem give the upper bound. The operator norm of a measurable matrix multiplier is its essential supremum, which proves sharpness. □

Example E5.3 (A reconstruction certificate)**.** Suppose a two channel bank has delay compensated defect

$$D(\mathrm{e}^{\mathrm{i}\omega}) = \begin{pmatrix} 0.01\cos\omega & 0 \\ 0 & 0.02\sin\omega \end{pmatrix}.$$

Then

$$\operatorname*{ess\,sup}_{\omega} \|D(\mathrm{e}^{\mathrm{i}\omega})\|_{\mathrm{op}} = 0.02.$$

Every input therefore has relative reconstruction error at most two percent in ℓ^2. The estimate is independent of the input length.

Theorem E5.4 (Stability under filter perturbation)**.** *Assume $RE = z^{-d} I_N$. Let*

$$\widetilde{E} = E + \Delta E, \qquad \widetilde{R} = R + \Delta R.$$

Set

$$e_0 = \operatorname{ess\,sup} \|E\|_{\mathrm{op}}, \qquad r_0 = \operatorname{ess\,sup} \|R\|_{\mathrm{op}},$$
$$\delta_E = \operatorname{ess\,sup} \|\Delta E\|_{\mathrm{op}}, \quad \delta_R = \operatorname{ess\,sup} \|\Delta R\|_{\mathrm{op}}.$$

Then the delay compensated reconstruction defect obeys

$$\varepsilon_{\mathrm{rec}} \le r_0\delta_E + e_0\delta_R + \delta_R\delta_E.$$

Proof. Expand

$$\widetilde{R}\widetilde{E} - RE = R\Delta E + \Delta R E + \Delta R \Delta E.$$

Take pointwise operator norms, then the essential supremum. Multiplication by the delay factor has unit modulus. □

Theorem E5.5 (Frame bounds from the polyphase symbol)**.** *Assume that*

$$AI_N \le E(\mathrm{e}^{\mathrm{i}\omega})^* E(\mathrm{e}^{\mathrm{i}\omega}) \le BI_N$$

for almost every ω, where $0 < A \le B < \infty$. Then the analysis bank satisfies

$$A\|x\|_2^2 \le \|\mathcal{A}_E x\|_2^2 \le B\|x\|_2^2.$$

The pointwise matrix

$$R_{\mathrm{can}}(\mathrm{e}^{\mathrm{i}\omega}) = (E^*E)^{-1}E^*$$

is a bounded left inverse and gives the canonical dual synthesis bank.

Proof. Apply the matrix inequality to the polyphase Fourier vector at every frequency and integrate. Plancherel's theorem gives the frame inequalities. The lower bound makes E^*E invertible almost everywhere, and direct multiplication gives $R_{\mathrm{can}}E = I_N$. The same spectral bounds show that the canonical dual is bounded. □

Corollary E5.6 (Coefficient noise under canonical synthesis)**.** *Under the hypotheses of theorem E5.5, suppose the observed coefficient vector is*

$$c = \mathcal{A}_E x + \nu.$$

Canonical synthesis gives

$$\hat{x} = R_{\mathrm{can}} c$$

and

$$\|\hat{x} - x\|_2 \le \frac{1}{\sqrt{A}} \|\nu\|_2.$$

Proof. The smallest singular value of E is at least $\sqrt{A}$, so the pointwise norm of its pseudoinverse is at most $1/\sqrt{A}$. Apply Plancherel's theorem to $R_{\mathrm{can}}\nu$. □

Theorem E5.7 (Perturbation of frame bounds)**.** *Under the hypotheses of theorem E5.5, let $\widetilde{E} = E + \Delta E$ and suppose*

$$\delta = \operatorname*{ess\,sup}_{\omega} \|\Delta E(\mathrm{e}^{\mathrm{i}\omega})\|_{\mathrm{op}} < \sqrt{A}.$$

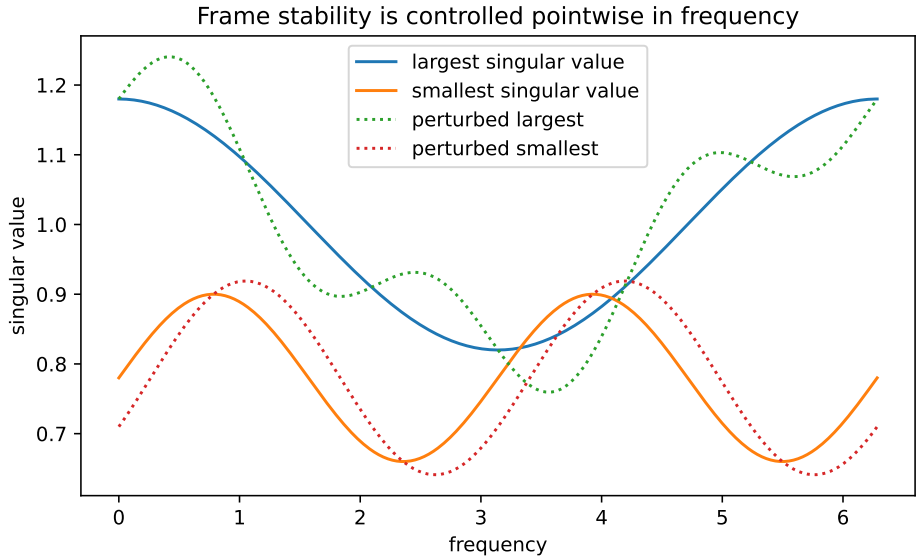

Figure E3. Pointwise singular value bounds govern both the original frame and its perturbed analysis bank.

Then $\widetilde{E}$ is a frame analysis bank with bounds

$$(\sqrt{A}-\delta)^2 \quad \textit{and} \quad (\sqrt{B}+\delta)^2.$$

Proof. For every vector v,

$$\|\widetilde{E}v\| \geq \|Ev\| - \|\Delta Ev\| \geq (\sqrt{A}-\delta)\|v\|.$$

The upper bound follows from

$$\|\widetilde{E}v\| \leq (\sqrt{B}+\delta)\|v\|.$$

Square the inequalities and integrate in frequency. □

Remark E5.8. Even when E is a Laurent polynomial matrix, the canonical dual need not have finite impulse response. Finite support of both analysis and synthesis is an additional algebraic condition.

Corollary E5.9 (Paraunitary bank)**.** *If $E(z)^*E(z) = I_N$ on the unit circle, then analysis is an isometry and synthesis may be chosen as $R(z) = E(z)^*$.*

Proof. Use theorem E5.5 with $A = B = 1$, then multiply the matrices. □

E5.1 Haar analysis

The Haar matrix is

$$E_H = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

For even and odd samples $e(n) = x(2n)$ and $o(n) = x(2n+1)$, the low and high coordinates are

$$a(n) = \frac{e(n)+o(n)}{\sqrt{2}}, \qquad d(n) = \frac{e(n)-o(n)}{\sqrt{2}}.$$

Corollary E5.10 (Haar reconstruction and energy)**.** *The Haar bank reconstructs exactly and*

$$\|x\|_2^2 = \|a\|_2^2 + \|d\|_2^2.$$

Proof. The matrix E_H is unitary. □

E5.2 Lifting steps

Let $P(z)$ and $Q(z)$ be Laurent polynomials. Define

$$L_P(z) = \begin{pmatrix} 1 & 0 \\ P(z) & 1 \end{pmatrix}, \qquad U_Q(z) = \begin{pmatrix} 1 & Q(z) \\ 0 & 1 \end{pmatrix}.$$

Theorem E5.11 (Exact lifting update)**.** *The lifting matrices are invertible with*

$$L_P^{-1} = L_{-P}, \qquad U_Q^{-1} = U_{-Q}.$$

If $R_0E_0 = I$, then every finite product V of lifting matrices gives another exact bank by

$$E = VE_0, \qquad R = R_0V^{-1}.$$

Every lifting step has determinant one.

Proof. Direct multiplication proves the inverse formulas and the determinant statement. The reconstructed product is

$$RE = R_0V^{-1}VE_0 = R_0E_0 = I.$$

□

Example E5.12 (A two neighbor predict and update transform)**.** Split a sequence into even and odd samples. Define

$$d(n) = o(n) - \frac{e(n) + e(n+1)}{2}$$

and

$$s(n) = e(n) + \frac{d(n-1) + d(n)}{4}.$$

The inverse is obtained in reverse order:

$$e(n) = s(n) - \frac{d(n-1) + d(n)}{4},$$

then

$$o(n) = d(n) + \frac{e(n) + e(n+1)}{2}.$$

Thus reconstruction is exact over every coefficient field in which two is invertible. This is a standard compactly supported biorthogonal lifting pattern [CDF92, Swe96, DS98].

E6 Wavelet packet trees and admissible bases

A packet transform is built by deciding at each node whether to retain the current coordinate space or to split it into children. The proof of reconstruction is local and does not depend on a particular wavelet family.

Definition E6.1 (Unitary packet tree)**.** A finite unitary packet tree consists of Hilbert spaces $\mathcal{H}_v$ at its vertices and, at every internal vertex v, a unitary map

$$U_v : \mathcal{H}_v \longrightarrow \bigoplus_{w \in \mathrm{child}(v)} \mathcal{H}_w.$$

An admissible pruning is a set of vertices that meets every root to terminal path exactly once.

Theorem E6.2 (Reconstruction on a pruned packet tree)**.** *Every admissible pruning $\mathcal{L}$ defines a unitary analysis map*

$$\mathcal{A}_{\mathcal{L}} : \mathcal{H}_{\mathrm{root}} \longrightarrow \bigoplus_{v \in \mathcal{L}} \mathcal{H}_v.$$

Its inverse is obtained by applying the adjoints of the local splits from the leaves toward the root. In particular,

$$\|x\|^2 = \sum_{v \in \mathcal{L}} \|x_v\|^2.$$

Proof. Proceed by induction on the depth of the retained subtree. If the root is retained, the statement is immediate. If the root is split, apply the unitary map U_{root}, then apply the induction hypothesis independently in each child subtree. A direct sum of unitary maps is unitary. Reversing the maps with adjoints gives synthesis. □

Corollary E6.3 (Coefficient perturbations in a unitary tree)**.** *Let $c = \mathcal{A}_{\mathcal{L}} x$ be the leaf coefficients of an admissible unitary pruning, and let $\hat{c} = c + e$. If $\hat{x}$ is synthesized from $\hat{c}$, then*

$$\|\hat{x} - x\| = \|e\|.$$

Thus coefficient quantization and coefficient noise are neither amplified nor attenuated by exact unitary synthesis.

Proof. The synthesis map is unitary by theorem E6.2. Hence

$$\hat{x} - x = \mathcal{A}_{\mathcal{L}}^{-1} e$$

has the same norm as e. □

Proposition E6.4 (Bounds for nonunitary local splits)**.** *Suppose every internal node has an analysis map U_v and constants $0 \le A_v \le B_v < \infty$ satisfying*

$$A_v \|x\|^2 \le \sum_{w \in \mathrm{child}(v)} \|(U_v x)_w\|^2 \le B_v \|x\|^2.$$

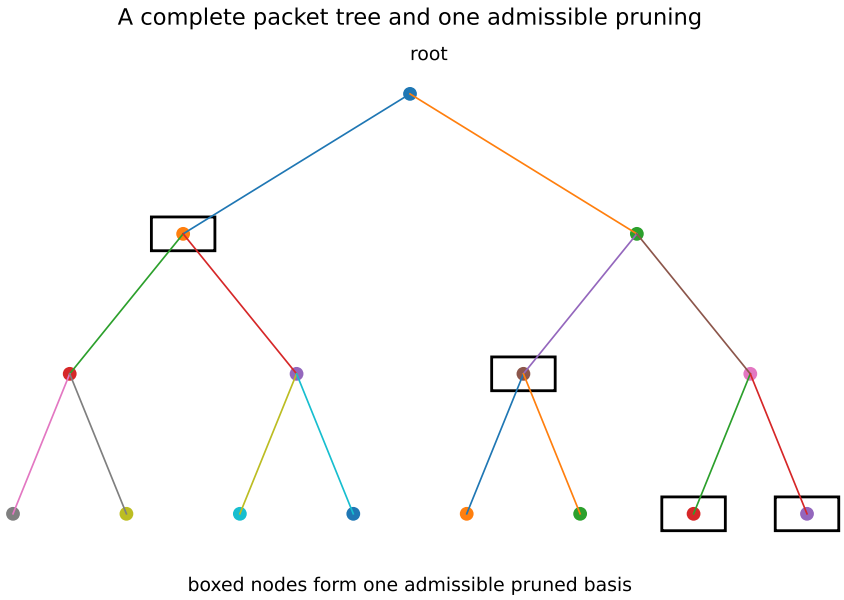

Figure E4. A complete packet tree and one admissible pruning. Retained nodes may occur at different depths.

Define recursively

$$a(v) = \begin{cases} 1, & v \text{ retained}, \\ A_v \min_w a(w), & v \text{ split}, \end{cases}$$

and

$$b(v) = \begin{cases} 1, & v \text{ retained}, \\ B_v \max_w b(w), & v \text{ split}. \end{cases}$$

Then the leaf analysis of the pruned tree has bounds $a(\mathrm{root})$ *and* $b(\mathrm{root})$.

Proof. Assume the child subtree bounds have been proved. Then

$$\sum_w \sum_{\ell \in \mathcal{L}_w} \|x_\ell\|^2 \geq \min_w a(w) \sum_w \|(U_v x)_w\|^2 \geq A_v \min_w a(w) \|x\|^2.$$

The upper bound follows in the same way with the maximum and B_v. Induction completes the proof. □

E6.1 Best basis recursion

> **The minimum is taken over feasible prunings**
>
> The value at a node is the least cost among all admissible prunings of the subtree rooted there. It is one optimal value. Individual competing prunings may have larger costs. The recursion compares retaining the node with the sum of the already optimal child values, with retention chosen on a tie.

Assign a real cost $c(v)$ to retaining each node. For an admissible pruning $\mathcal{L}$, let

$$C(\mathcal{L}) = \sum_{v \in \mathcal{L}} c(v).$$

The cost may measure entropy, coefficient count, an approximation penalty, or any other additive local objective.

Theorem E6.5 (Exact additive best basis recursion)**.** *For each vertex define*

$$F(v) = \min \left\{ c(v), \sum_{w \in \text{child}(v)} F(w) \right\},$$

with $F(v) = c(v)$ at terminal vertices. Then $F(v)$ is the minimum cost among all admissible prunings of the subtree rooted at v. A minimizing pruning is recovered by retaining v when the first term is no larger than the second and splitting it otherwise.

Proof. Every admissible pruning of the subtree has exactly two forms. It either retains v, with cost $c(v)$, or splits v and independently chooses an admissible pruning in every child subtree. The minimum in the second case is the sum of the child minima. This gives the recursion and the reconstruction rule. In an equality case both choices minimize, and the stated rule retains the node. □

Theorem E6.6 (Stability of the optimal cost)**.** *Let c and $\tilde{c}$ be two node cost functions. For an admissible pruning $\mathcal{L}$, set*

$$\varepsilon(\mathcal{L}) = \sum_{v \in \mathcal{L}} |c(v) - \tilde{c}(v)|$$

and let

$$\varepsilon_* = \max_{\mathcal{L}} \varepsilon(\mathcal{L}).$$

If F_* and $\widetilde{F}_*$ are the two optimal root costs, then

$$|F_* - \widetilde{F}_*| \le \varepsilon_*.$$

Proof. For every admissible pruning,

$$|C(\mathcal{L}) - \widetilde{C}(\mathcal{L})| \le \varepsilon_*.$$

Evaluate $\widetilde{C}$ on a minimizer for C to obtain $\widetilde{F}_* \le F_* + \varepsilon_*$. Reverse the roles to obtain $F_* \le \widetilde{F}_* + \varepsilon_*$. □

Corollary E6.7 (Stability of the selected basis)**.** *Assume the optimal pruning $\mathcal{L}_*$ for c is unique and at least one competing pruning exists. Define $g = \min_{\mathcal{L} \ne \mathcal{L}_*} (C(\mathcal{L}) - C(\mathcal{L}_*)) > 0$. If*

$$2\varepsilon_* < g,$$

then the optimal pruning for $\tilde{c}$ is the same. If only one admissible pruning exists, it remains selected under every cost change without a gap condition.

Proof. The cost of the original minimizer can increase by at most ε_*, while the cost of every competitor can decrease by at most ε_*. The original gap therefore remains positive. □

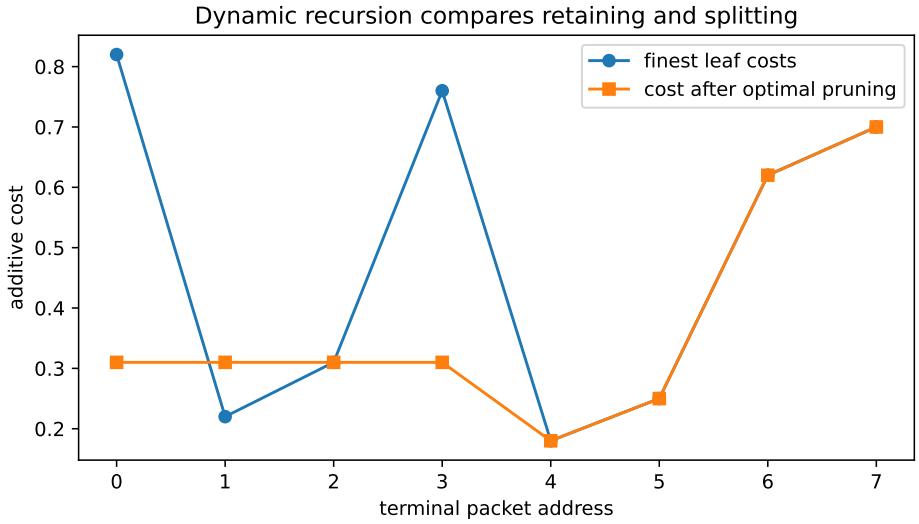

Figure E5. An additive best basis recursion compares the cost of retaining a packet with the total cost of splitting it.

E7 Singular packets and exact reconstruction

Trace data identify the singular part

A value jump needs a step packet. A jump in a derivative needs a truncated power of the corresponding order. Subtracting these finite packets matches the one-sided traces and leaves the regular remainder covered by the theorem's Sobolev assumptions. The packet construction and the approximation operator play separate roles.

A packet decomposition becomes useful for approximation when it separates a component that should be retained from a component that should be compressed. The simplest singular packets are steps. Higher order packets record jumps in derivatives.

For $m \geq 0$ and $0 < \tau < 1$, define

$$\phi_{m,\tau}(t) = \frac{(t-\tau)_+^m}{m!}.$$

Thus $\phi_{0,\tau} = \mathbf{1}_{[\tau,1]}$. On each side of τ, the packet is a polynomial. Its derivative of order m has a unit jump at τ.

Definition E7.1 (Sobolev step packet class)**.** Fix $r \geq 1$, $1 \leq p \leq \infty$, and an integer $Q \geq 0$. The class $\mathcal{F}_{r,p}(Q)$ consists of functions

$$f = s + \sum_{q=1}^{Q} a_q \phi_{0,\tau_q}$$

with $s \in W^{r,p}(0,1)$ and

$$0 < \tau_1 < \cdots < \tau_Q < 1.$$

No lower bound on the jump amplitudes is required for representation. Recovery results later impose such a bound.

Theorem E7.2 (Higher order singular packet decomposition). *Let*

$$0 = \tau_0 < \tau_1 < \cdots < \tau_Q < \tau_{Q+1} = 1.$$

Suppose the restriction of f to every interval (τ_q, τ_{q+1}) belongs to $W^{r,p}$, and choose the one-dimensional Sobolev representatives whose derivatives through order $r-1$ have one-sided traces at the endpoints. Define

$$a_{q,m} = \left[f^{(m)}\right]_{\tau_q} = f^{(m)}(\tau_q+) - f^{(m)}(\tau_q-)$$

and

$$j_f(t) = \sum_{q=1}^{Q} \sum_{m=0}^{r-1} a_{q,m} \phi_{m,\tau_q}(t).$$

Then

$$s_f = f - j_f$$

has matching one-sided derivatives through order $r-1$ at every breakpoint and belongs to $W^{r,p}(0,1)$. Its weak derivative of order r equals the piecewise classical derivative $f^{(r)}$ almost everywhere.

Proof. For $0 \le \ell \le m$, the classical derivative of $\phi_{m,\tau}$ on the two open sides is

$$\phi_{m,\tau}^{(\ell)}(t) = \frac{(t-\tau)_+^{m-\ell}}{(m-\ell)!}.$$

This derivative has zero jump when $\ell < m$ and a unit jump when $\ell = m$. Derivatives of order larger than m vanish on both open sides. It follows that subtracting the term $a_{q,m}\phi_{m,\tau_q}$ removes exactly the jump in the derivative of order m without changing the other classical trace jumps. Hence s_f has matching traces through order $r-1$.

On each partition interval, j_f is a polynomial of degree at most $r-1$, so its weak derivative of order r is zero there. A piecewise $W^{r,p}$ function whose traces through order $r-1$ match across every breakpoint belongs to $W^{r,p}(0,1)$. Repeated integration by parts on the partition intervals shows that all boundary terms cancel. Thus the weak derivative of order r is the piecewise weak derivative of f. □

Corollary E7.3 (Uniqueness of the trace packet). *Fix the breakpoints τ_q. If*

$$f = s + \sum_{q=1}^{Q} \sum_{m=0}^{r-1} b_{q,m} \phi_{m,\tau_q}$$

with $s \in W^{r,p}(0,1)$, then

$$b_{q,m} = \left[f^{(m)}\right]_{\tau_q}.$$

The finite truncated power packet is therefore the unique packet supported at the declared breakpoints that removes all trace jumps through order $r-1$.

Proof. Every representative in $W^{r,p}(0,1)$ has derivatives through order $r-1$ that admit absolutely continuous representatives on compact subintervals, with matching one-sided traces at each interior point. Taking the jump of the derivative of order m therefore removes the contribution of s. The packet ϕ_{m,τ_q}

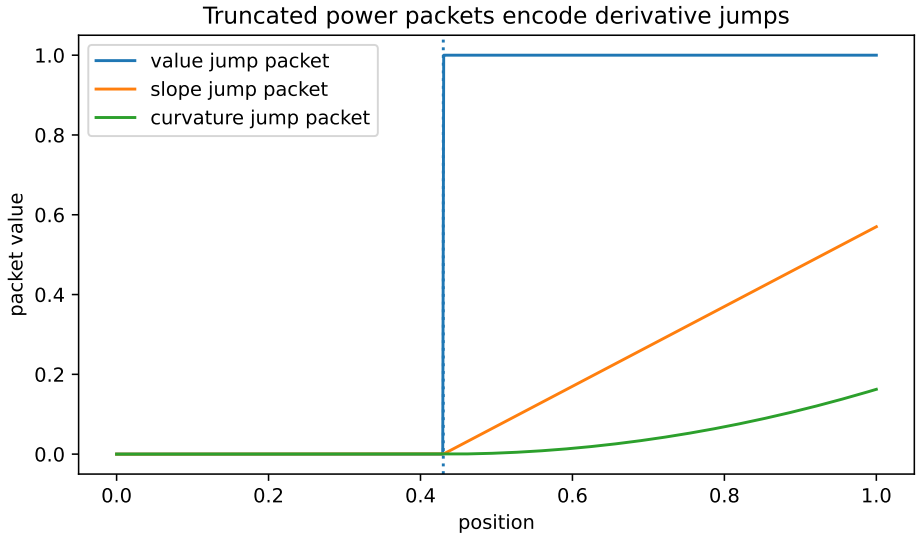

Figure E6. Truncated power packets encode jumps in a function and in its successive derivatives.

has unit jump in its derivative of order m, while all other declared packets have zero jump at that derivative order and breakpoint. Hence the remaining jump is exactly $b_{q,m}$. □

Remark E7.4. The theorem isolates only finitely many trace jumps. More general free discontinuity models may contain jump sets, Cantor parts, or singular derivatives that are not represented by a finite truncated power sum. The natural ambient theory is related to bounded variation and free discontinuity spaces [AFP00].

Let X be a normed linear space and let $Q : X \to X$ be bounded and linear. The next identity is elementary, but it is the central separation principle.

Theorem E7.5 (Exact retained packet identity). *Let $f = s + j$ in X. Define*

$$\tilde{f} = Qs + j.$$

Then

$$\boxed{f - \tilde{f} = (I - Q)s.}$$

Consequently,

$$\|f - \tilde{f}\| = \|s - Qs\|.$$

Proof. Subtract:

$$f - \tilde{f} = s + j - Qs - j = (I - Q)s.$$

□

Remark E7.6. The theorem assumes that the packet j is known. It does not supply a detector. It also does not say that every representation of f as $s + j$ is useful. Once a meaningful packet has been identified, its approximation error can be removed from the smooth approximation problem exactly.

Corollary E7.7 (Sobolev rate after packet separation). *Suppose Q_m satisfies*

$$\|s - Q_m s\|_{L^p} \le C 2^{-mr} \|s\|_{W^{r,p}}$$

for every $s \in W^{r,p}(0,1)$. If $f = s + j$ and j is retained, then

$$\|f - (Q_m s + j)\|_{L^p} \le C 2^{-mr} \|s\|_{W^{r,p}}.$$

The same conclusion applies to the higher order decomposition in theorem E7.2.

Proof. Use theorem E7.5 and the assumed approximation estimate. □

Theorem E7.8 (Reconstruction with an estimated packet). *Let $Q_m : X \to X$ be linear, let $f = s + j$, let $\hat{j}$ be an estimated packet, and define*

$$\hat{f}_m = Q_m(f - \hat{j}) + \hat{j}.$$

Then

$$\boxed{f - \hat{f}_m = (I - Q_m)s + (I - Q_m)(j - \hat{j}).}$$

If Q_m is bounded, then

$$\|f - \hat{f}_m\| \le \|s - Q_m s\| + (1 + \|Q_m\|)\|j - \hat{j}\|.$$

Proof. Since $f - \hat{j} = s + (j - \hat{j})$,

$$\hat{f}_m = Q_m s + Q_m(j - \hat{j}) + \hat{j}.$$

Subtract this expression from $s + j$. The norm bound follows from

$$\|(I - Q_m)u\| \le (1 + \|Q_m\|)\|u\|.$$

□

E8 Exact error formulas for estimated packets

The error of an estimated packet is often described by a segmentation score. For approximation, an exact norm formula is more useful because it separates value errors from geometric disagreement.

Theorem E8.1 (Exact scalar region formula). *Let E, F be measurable subsets of a measure space, let $a, b \in \mathbb{C}$, and let $1 \le p < \infty$. Then*

$$\|a\mathbf{1}_E - b\mathbf{1}_F\|_p^p = |a-b|^p \mu(E \cap F) + |a|^p \mu(E \setminus F) + |b|^p \mu(F \setminus E).$$

For equal amplitudes,

$$\|a\mathbf{1}_E - a\mathbf{1}_F\|_p = |a| \mu(E \triangle F)^{1/p}.$$

Proof. The sets $E \cap F$, $E \setminus F$, and $F \setminus E$ are disjoint. The difference takes the values $a - b$, a, and $-b$ on these three sets and is zero elsewhere. Integrating its pth power gives the formula. □

Corollary E8.2 (Location error for one step). *Let $0 \le \tau, \hat{\tau} \le 1$ and $H_\tau = \mathbf{1}_{[\tau,1]}$. For $1 \le p < \infty$,*

$$\|aH_\tau - aH_{\hat{\tau}}\|_p = |a| |\tau - \hat{\tau}|^{1/p}.$$

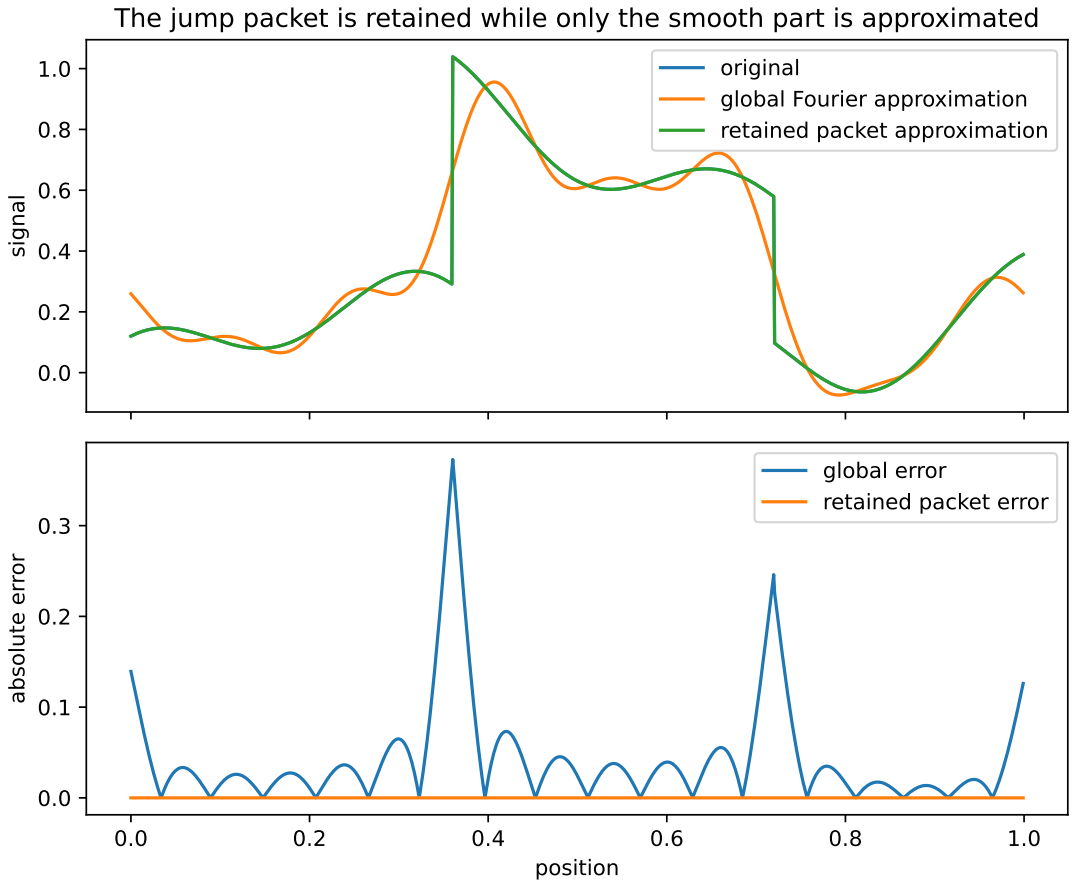

Figure E7. A global Fourier approximation must represent the jumps. A retained packet approximation applies the Fourier truncation only to the smooth component.

In the supremum norm, the error equals $|a|$ whenever $\tau \neq \hat{\tau}$.

Proof. The symmetric difference of the two intervals has length $|\tau - \hat{\tau}|$. The supremum statement follows because the two steps differ by a on a nonempty interval. □

Theorem E8.3 (Location stability for higher order packets). *Let $m \geq 1$, $1 \leq p < \infty$, and $0 \leq \tau, \hat{\tau} \leq 1$. Then*

$$\|\phi_{m,\tau} - \phi_{m,\hat{\tau}}\|_{L^p(0,1)} \leq \frac{|\tau - \hat{\tau}|}{(m-1)!((m-1)p+1)^{1/p}}.$$

For $p = \infty$,

$$\|\phi_{m,\tau} - \phi_{m,\hat{\tau}}\|_{\infty} \leq \frac{|\tau - \hat{\tau}|}{(m-1)!}.$$

Thus location error is Lipschitz for every derivative jump packet of positive order, while a value jump has only the finite L^p modulus in corollary E8.2.

Proof. Assume $\tau < \hat{\tau}$. Differentiation with respect to the location parameter gives

$$\frac{\partial}{\partial u}\phi_{m,u}(t) = -\phi_{m-1,u}(t)$$

for almost every t. Hence

$$\phi_{m,\tau} - \phi_{m,\hat{\tau}} = \int_{\tau}^{\hat{\tau}} \phi_{m-1,u}\,\mathrm{d}u.$$

Minkowski's inequality gives

$$\|\phi_{m,\tau} - \phi_{m,\hat{\tau}}\|_p \leq |\tau - \hat{\tau}| \sup_u \|\phi_{m-1,u}\|_p.$$

The supremum is bounded by the norm of $t^{m-1}/(m-1)!$ on $[0,1]$, which is the stated constant. The supremum norm argument is identical. □

E8.1 Several regions

Let $(E_i)_{i=0}^{I}$ and $(F_j)_{j=0}^{J}$ be measurable partitions of the same domain, up to null sets. Let a_i and b_j be the corresponding values. The index zero may be used for a background region.

Theorem E8.4 (Overlap matrix formula). *Define*

$$M_{ij} = \mu(E_i \cap F_j).$$

For $1 \leq p < \infty$,

$$\left\| \sum_{i=0}^{I} a_i \mathbf{1}_{E_i} - \sum_{j=0}^{J} b_j \mathbf{1}_{F_j} \right\|_p^p = \sum_{i=0}^{I} \sum_{j=0}^{J} |a_i - b_j|^p M_{ij}.$$

The row sums of M are $\mu(E_i)$, and the column sums are $\mu(F_j)$.

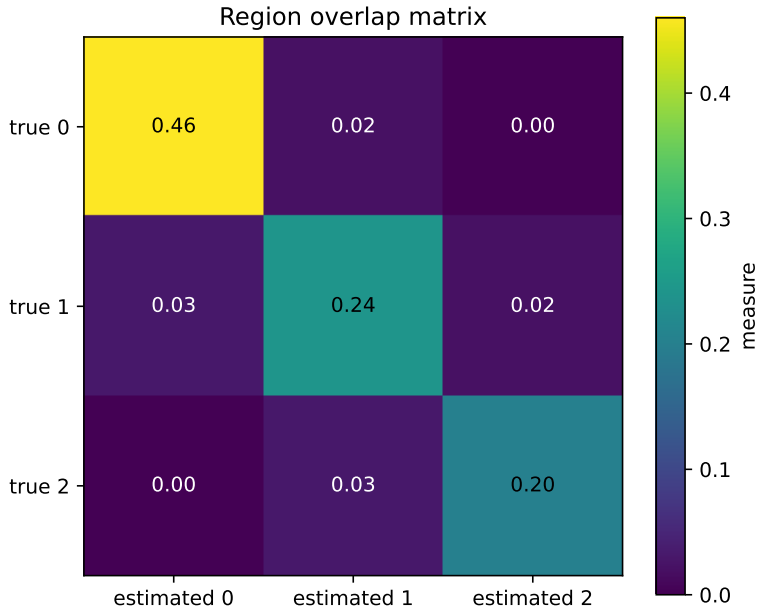

Figure E8. An overlap matrix records both correct regions and every type of misclassification. The exact packet norm weights each entry by the corresponding value difference.

Proof. The intersections $E_i \cap F_j$ form a measurable partition. On such an intersection, the two piecewise constant functions have values a_i and b_j. Integrate the constant error over every intersection. The marginal identities follow by summing the partition pieces in a fixed row or column. □

Corollary E8.5 (Background and packet error)**.** *Suppose the true and estimated packets use the same amplitude list $(a_i)_{i=0}^{I}$, but possibly different regions. Then*

$$\|j - \hat{j}\|_p^p = \sum_{i,k} |a_i - a_k|^p \mu(E_i \cap F_k).$$

Only off-diagonal overlaps contribute.

Proof. Apply theorem E8.4 with $b_k = a_k$. The diagonal terms vanish. □

E8.2 Boundary tube control

For a closed set Γ, write

$$N_\delta(\Gamma) = \{x : \operatorname{dist}(x, \Gamma) < \delta\}.$$

Definition E8.6 (Linear tube bound)**.** A boundary Γ has a linear tube bound if there are constants C_Γ and $\delta_0 > 0$ such that

$$\mu(N_\delta(\Gamma)) \le C_\Gamma \delta$$

for $0 < \delta < \delta_0$.

Bounded Lipschitz domains and many finite perimeter sets have estimates of this form, with constants controlled by geometric size. The next theorem only requires the displayed bound.

Theorem E8.7 (Geometric packet bound)**.** *Let E be a region with boundary Γ, and suppose*

$$E \triangle F \subseteq N_\delta(\Gamma).$$

If Γ has a linear tube bound and $0 < \delta < \delta_0$ lies in its stated range, then for $1 \le p < \infty$,

$$\|a\mathbf{1}_E - a\mathbf{1}_F\|_p \le |a|(C_\Gamma \delta)^{1/p}.$$

If amplitudes a and b differ, then

$$\|a\mathbf{1}_E - b\mathbf{1}_F\|_p \le |a-b|\mu(E \cap F)^{1/p} + (|a| + |b|)(C_\Gamma \delta)^{1/p}.$$

Proof. The equal amplitude case follows from theorem E8.1 and the tube inclusion. For unequal amplitudes, split the error into its value mismatch on $E \cap F$ and the two disagreement pieces. Apply the triangle inequality and the same tube estimate. □

Example E8.8 (A perturbed disk)**.** Let E and F be concentric disks of radii r and $r+\delta$ in $\mathbb{R}^2$, with $\delta > 0$. Then

$$\mu(E \triangle F) = \pi\big((r+\delta)^2 - r^2\big) = 2\pi r\delta + \pi\delta^2.$$

For equal amplitude a, the exact L^2 packet error is

$$|a|\sqrt{2\pi r\delta + \pi\delta^2}.$$

This gives the expected square root dependence on boundary displacement.

E9 Stable recovery of separated jumps

The detector needs a visible interval of thresholds

A smooth cell and bounded sample noise give one upper contrast bound. A jump cell gives a lower contrast bound after the same uncertainty is subtracted. Recovery is possible when the lower jump bound exceeds the upper smooth bound. The gap is a condition on the observation model, rather than an automatic consequence of packet coordinates.

The previous sections describe the error after a packet has been estimated. We now give a direct recovery theorem for one-dimensional separated jumps. The detector is intentionally simple because the aim is to expose the exact contrast gap.

Let

$$t_k = kh, \qquad k = 0, \dots, n, \qquad h = \frac{1}{n}.$$

Assume

$$f(t) = s(t) + \sum_{q=1}^{Q} a_q H_{\tau_q}(t), \qquad H_\tau(t) = \mathbf{1}_{[\tau,1]}(t),$$

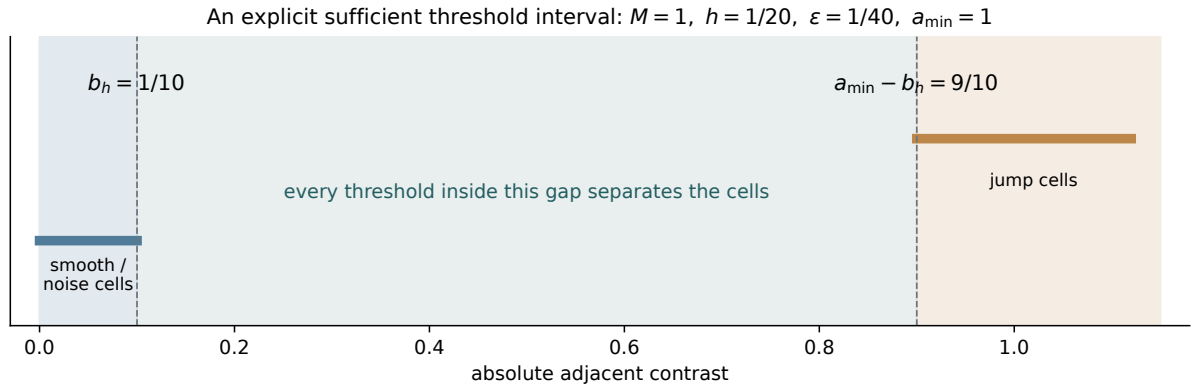

Figure E9. A sufficient threshold interval from exact rational contrast bounds. With the displayed model parameters, smooth and noise contrasts are at most $1/10$ and jump contrasts are at least $9/10$. Every threshold strictly between those values separates the cells under the sampling assumptions stated below. The figure does not assert an optimal threshold for other observation models.

where s is Lipschitz with constant M, and $Q \geq 1$ is finite with nonzero jump amplitudes. The zero-jump case requires no minimum-amplitude condition. Suppose no jump lies at a sample point and no grid cell contains more than one jump. Observe

$$y_k = f(t_k) + \eta_k.$$

Define the adjacent contrast

$$D_k = y_{k+1} - y_k.$$

Lemma E9.1 (Contrast gap)**.** *Assume* $|\eta_k| \leq \varepsilon$ *and set*

$$b_h = Mh + 2\varepsilon.$$

If the cell (t_k, t_{k+1}) *contains no jump, then*

$$|D_k| \leq b_h.$$

If it contains one jump of amplitude a_q*, then*

$$|D_k - a_q| \leq b_h$$

and therefore

$$|D_k| \geq |a_q| - b_h.$$

Proof. In a cell without a jump,

$$D_k = s(t_{k+1}) - s(t_k) + \eta_{k+1} - \eta_k.$$

The Lipschitz and noise bounds give $|D_k| \leq Mh + 2\varepsilon$. In a cell with one jump, the same formula has the additional term a_q, which proves the second estimate. □

Theorem E9.2 (Deterministic jump cell recovery)**.** *Let*

$$a_{\min} = \min_q |a_q|$$

and assume

$$a_{\min} > 2b_h.$$

Choose a threshold θ satisfying

$$b_h < \theta < a_{\min} - b_h.$$

Then

$$\widehat{\mathcal{K}} = \{k : |D_k| > \theta\}$$

is exactly the set of grid cells containing jumps. If $\hat{\tau}_q$ is the midpoint of the detected cell and $\hat{a}_q = D_k$, then after matching by order,

$$|\hat{\tau}_q - \tau_q| \le \frac{h}{2}$$

and

$$|\hat{a}_q - a_q| \le b_h.$$

Proof. By lemma E9.1, every cell without a jump has contrast at most $b_h < \theta$. Every cell with a jump has contrast at least $a_{\min} - b_h > \theta$. Hence the detected set is exact. The midpoint of a cell is within $h/2$ of every point in that cell. The amplitude estimate is the second inequality in lemma E9.1. □

Corollary E9.3 (Jump count and sign recovery)**.** *Under the hypotheses of theorem E9.2, the number of detected cells equals Q, and*

$$\operatorname{sgn}(\hat{a}_q) = \operatorname{sgn}(a_q)$$

for every real valued jump.

Proof. Exact cell recovery gives the jump count. Since

$$|\hat{a}_q - a_q| \le b_h < |a_q|,$$

the amplitude estimate cannot cross zero. □

Corollary E9.4 (Packet reconstruction after detection)**.** *Let*

$$j = \sum_{q=1}^{Q} a_q H_{\tau_q}, \qquad \hat{j} = \sum_{q=1}^{Q} \hat{a}_q H_{\hat{\tau}_q}.$$

Under the hypotheses of theorem E9.2, for $1 \le p < \infty$,

$$\|j - \hat{j}\|_p \le Q b_h + \left(\frac{h}{2} \sum_{q=1}^{Q} |a_q|^p \right)^{1/p}.$$

If Q_m is bounded and linear and

$$\hat{f}_m = Q_m(f - \hat{j}) + \hat{j},$$

then

$$\|f-\hat{f}_m\|_p \le \|s-Q_m s\|_p + (1+\|Q_m\|)\left[Qb_h+\left(\frac{h}{2}\sum_q |a_q|^p\right)^{1/p}\right].$$

Proof. Write

$$j-\hat{j}=\sum_q (a_q-\hat{a}_q)H_{\hat{\tau}_q}+\sum_q a_q(H_{\tau_q}-H_{\hat{\tau}_q}).$$

The first sum has norm at most $\sum_q |a_q-\hat{a}_q| \le Qb_h$. The location error interval for the qth jump is contained in its detected grid cell and has length at most $h/2$. Distinct detected cells are disjoint, so the location errors have disjoint supports. Their pth powers therefore add exactly, which gives the displayed location term. The reconstruction estimate follows from theorem E7.8. □

Remark E9.5 (Why finite L^p matters). A shifted step does not converge in the supremum norm until the location is exact. The finite L^p error does converge because the disagreement is confined to an interval whose length tends to zero.

Corollary E9.6 (Deterministic consistency)**.** *Assume $h \to 0$ along grids satisfying the preceding sampling assumptions, $\varepsilon_h \to 0$, the number of jumps is fixed, and the nonzero jump amplitudes and positive minimum separation remain fixed. Then the detected packet converges to the true packet in every finite L^p norm. If Q_m has a vanishing smooth approximation error and uniformly bounded norm, the complete reconstruction also converges in L^p.*

Proof. The gap condition holds for sufficiently small h. Then $b_h \to 0$, and the bound in corollary E9.4 tends to zero. □

Example E9.7 (A numerical threshold certificate)**.** Take $h=1/256$, $M=0.5$, and $\varepsilon=0.002$. Then

$$b_h=\frac{0.5}{256}+0.004<0.00596.$$

If every jump has magnitude at least 0.08, then $0.08>2b_h$. Any threshold between 0.00596 and 0.07404 recovers the exact jump cells. The location error is at most

$$\frac{1}{512}$$

and every amplitude error is less than 0.00596.

E9.1 Sub-Gaussian noise

Assume the noise variables are independent, centered, and σ sub-Gaussian:

$$\mathbb{E}\mathrm{e}^{\lambda\eta_k} \le \mathrm{e}^{\sigma^2\lambda^2/2}.$$

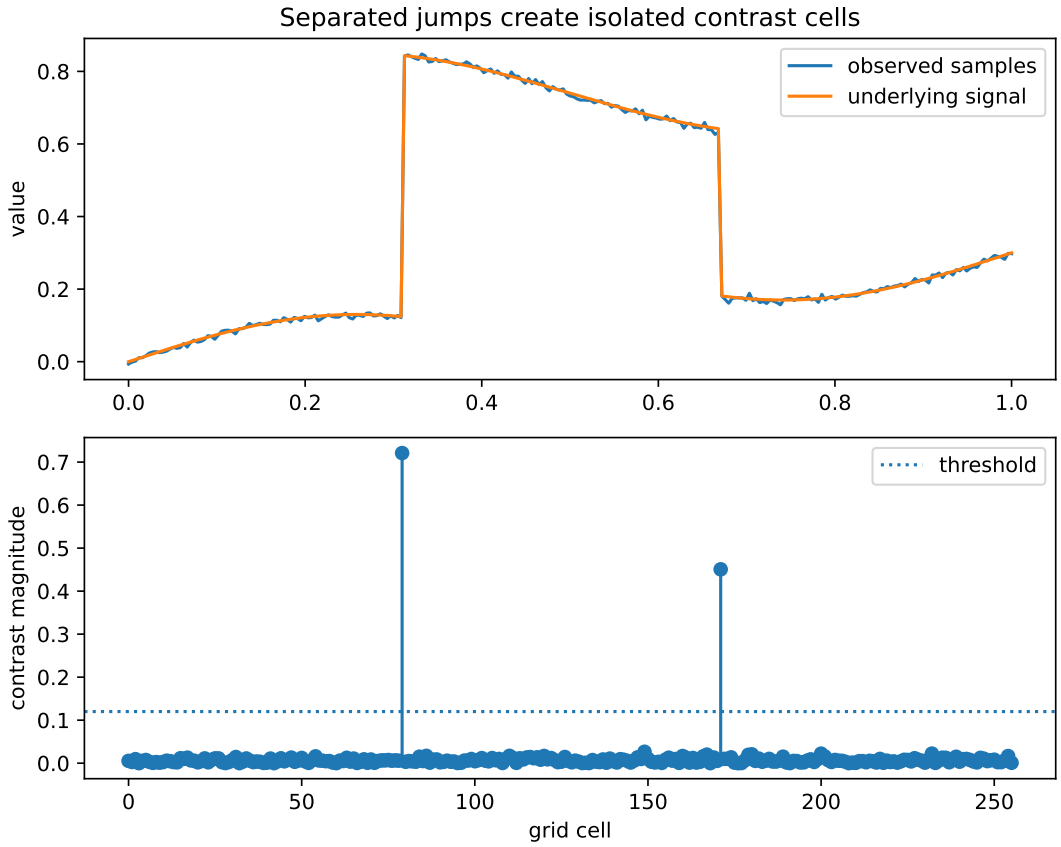

Figure E10. Separated jumps create isolated adjacent sample contrasts above the smooth and noise background.

Theorem E9.8 (Probability recovery bound)**.** *Fix $0 < \delta < 1$ and define*

$$t_{n,\delta} = 2\sigma\sqrt{\log\left(\frac{2n}{\delta}\right)}$$

and

$$b_{h,\delta} = Mh + t_{n,\delta}.$$

With probability at least $1 - \delta$, every contrast satisfies the conclusions of lemma E9.1 with b_h replaced by $b_{h,\delta}$.
If

$$a_{\min} > 2b_{h,\delta},$$

then thresholding between $b_{h,\delta}$ and $a_{\min} - b_{h,\delta}$ recovers every jump cell with probability at least $1 - \delta$. The same location and amplitude bounds hold with $b_{h,\delta}$.

Proof. If $\sigma = 0$, every centered zero-sub-Gaussian noise variable vanishes almost surely, and the noise-free deterministic conclusion applies. For $\sigma > 0$, the difference $\eta_{k+1} - \eta_k$ is sub-Gaussian with variance proxy $2\sigma^2$, so

$$\mathbb{P}(|\eta_{k+1} - \eta_k| > t) \le 2\exp\left(-\frac{t^2}{4\sigma^2}\right).$$

A union bound over the n cells gives

$$\mathbb{P}\left(\max_k |\eta_{k+1} - \eta_k| > t_{n,\delta}\right) \le \delta.$$

On the complementary event, repeat the deterministic proof. □

Corollary E9.9 (Repeated measurements)**.** *Suppose R observations are averaged at every sample location, with all noise variables independent across sites and repetitions and each centered and σ sub-Gaussian. Then theorem E9.8 holds with σ replaced by $\sigma/\sqrt{R}$. In particular, a sufficient recovery condition is*

$$a_{\min} > 2Mh + \frac{4\sigma}{\sqrt{R}}\sqrt{\log\left(\frac{2n}{\delta}\right)}.$$

Proof. The average of R independent σ sub-Gaussian variables is $\sigma/\sqrt{R}$ sub-Gaussian. Substitute this parameter in theorem E9.8. □

Remark E9.10. The displayed uniform noise certificate scales as $\sigma\sqrt{\log n}$. At fixed positive σ, it does not imply consistency of this detector. Decreasing the noise scale or averaging repeated measurements gives sufficient regimes. Other averaging schemes require their own analysis.

Corollary E9.11 (Probability consistency)**.** *Let $\sigma_n\sqrt{\log n} \to 0$ and $h = 1/n$. For every fixed $0 < \delta < 1$, along grids satisfying the preceding sampling assumptions, all jump cells are recovered with probability at least $1 - \delta$ for sufficiently large n. For the fixed finite jump model above, along grids satisfying the preceding sampling assumptions, the packet error converges to zero in probability in every finite L^p norm.*

Proof. For each fixed $\delta > 0$, $b_{h,\delta} \to 0$. Apply theorem E9.8 and corollary E9.4. For any error tolerance $\epsilon > 0$, the high-probability bound is eventually smaller than ϵ, so the limit superior of the probability that the packet error exceeds ϵ is at most δ. Since δ is arbitrary, convergence is in probability. □

E9.2 Signals with values in a normed space

The recovery proof does not depend on an ordering of the signal values.

Proposition E9.12 (Vector jump recovery). *Let the values lie in a normed space V. Assume*

$$\|s(t) - s(u)\|_V \le M|t-u|, \qquad \|\eta_k\|_V \le \varepsilon,$$

and let the jump vectors satisfy $\|a_q\|_V \ge a_{\min}$. Thresholding $\|D_k\|_V$ gives the same recovery theorem under the condition

$$a_{\min} > 2(Mh + 2\varepsilon).$$

Proof. Only the triangle inequality was used in lemma E9.1 and theorem E9.2. □

E10 Haar localization and annihilating differences

The adjacent difference detector is local in the sample domain. Wavelet coefficients and higher differences give related multiscale packets. In the Haar subsections the signal is defined on $\mathbb{R}$. Here the step convention is $H_\tau(t) = \mathbf{1}_{[\tau,\infty)}(t)$, whose restriction to $(0,1)$ agrees with the preceding interval step. A chosen extension beyond the observation interval must use this half-line step convention, and the smooth extension must satisfy the stated Lipschitz hypothesis on every displayed wavelet support.

E10.1 Haar coefficient separation

Let

$$I_{j,k} = [k2^{-j}, (k+1)2^{-j})$$

and let $\psi_{j,k}$ be the normalized Haar wavelet supported on $I_{j,k}$, positive on the left half and negative on the right half.

Theorem E10.1 (Smooth Haar coefficient bound). *If s is Lipschitz with constant M, then*

$$|\langle s, \psi_{j,k}\rangle| \le \frac{M}{4}\, 2^{-3j/2}.$$

Proof. Let $L = 2^{-j}$ and let a be the left endpoint of the support. Pair every point $t \in [a, a + L/2]$ with $t + L/2$. Then

$$\langle s, \psi_{j,k}\rangle = L^{-1/2} \int_a^{a+L/2} \overline{s(t) - s(t + L/2)}\ \mathrm{d}t.$$

The integrand has magnitude at most $ML/2$, and the integration interval has length $L/2$. The result is $ML^{3/2}/4$. □

Theorem E10.2 (Exact Haar coefficient of a step). *Let $\tau \in I_{j,k}$, let $L = 2^{-j}$, and write*

$$u = \frac{\tau - kL}{L} \in [0,1].$$

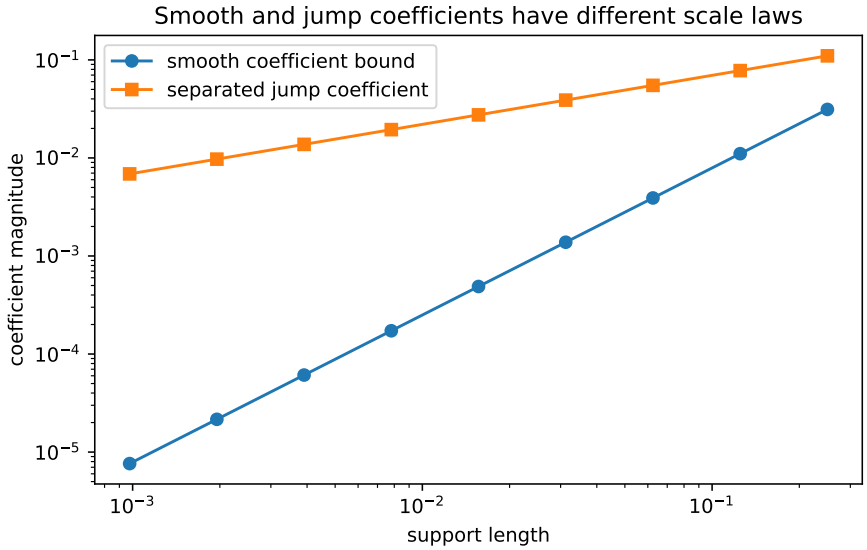

Figure E11. The smooth contribution decays like $L^{3/2}$, while a separated jump contribution decays like $L^{1/2}$.

Then

$$\left|\langle aH_\tau, \psi_{j,k}\rangle\right| = |a| L^{1/2} \min\{u, 1-u\}.$$

Every Haar coefficient whose support does not cross τ is zero.

Proof. Away from the jump, the step is constant on the support and the Haar wavelet has zero mean. When the jump lies in the support, integrate the positive and negative halves directly. If $u \le 1/2$, the magnitude is $|a| u L^{1/2}$. If $u \ge 1/2$, it is $|a|(1-u)L^{1/2}$. □

Corollary E10.3 (Scale separation). *Suppose $f = s + aH_\tau + \eta$, where s is M Lipschitz and $\|\eta\|_\infty \le \varepsilon$. If the jump lies at relative distance at least ρ from both ends of $I_{j,k}$, then*

$$|\langle f, \psi_{j,k}\rangle| \ge \left(|a|\rho - \varepsilon - \frac{M}{4} L\right) L^{1/2}.$$

A wavelet support without a jump satisfies

$$|\langle f, \psi_{j,k}\rangle| \le \left(\varepsilon + \frac{M}{4} L\right) L^{1/2}.$$

Thus a threshold gap exists whenever

$$|a|\rho > 2\varepsilon + \frac{M}{2} L.$$

Proof. Combine theorems E10.1 and E10.2. The noise coefficient is at most

$$\|\eta\|_\infty \|\psi_{j,k}\|_1 = \varepsilon L^{1/2}.$$

The final inequality makes the lower bound on a jump support larger than the upper bound on a smooth support. □

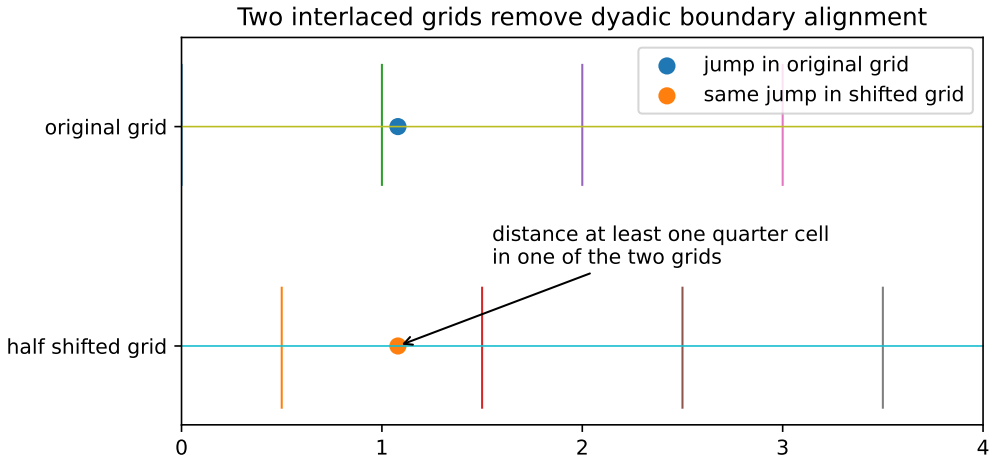

Figure E12. The boundaries of the two grids interlace. Every jump is well inside a cell in at least one grid.

E10.2 Two shifted grids

A jump on a dyadic boundary can be invisible to a wavelet at that scale. One additional grid removes this exact alignment.

Theorem E10.4 (Half cell shift guarantee). *Fix a cell length $L > 0$. Consider the grid with boundaries kL and the grid with boundaries $(k + 1/2)L$. Every point $\tau \in \mathbb{R}$ lies in a cell of at least one grid at distance at least $L/4$ from both cell boundaries.*

Proof. Reduce τ modulo L and write its representative as $x \in [0, L)$. If

$$L/4 \le x \le 3L/4,$$

then the distance from x to both boundaries of its cell in the original grid is at least $L/4$. If $x < L/4$ or $x > 3L/4$, then x lies in the cell of the shifted grid bounded by $-L/2$ and $L/2$, or in its translate, at distance at least $L/4$ from both shifted boundaries. One of the two grids therefore has the required property. □

Corollary E10.5 (Alignment free two grid Haar detection). *Assume the support length L is smaller than the minimum jump separation. Analyze the signal with Haar wavelets on the original grid and on the half shifted grid. Every jump appears in a support with $\rho \ge 1/4$ in one of the two systems. Therefore a threshold gap exists independently of alignment whenever*

$$\frac{|a|}{4} > 2\varepsilon + \frac{M}{2}L.$$

Proof. Apply theorem E10.4 and then corollary E10.3 with $\rho = 1/4$. The separation assumption prevents a selected support from containing two jumps. □

E10.3 Higher differences

Let

$$(\Delta x)(n) = x(n + 1) - x(n).$$

Then

$$\Delta^m x(n) = \sum_{r=0}^{m} (-1)^{m-r} \binom{m}{r} x(n+r).$$

Theorem E10.6 (Polynomial annihilation and boundary support)**.** *Let x be a sequence that agrees with a polynomial of degree at most d on each interval of a finite partition of $\mathbb{Z}$. Then*

$$\Delta^{d+1} x(n) = 0$$

whenever the complete stencil

$$\{n, n+1, \dots, n+d+1\}$$

lies inside one polynomial piece. Hence $\Delta^{d+1} x$ is supported in a band of at most $d+1$ addresses before each breakpoint.

Proof. The $(d+1)$st forward difference of a polynomial of degree at most d is zero. The only stencils for which this argument does not apply are those crossing a breakpoint. □

Proposition E10.7 (Noise amplification by differences)**.** *If $\|\eta\|_\infty \le \varepsilon$, then*

$$\|\Delta^m \eta\|_\infty \le 2^m \varepsilon.$$

Therefore no false response above $2^{d+1}\varepsilon$ can occur on a stencil lying inside one polynomial piece.

Proof. The absolute values of the binomial coefficients in Δ^m sum to 2^m. □

Corollary E10.8 (Robust breakpoint bands)**.** *Assume every true breakpoint produces at least one response of magnitude ρ in its $(d+1)$st difference band. If*

$$\rho > 2^{d+2}\varepsilon,$$

then thresholding at any level between $2^{d+1}\varepsilon$ and $\rho - 2^{d+1}\varepsilon$ detects a nonempty cluster near every breakpoint and creates no cluster away from the breakpoint bands.

Proof. Use theorem E10.6 and proposition E10.7. Noise cannot cross the threshold away from a breakpoint. At a response of magnitude ρ, the perturbed magnitude remains at least $\rho - 2^{d+1}\varepsilon$, which is above the threshold. □

E11 Packet separation and the Gibbs phenomenon

A Fourier partial sum is global. When the target has a jump, the partial sum must approximate that jump using continuous trigonometric polynomials. This creates the classical Gibbs oscillation. Standard accounts and recovery methods appear in [Zyg02, GS97].

Standard Fact E11.1 (Classical square-wave Gibbs behavior). Let $q(x) = \frac{1}{2}\operatorname{sign}(\sin x)$, whose jump at zero has size one. For $n \ge 1$, its partial sum through the first n positive odd frequencies is

$$Q_n(x) = \frac{2}{\pi} \sum_{k=0}^{n-1} \frac{\sin((2k+1)x)}{2k+1}.$$

At $x_n = \pi/(2n)$,

$$x_n \longrightarrow 0, \qquad Q_n(x_n) \longrightarrow \frac{\mathrm{Si}(\pi)}{\pi} = \frac{1}{2} + G, \qquad G \approx 0.089489872236,$$

where $\mathrm{Si}(z) = \int_0^z \sin(t)/t\, dt$ and $G = \mathrm{Si}(\pi)/\pi - 1/2 > 0$. Thus a nonzero overshoot persists along points approaching the jump. Scaling by a real amplitude a gives an overshoot or undershoot of magnitude $|a|G$.

For the limit, put $u_k = (k + \frac{1}{2})/n$. The identity

$$Q_n(x_n) = \frac{1}{\pi n} \sum_{k=0}^{n-1} \frac{\sin(\pi u_k)}{u_k} \longrightarrow \frac{1}{\pi} \int_0^1 \frac{\sin(\pi u)}{u}\, du = \frac{\mathrm{Si}(\pi)}{\pi}$$

is a midpoint Riemann sum, since the integrand has continuous value π at zero. This is the normalized classical example in [Nat26, Section 6.16(i), equations 6.16.1–6.16.4].

The square-wave example supplies a classical comparison. The following retained-packet identities do not require a general overshoot theorem. They change the approximation problem because the discontinuity is no longer represented by the Fourier partial sum.

Theorem E11.2 (Uniform convergence with exact jump packets)**.** *Let $f = s + j$ on a compact domain, where j is any bounded singular packet. Suppose $Q_m s \to s$ uniformly. Then*

$$\tilde{f}_m = Q_m s + j$$

converges uniformly to f, even when f is discontinuous:

$$\|f - \tilde{f}_m\|_\infty = \|s - Q_m s\|_\infty \longrightarrow 0.$$

There is no error proportional to the jump size because the jump is shared exactly by f and $\tilde{f}_m$.

Proof. Apply theorem E7.5 in the supremum norm. □

Theorem E11.3 (Estimated packet Gibbs bound). *Let Q_m be linear and uniformly bounded on L^p, with*

$$\sup_m \|Q_m\| \le C_Q.$$

For $f = s + j$ and an estimated packet $\hat{j}_m$, define

$$\hat{f}_m = Q_m(f - \hat{j}_m) + \hat{j}_m.$$

Then

$$\|f - \hat{f}_m\|_p \le \|s - Q_m s\|_p + (1 + C_Q)\|j - \hat{j}_m\|_p.$$

Consequently, smooth approximation and packet recovery may be improved independently. No claim of Gibbs removal is justified unless both terms are controlled in the norm under consideration.

Proof. This is theorem E7.8 with the uniform operator bound. □

Corollary E11.4 (Boundary band error). *Let Γ be the singular boundary and assume*

$$\mu(N_\delta(\Gamma)) \le C_\Gamma \delta$$

for small δ. For finite p,

$$\|f - \tilde{f}_m\|_{L^p(N_\delta(\Gamma))} \le (C_\Gamma \delta)^{1/p} \|s - Q_m s\|_\infty.$$

Proof. The error equals $s - Q_m s$. Bound it by its supremum and multiply by the measure of the boundary tube. □

Example E11.5 (Square wave Fourier tail). Let

$$j(t) = \mathbf{1}_{[-a,a]}(t)$$

on the circle and let s be smooth. If Q_m is a Fourier partial sum, then $Q_m(s + j)$ has the ordinary oscillatory boundary layer. In contrast,

$$Q_m s + j$$

has error exactly $s - Q_m s$. The visual comparison in figure E13 illustrates this change in approximation target. It is not a new Fourier summability theorem.

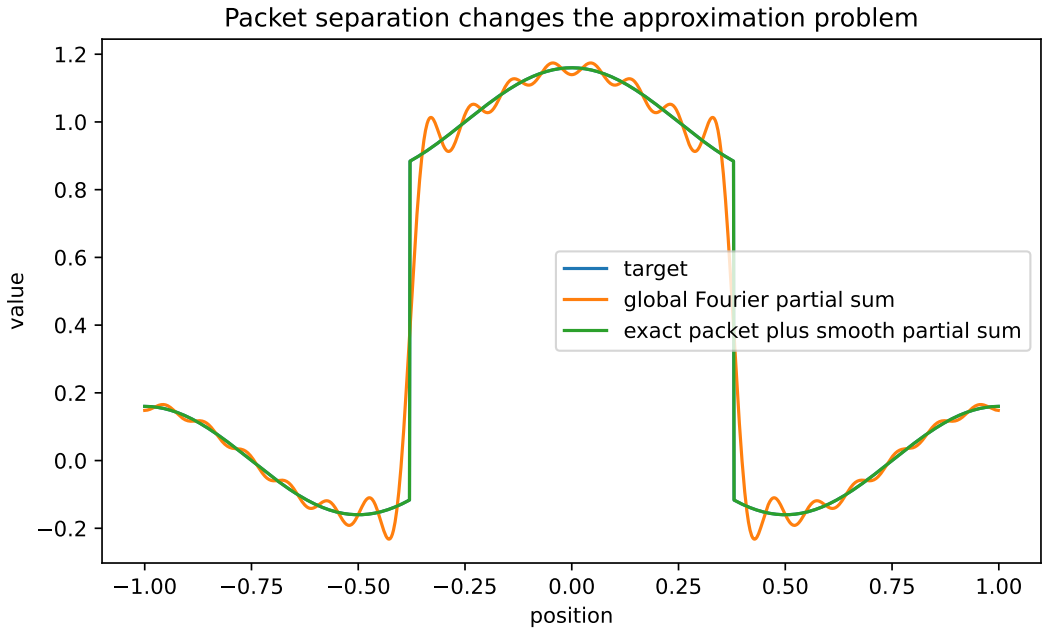

Figure E13. Global Fourier truncation represents the jump and exhibits an oscillatory boundary layer. Packet separation retains the jump and approximates only the smooth component.

E12 Nonlinear interactions in residue coordinates

Linear transfer matrices do not directly describe nonlinear products. Residue coordinates still obey exact conservation laws because integer addresses add modulo the packet modulus.

Theorem E12.1 (Residue law for Cauchy products)**.** *Let*

$$F(z) = \sum_{n \geq 0} f_n z^n, \qquad G(z) = \sum_{n \geq 0} g_n z^n$$

be formal power series. The same statement holds for power series that converge on a common disk. Decompose both series into residue packets modulo N:

$$F = \sum_{r=0}^{N-1} F_r, \qquad G = \sum_{s=0}^{N-1} G_s.$$

If $H = FG$, then its residue packet H_t is

$$\boxed{H_t = \sum_{r+s \equiv t \pmod{N}} F_r G_s.}$$

Proof. Every monomial in $F_r G_s$ has degree congruent to $r + s$ modulo N. Conversely, every coefficient of degree congruent to t is formed from pairs whose residues sum to t. Grouping the Cauchy product by this residue gives the formula. □

Theorem E12.2 (Shifted pointwise monomial law)**.** *Let*

$$y(n) = \prod_{j=1}^{m} x(n - a_j)$$

and write

$$a_j = Nc_j + b_j, \qquad 0 \le b_j < N.$$

For output residue r, define

$$r_j \equiv r - b_j \pmod{N}, \qquad 0 \le r_j < N,$$

and let

$$\kappa_{r,b_j} = \begin{cases} 1, & r < b_j, \\ 0, & r \ge b_j. \end{cases}$$

Then the output channel is

$$\boxed{y_r(q) = \prod_{j=1}^{m} x_{r_j}(q - c_j - \kappa_{r,b_j}).}$$

Proof. For $n = Nq + r$,

$$n - a_j = N(q - c_j) + r - b_j.$$

If $r \ge b_j$, this address has residue $r - b_j$ and coarse index $q - c_j$. If $r < b_j$, add N to the residue and subtract one from the coarse index. Multiplying the resulting channel values gives the formula. □

Corollary E12.3 (Polynomial shift filters)**.** *Every finite polynomial in shifted samples has an exact finite expression in residue coordinates. Each monomial selects a deterministic list of input residues and coarse shifts, and the complete output is their finite sum.*

Proof. Apply theorem E12.2 to each monomial and add the results. □

Example E12.4 (Quadratic nearest neighbor interaction)**.** For

$$y(n) = x(n)x(n-1)$$

and modulus N,

$$y_r(q) = \begin{cases} x_r(q)x_{r-1}(q), & r \ge 1, \\ x_0(q)x_{N-1}(q-1), & r = 0. \end{cases}$$

The carry at residue zero is the nonlinear analogue of a transfer crossing a coarse cell boundary.

E13 Finite numerical illustrations

The figures and tables in this section are finite checks and examples. They are not substitutes for the preceding proofs. Their purpose is to show the scale and shape of the terms appearing in the exact estimates.

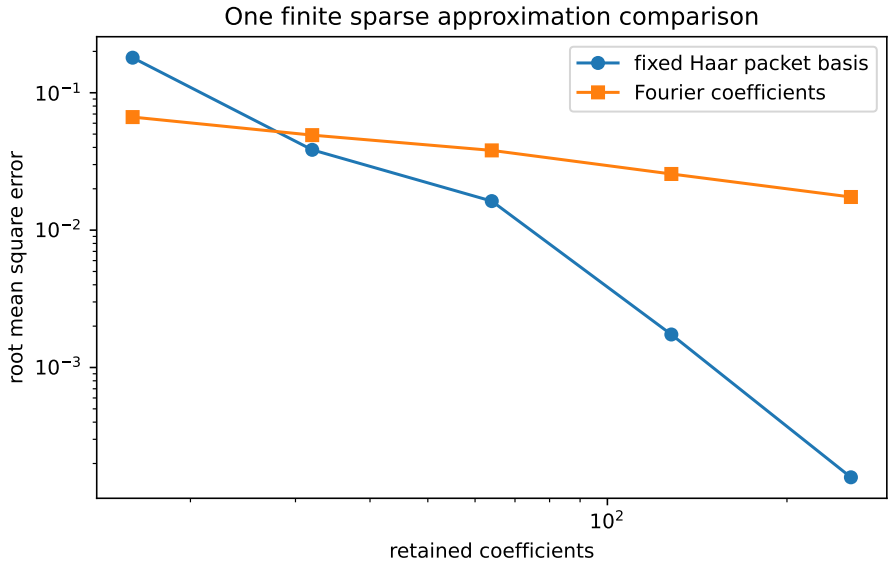

Figure E14. One finite sparse approximation comparison. Fourier coordinates are better at the smallest budget, while the fixed Haar packet basis becomes better after localized edge coordinates are resolved.

Table E1. Finite sparse approximation record for one test signal.

retained	Haar packet RMSE	Fourier RMSE
16	1.7999×10^{-1}	6.6522×10^{-2}
32	3.8414×10^{-2}	4.9153×10^{-2}
64	1.6267×10^{-2}	3.8056×10^{-2}
128	1.7387×10^{-3}	2.5631×10^{-2}
256	1.5870×10^{-4}	1.7424×10^{-2}

A fixed depth Haar packet transform and a Fourier basis were applied to the same piecewise smooth test signal. The largest coefficients were retained in each representation.

The table does not prove that Haar packets dominate Fourier coordinates for every signal. Smooth periodic oscillations may favor Fourier coordinates. Curved edges in two dimensions may favor directional systems. The geometric approximation results in [Don99, CD04] give much deeper statements for specific image classes.

The estimated packet rows used a narrow positive contrast synthetic model. They are not evidence for a general segmentation theorem. The exact packet rows verify theorem E7.5 numerically after the packet is supplied.

Table E2. Finite edge reconstruction record from the original computational study.

case	global	exact packet	estimated packet
one-dimensional step	5.4023×10^{-2}	1.3692×10^{-4}	2.4029×10^{-2}
two-dimensional disk	3.7643×10^{-2}	6.4752×10^{-5}	3.4043×10^{-3}
multiple regions	3.3740×10^{-2}	5.2118×10^{-7}	not evaluated

E14 Cyclic Cayley coordinates

Keep the rotation and its chart separate

For the phase factorization below, M and N are positive phase orders. The reflection coordinate rotates in the unit disk. The Cayley map expresses that same motion as a fractional linear impedance action. A pole of the chart does not mean that the projective action fails. This realization is independent of the separated jump detector.

This section records a secondary realization from the original signal manuscript. It is logically independent of the recovery theorems. The classical Smith chart uses the Cayley transform between normalized impedance and a reflection coordinate [Smi69].

Let

$$\mathbb{H} = \{z \in \mathbb{C} : \Re z > 0\}$$

and define

$$C(z) = \frac{z-1}{z+1}.$$

It maps $\mathbb{H}$ conformally onto the unit disk $\mathbb{D}$, with inverse

$$C^{-1}(w) = \frac{1+w}{1-w}.$$

For $\theta \in \mathbb{R}$, let

$$R_\theta(w) = \mathrm{e}^{\mathrm{i}\theta} w.$$

Theorem E14.1 (Cyclic Möbius action)**.** *The pullback*

$$\Phi_\theta = C^{-1} R_\theta C$$

is the fractional linear map

$$\boxed{\Phi_\theta(z) = \frac{(1+\mathrm{e}^{\mathrm{i}\theta})z + (1-\mathrm{e}^{\mathrm{i}\theta})}{(1-\mathrm{e}^{\mathrm{i}\theta})z + (1+\mathrm{e}^{\mathrm{i}\theta})}.}$$

It preserves $\mathbb{H}$ and satisfies

$$\Phi_\theta \Phi_\varphi = \Phi_{\theta+\varphi}.$$

For an integer $N \geq 1$ and $\theta = 2\pi/N$, the map has order N.

Proof. Substitute $\mathrm{e}^{\mathrm{i}\theta}(z-1)/(z+1)$ into C^{-1} and simplify. Preservation of $\mathbb{H}$ follows because C maps it to $\mathbb{D}$, rotation preserves $\mathbb{D}$, and C^{-1} maps back. The group law follows by conjugating the rotation group law. When $\theta = 2\pi/N$, the Nth power is the identity. Conversely, if its kth power is the identity, conjugation by C and evaluation at $w = 1/2$ give $\mathrm{e}^{2\pi \mathrm{i} k/N} = 1$, so N divides k. Hence the order is exactly N. □

Corollary E14.2 (Impedance and admittance)**.** *For $N = 2$, $\theta = \pi$ and*

$$\Phi_\pi(z) = \frac{1}{z}.$$

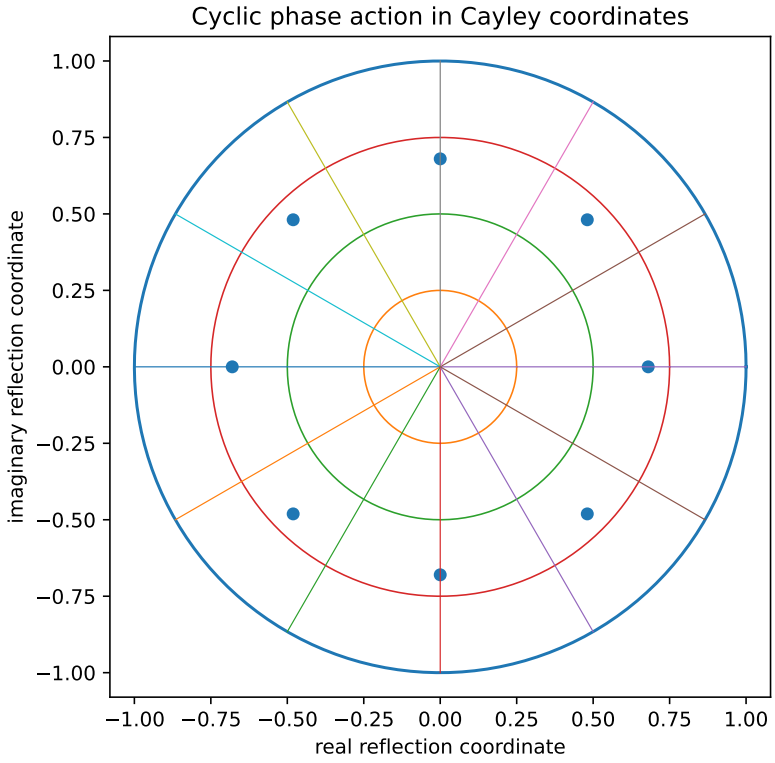

Figure E15. The cyclic action is an ordinary phase rotation in the reflection disk and a fractional linear action in the impedance half plane.

Thus the two phase action is normalized impedance and admittance inversion.

Proof. Insert $e^{i\pi} = -1$ in the formula of theorem E14.1. □

Proposition E14.3 (Radial and phase coordinates)**.** *Write*

$$C(z) = \rho e^{i\varphi}, \qquad 0 \le \rho < 1.$$

Then

$$C(\Phi_\theta(z)) = \rho e^{i(\varphi+\theta)}.$$

The radial mismatch ρ is invariant and the phase coordinate advances by θ.

Proof. This is the defining conjugacy $C\Phi_\theta = R_\theta C$. □

Proposition E14.4 (Coprime phase factorization)**.** *Let M and N be coprime. The cyclic phase labels modulo MN are equivalent to pairs of labels modulo M and modulo N:*

$$\mathbb{Z}/(MN)\mathbb{Z} \cong \mathbb{Z}/M\mathbb{Z} \times \mathbb{Z}/N\mathbb{Z}.$$

Under this identification, the rotation by $2\pi/(MN)$ is determined by its two projected cyclic actions.

Proof. This is the Chinese remainder theorem applied to the additive phase label. A label modulo MN is uniquely determined by its two residues, and addition of labels is preserved. □

E15 Limits and further directions

The one-dimensional recovery theorem identifies an explicit admissible threshold interval for an adjacent contrast detector. More general recovery requires a broader observation model. A multiscale average can reduce fixed sample noise, but its bias depends on the smoothness class and the separation of nearby jumps. A useful next theorem should select the averaging scale from the data while retaining a finite probability certificate.

Higher dimensional recovery requires geometry. The overlap and tube formulas in appendix E8 become quantitative once a boundary estimate is known. What remains is a stable method that recovers topology, orientation, curvature, and region values under a declared noise model. Wedgelets and curvelets show why directional geometry is essential for broad image classes [Don99, CD04].

The best basis recursion is exact for additive objectives. Cross packet leakage, shared computation, and global hardware constraints introduce couplings between subtrees. Those problems require a larger compiler or an approximation theorem. The cost stability results in theorem E6.6 and corollary E6.7 identify one condition under which the additive decision survives perturbation.

The higher order singular packet theorem removes finitely many trace jumps. A more complete approximation theory should connect packet norms to geometric measure quantities in BV, piecewise Sobolev spaces, and free discontinuity models. It should also determine when a redundant packet dictionary can identify the derivative order of a singularity rather than merely its location.

Finally, the two shifted Haar grids remove one exact alignment failure, but they are redundant. A complete redundant theory should provide stable synthesis, noise aware coefficient aggregation, and a best basis rule that does not count the same singularity several times.

E16 Conclusion

Finite index sublattices give exact coordinates for lattice signals. In those coordinates, convolution is a matrix of transfer kernels. Perfect reconstruction is a matrix inverse identity. Approximate reconstruction is controlled by a multiplier norm. Frame bounds are pointwise singular value bounds. Lifting steps are exact triangular coordinate changes. Every admissible packet tree gives a complete coordinate system, and every additive tree objective has an exact dynamic recursion.

The singular packet theory separates representation from recovery. A finite family of truncated powers records jumps in a function and its derivatives, leaving a globally Sobolev remainder under explicit trace assumptions. If the packet is known and retained, the error is exactly the smooth approximation error. If the packet is estimated, exact region overlap and location formulas quantify the remaining defect, while the reconstruction operator contributes a transparent stability factor.

For separated one-dimensional jumps, a deterministic contrast gap gives exact cell recovery, midpoint location accuracy, and amplitude control. A sub-Gaussian version follows from one union bound, and repeated measurements reduce the effective noise scale. Haar coefficients provide a second separation law because smooth coefficients decay one full power of scale faster than jump coefficients. Two shifted grids remove boundary alignment at a fixed scale. Higher differences annihilate piecewise polynomial interiors and confine their response to breakpoint bands.

The resulting chain is

$$\begin{aligned}&\text{lattice coordinates} \longrightarrow \text{transfer blocks} \longrightarrow \text{stable filter banks} \longrightarrow \text{packet trees}\\ &\longrightarrow \text{singular packet model} \longrightarrow \text{local recovery} \longrightarrow \text{smooth approximation rate.}\end{aligned}$$

Every arrow is exact or quantitatively controlled under the hypotheses stated in the corresponding result.

Part III: Forty worked visual plates

A second route through the mathematics

These forty plates develop the finite models used in the separate visual guide. Plates V.1–V.40 stay fixed across both documents. They lead from exact signal coordinates through filter transfers, adaptive decisions, packet errors, stable banks, and separated jump recovery. Every page gives the relevant manuscript locator. Finite arithmetic and diagrams explain the stated hypotheses and do not extend the formal contract.

How to use this volume

Forty worked pages and thirty-seven editable vector figures follow exact signal coordinates, a fully enumerated packet tree, and a reflection orbit, then extend the route to stable banks, singular trace packets, and conditional recovery of separated jumps.

Part I / A route through the examples

Plates V.1 through V.40 identify worked pages independently of PDF pagination. Each page names its corresponding statements in the mathematical text. The Lean guide records the separate formal contract.

Plate V.1 Three objects, three different questions

Plate V.2 An atlas of the objects

Plate V.3 Decimation is a permutation, not a loss

Plate V.4 Refine packets on a common lattice

Plate V.5 A filter becomes a matrix of actual delays

Plate V.6 One sample is not one channel step

Plate V.7 Perfect reconstruction is an operator identity

Plate V.8 A jump can hide from the first Haar split

Plate V.9 Lifting preserves information, not energy

Plate V.10 The second level resolves the hidden change

Plate V.11 Deleting coefficients is the approximation step

Plate V.12 A mixed-depth basis must cover every branch

Plate V.13 Solve every alternative without searching every alternative

Plate V.14 How far can the costs move before the tree changes?

Plate V.15 Retain the jump and approximate the other packet

Plate V.16 Why a Fourier cutoff cannot reproduce this jump pointwise

Plate V.17 Small location errors, different norms

Plate V.18 Separate amplitude error from mask error

Plate V.19 Geometry localizes error while data may leave it ambiguous

Plate V.20 Two products, two packet laws

Plate V.21 Nonlinear neighbors cross channel boundaries

Plate V.22 One reflection circle, four very different impedances

Plate V.23 A pole is a chart boundary, not a broken group action

Plate V.24 Residue labels are not impedance averages

Plate V.25 Sensitivity grows before the pole is reached

Plate V.26 What the reader can now verify

Three reading routes

Signal coordinates: Plates V.3–V.11, then Plate V.20 and Plate V.21. **Selection and error:** Plates V.12–V.19. **Nonlinear geometry:** Plates V.22–V.25.

One model per question

The sixteen-sample signal gives exact rational values. The depth-three tree has twenty-six complete prunings. The reflection orbit has four exact quarter-turn points. These bounded examples expose the chapter's mechanisms without replacing its general statements.

Read the hypotheses with the picture

Zero extension, periodic indexing, and infinite sequences describe different objects. Known jumps differ from estimated jumps. A finite optimum depends on a specified cost, and a coordinate transformation does not establish an optimal sampling rule. Plate V.26 records the evidence behind this guide.

Part II / From coordinates to recovery

The expanded traditional development supplies additional theorems beyond the inherited twenty-result formal contract. These fourteen new worked pages follow its hypotheses through exact examples and quantitative bounds.

Plate V.27 What the extended developments add

Plate V.28 Six image phases are six exact address classes

Plate V.29 A positive singular-value gap survives perturbation

Plate V.30 Nonunitary tree bounds propagate along branches

Plate V.31 Derivative jumps have their own packets

Plate V.32 The approximation operator also acts on packet error

Plate V.33 An overlap matrix is an exact error ledger

Plate V.34 A shifted step and a shifted ramp have different moduli

Plate V.35 A strict contrast gap locates every separated jump cell

Plate V.36 Repeated observations shrink the noise side of the gap

Plate V.37 Haar sees a jump only through its position in the support

Plate V.38 Two half-shifted grids remove exact alignment failure

Plate V.39 Higher differences annihilate polynomial interiors

Plate V.40 Conditional Gibbs control closes the reconstruction estimate

A connected route

The lattice example extends exact addressing. Frame bounds then quantify the stability of analysis and synthesis. Trace packets remove specified singularities, while overlap and location formulas measure errors in their estimates. Three local detectors address separated jumps under contrast hypotheses. The final page combines the recovered packet with a chosen approximation operator.

Keep the evidence attached to its claim

The twenty-result core carries its preserved Lean map. Part II carries traditional proofs and the recorded mathematical review, with a separate exact checker for the worked examples. The symbolic visual suite, arithmetic runs, saved compiler transcripts, and rendered figures each have a stated scope. Neither a figure nor a finite check expands the formal theorem map.

What the example numbers mean

The additional checker uses exact rational arithmetic. Its logarithmic sampling budget is enclosed using a positive Taylor partial sum. Curve coordinates are converted to decimal positions for drawing. Displayed formulas retain exact values. All plates drawn from the source are editable TikZ, and the final comparison figure is preserved from the expanded manuscript's vector source.

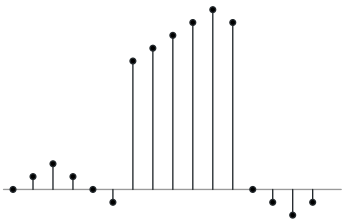

Plate V.1 / PAPER V / A WORKED VISUAL COMPANION

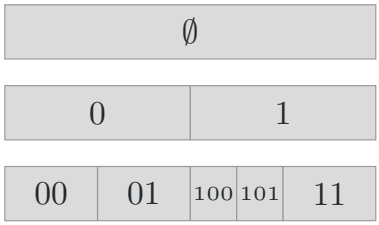
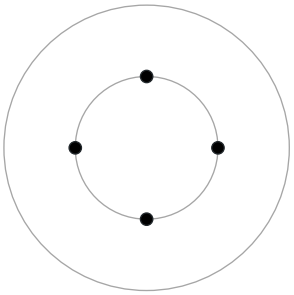
Three objects, three different questions

Chapter V: Section 1, Section 6, Section 11, Section 13.



A packet calculus can reorganize a signal exactly, choose among finitely many representations, or describe a nonlinear coordinate geometry. These are not the same task. This guide keeps one concrete object in view for each, so that the reader can compute rather than only follow arrows.

SIGNAL COORDINATES



$f = s + j \quad \text{in } \mathbb{Q}^{16}$

FINITE TREE CHOICES

26 complete prunings

REFLECTION ORBIT

$\Gamma = \frac{1}{2} i^k$

A signal that can be checked by hand

Our main finite signal is $f = s + j \in \mathbb{Q}^{16}$. The background repeats

$$\tfrac{1}{4}(0, 1, 2, 1, 0, -1, -2, -1),$$

and $j[n] = 3$ at $6 \le n < 12$, with $j[n] = 0$ elsewhere. This is a discrete background model, not an assertion of continuum smoothness. Its energy is exactly 57. We use it for residue coordinates, Haar transforms, coefficient deletion, and known-packet cancellation.

A tree whose alternatives can all be seen

The full binary tree of depth three has only 26 complete prunings. We enumerate all of them, compute a unique mixed-depth optimum, and certify its stability with rational costs. The displayed objective is deliberately explicit, not claimed to be a universal score for signal quality.

A coordinate orbit with no hidden numerical poles

The four reflection points $\Gamma = i^k/2$ map to four exact impedances. A second orbit passes through infinity. Homogeneous coordinates make that point an ordinary part of the construction.

> **Read this as:** Exact coordinates preserve information. An optimizer chooses coordinates. An estimator must still identify information not already supplied.

Plate V.2 / READING CONVENTIONS / KEEP THE TYPES VISIBLE

An atlas of the objects

Chapter V: Section 20 (notation crosswalk), Section 21 (formal correspondence).

Several symbols in the chapter describe different realizations of the same operator language. The following distinctions are used throughout this guide.

Object	Literal meaning	What it is not
S, δ_0	Sample shift and unit impulse	A finite truncation of every ℓ^2 signal
$P_{N,r} f$	A masked signal on the original lattice	The shorter decimated channel
$f_r[q]$	The value $f[Nq + r]$	An average of neighboring samples
D	One channel-index delay	Necessarily one original-sample delay
$E(D), R(D)$	Finite Laurent analysis and synthesis matrices	Values at one test frequency
W_α	The addressed Haar analysis operator	An edge detector by itself
$W_\alpha^* W_\alpha$	A projector on the original signal space	A scalar packet energy
Λ	A complete covering antichain of a finite tree	An arbitrary collection of nodes
$j, \hat{j}$	Known and estimated discontinuity packets	Interchangeable hypotheses
Γ, z	Reflection coefficient and normalized impedance	Coefficients that can be linearly interchanged

Three arithmetic conventions

FIR examples use bilateral sequences with finite support and *zero extension*. Haar examples use vectors of length 16, with lengths divisible by the required powers of two. The three-tap smoother and nonlinear neighbor example use *periodic* indexing. These boundary conventions are stated where they enter. None is silently substituted for another. The polynomial variable t on Plate V.20 indexes coefficients. The delay symbol D acts on channels. The Smith variable z is impedance. Keeping them separate prevents a visual resemblance from becoming an invalid identity.

> **Read this as:** A correct formula needs the correct object, product, norm, and boundary convention. A familiar matrix does not supply them automatically.

Plate V.3 / EXACT ADDRESSES / THE RUNNING SIGNAL

Decimation is a permutation, not a loss

Chapter V: Theorem 2.1, Corollary 2.2.

For four phases, write every sample address uniquely as $n = 4q + r$ with $0 \le r < 4$. Analysis stores $f[n]$ at channel address (r, q). Synthesis puts that exact value back at $4q + r$.

FOUR PHASES: EVERY ADDRESS APPEARS ONCE

	$q=0$	$q=1$	$q=2$	$q=3$	
$r=0$	$n=0:\ 0$	$n=4:\ 0$	$n=8:\ 3$	$n=12:\ 0$	$n = 4q + r$
$r=1$	$n=1:\ \frac{1}{4}$	$n=5:\ -\frac{1}{4}$	$n=9:\ \frac{13}{4}$	$n=13:\ -\frac{1}{4}$	$-1 = 4(-1) + 3$
$r=2$	$n=2:\ \frac{1}{2}$	$n=6:\ \frac{5}{2}$	$n=10:\ \frac{7}{2}$	$n=14:\ -\frac{1}{2}$	
$r=3$	$n=3:\ \frac{1}{4}$	$n=7:\ \frac{11}{4}$	$n=11:\ \frac{13}{4}$	$n=15:\ -\frac{1}{4}$	$-5 = 4(-2) + 3$

Every cell contains an original address and its rational sample value. Shading marks the known jump packet, not an estimated feature or a frequency band.

What has changed? Only where the values are stored

The complete tuple of channels contains sixteen values, just as the original vector does. A single decimated channel is shorter, but keeping all four loses no samples. The residue projector $P_{4,r}f$ is different: it keeps the original lattice and writes zeros outside phase r.

$$\mathcal{S}_4\mathcal{A}_4 f = f, \qquad \|f\|_2^2 = \sum_{r=0}^{3} \|f_r\|_2^2 = 57.$$

The norm on the channel tuple is the sum-of-squares Hilbert norm, not the maximum of the channel norms. This distinction matters in the infinite-dimensional statement.

Negative addresses are ordinary addresses

Euclidean division, rather than truncation toward zero, gives $-1 = 4(-1) + 3$ and $-5 = 4(-2) + 3$. The finite tests exercise both positive and negative sample addresses. The algebraic identity applies before any plotting window or finite buffer is chosen.

> **Read this as:** Downsampling one channel discards information. Splitting into all residue channels is an invertible address change.

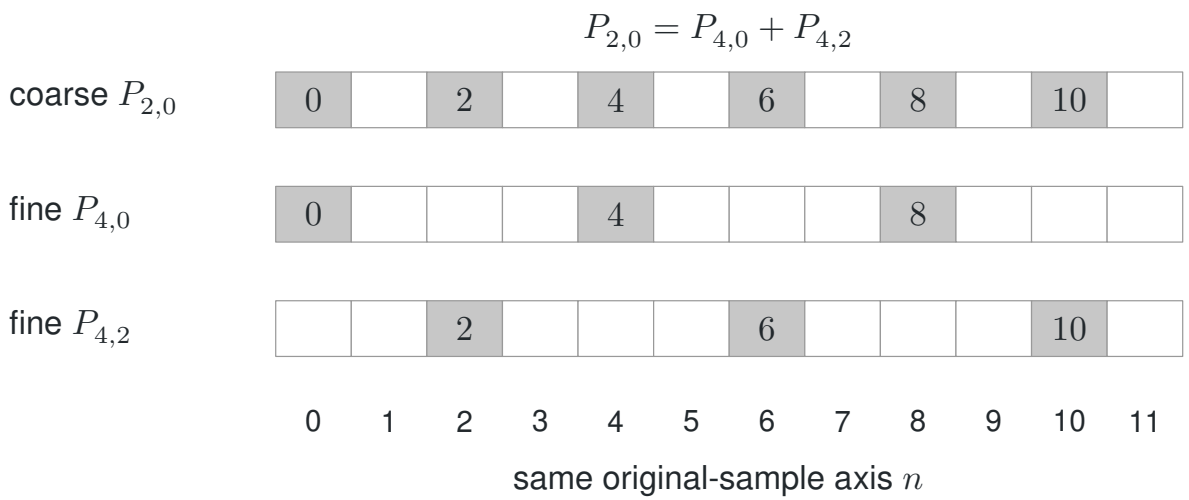


Plate V.4 / EXACT REFINEMENT / WHAT CAN BE ADDED

Refine packets on a common lattice

Chapter V: Theorem 2.3.

An even sample belongs to exactly one of residues 0 and 2 modulo four. Therefore the coarse even mask is the sum of two disjoint fine masks:

$$P_{2,0} = P_{4,0} + P_{4,2}.$$

The common horizontal axis is the original sample index. Empty cells denote masked-out addresses. There are no interpolated samples between the displayed cells.

Why the coordinate convention matters

The decimated channel $f_0[q] = f[2q]$ has its own index q. At modulus four the descendants are $f[4q]$ and $f[4q+2]$. These shorter arrays must be interleaved to recover the coarse channel. Adding them entrywise instead produces sums of different original samples. For example, at the first descendant address the values $f[0] = 0$ and $f[2] = 1/2$ are two separate values. Their sum $1/2$ cannot tell us both of them. Exact refinement is a disjoint partition, not an averaging rule or a new measurement.

The general formula

When N divides M,

$$P_{N,r} = \sum_{\substack{0 \le a < M \\ a \equiv r \pmod{N}}} P_{M,a}.$$

The divisibility hypothesis ensures that every fine residue class lies entirely inside one coarse class. Without it, this particular descendant relation is not the right refinement rule.

> **Read this as:** Finer coordinates can preserve the object exactly. Compressing their values to averages is an additional operation, with an additional information-loss question.

Plate V.5 / FIR TRANSFER / A FOUR-TAP EXAMPLE

A filter becomes a matrix of actual delays

Chapter V: Theorem 3.1.

Take the causal filter $h = (1, 2, -1, 1)$, with taps at $0, 1, 2, 3$, acting by $y[n] = \sum_q h[q] f[n-q]$. Resolve the input into even and odd channels. Let D denote one delay in the *channel* index.

$$h = (1, 2, -1, 1), \qquad D : \; u[n] \mapsto u[n-1]$$

	input 0	input 1
output 0	$1 - D$	$D^2 + 2D$
output 1	$D + 2$	$1 - D$

$$y_0 = (1 - D)x_0 + (2D + D^2)x_1$$

Reading one matrix entry

The odd-input contribution to the even output is $(2D + D^2)f_1$. The tap at original delay one reaches the preceding odd channel sample. The tap at delay three reaches the odd channel two positions back. These are different delays despite coming from the same input phase. The two channel equations are

$$y_0[n] = f_0[n] - f_0[n-1] + 2f_1[n-1] + f_1[n-2],$$
$$y_1[n] = 2f_0[n] + f_0[n-1] + f_1[n] - f_1[n-1].$$

Interleaving gives exactly the direct convolution, including its boundary samples under zero extension.

The general address calculation

For N phases, the block from input s to output k has kernel $h_{ks}[m] = h[Nm + k - s]$. This comes from the exact identity $Nn + k - q = N(n - m) + s$. It is a finite reindexing of taps, so no numerical transform of the input is needed. Evaluation of a bilateral transform is a separate step with the summability hypotheses stated in the manuscript.

> **Read this as:** The matrix does not approximate the filter. Its entries record which input phase is used, how far back to read, and what coefficient to multiply.

Plate V.6 / DELAY UNITS / AN IMPULSE MAKES THE DIFFERENCE VISIBLE

One sample is not one channel step

Chapter V: Theorem 4.1.

A one-sample delay swaps the two phases and wraps one of them into the preceding channel index. Its matrix is $J(D)$, not DI_2.

one original sample two original samples

$$J(D)^2 = \begin{bmatrix} 0 & D \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} D & 0 \\ 0 & D \end{bmatrix}$$

$\delta_0 \mapsto \delta_1$

$\delta_0 \mapsto \delta_2$

$$y_0[n] = x_1[n-1], \quad y_1[n] = x_0[n]$$

channel delay 1 at $N = 2$ is original-sample delay 2

Trace one impulse

The input δ_0 has a single nonzero value in even channel address zero. Under $J(D)$ it appears in odd channel address zero: this is the original sample δ_1. Under DI_2 it stays even but moves to channel address one: this is δ_2. Thus

$$J(D)^2 = DI_2, \qquad H(D) = I_2 + 2J(D) - J(D)^2 + J(D)^3$$

recovers the previous page's four-tap transfer matrix. The same delay algebra explains both the off-diagonal phase swap and the channel powers.

Signed delays need the same care

For an original-sample delay d at modulus N,

$$y_k[n] = f_{(k-d) \bmod N}\left[n + \left\lfloor \frac{k-d}{N} \right\rfloor\right].$$

This includes advances when $d < 0$. The finite verification checks the formula on signed sample addresses. A bank with product $D^q I_N$ delays the original signal by Nq samples, not q samples.

> **Read this as:** Always state the unit of a delay. A phase permutation and a channel delay together can represent one original sample.

Plate V.7 / FILTER BANKS / WHY A FREQUENCY SPOT-CHECK IS INSUFFICIENT

Perfect reconstruction is an operator identity

Chapter V: Theorem 4.1.

Consider the finite Laurent bank

$$E(D) = \begin{pmatrix} 1 & D \\ 0 & 1 \end{pmatrix}, \qquad R(D) = \begin{pmatrix} 1 & -D \\ 0 & 1 \end{pmatrix}.$$

Its synthesis cancels the exact delayed cross-channel contribution introduced by analysis.

$E(D)$

1	D
0	1

$R(D)$

1	$-D$
0	1

$$R(D)E(D) = I$$

every impulse is recovered

$$B(D) = \operatorname{diag}(D, 1): \quad B(1) = I, \quad B(D) \neq I$$

testing one frequency cannot detect a channel delay

Two inverses, all inputs

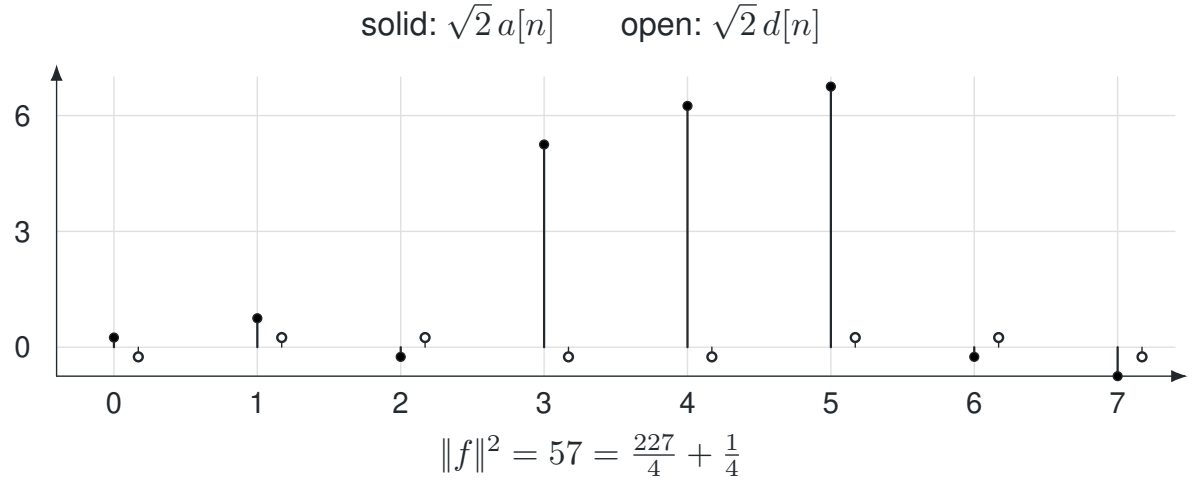
Direct polynomial multiplication gives $RE = ER = I_2$. Since D acts as a shift, these identities imply perfect reconstruction on every bilateral channel sequence. With finite kernels, composition requires only finitely many operations at each address. The converse uses impulses. Insert an impulse in one input channel. Each output channel lists every coefficient of the corresponding transfer polynomial. If all such responses vanish for $RE - I$, every coefficient is zero. Hence the polynomial matrix itself is zero.

A deliberately misleading test

The matrix $B(D) = \operatorname{diag}(D, 1)$ satisfies $B(1) = I_2$. At that one transform value it appears perfect. In the time domain, however, it delays only the first channel. An impulse in that channel immediately distinguishes it from the identity. This is why a small set of successful frequency evaluations is not automatically a proof of the full Laurent identity. A separate degree bound and a sufficient interpolation argument would be needed to turn finitely many evaluations into such a certificate.

> **Read this as:** Exact reconstruction concerns every coefficient of the transfer operator, not just an attractive response curve or one evaluation point.

Plate V.8 / HAAR ENERGY / EDGE ALIGNMENT



A jump can hide from the first Haar split

Chapter V: Corollary 4.2.

For the running signal, Haar analysis gives

$$a[n] = \frac{f[2n] + f[2n+1]}{\sqrt{2}}, \qquad d[n] = \frac{f[2n] - f[2n+1]}{\sqrt{2}}.$$

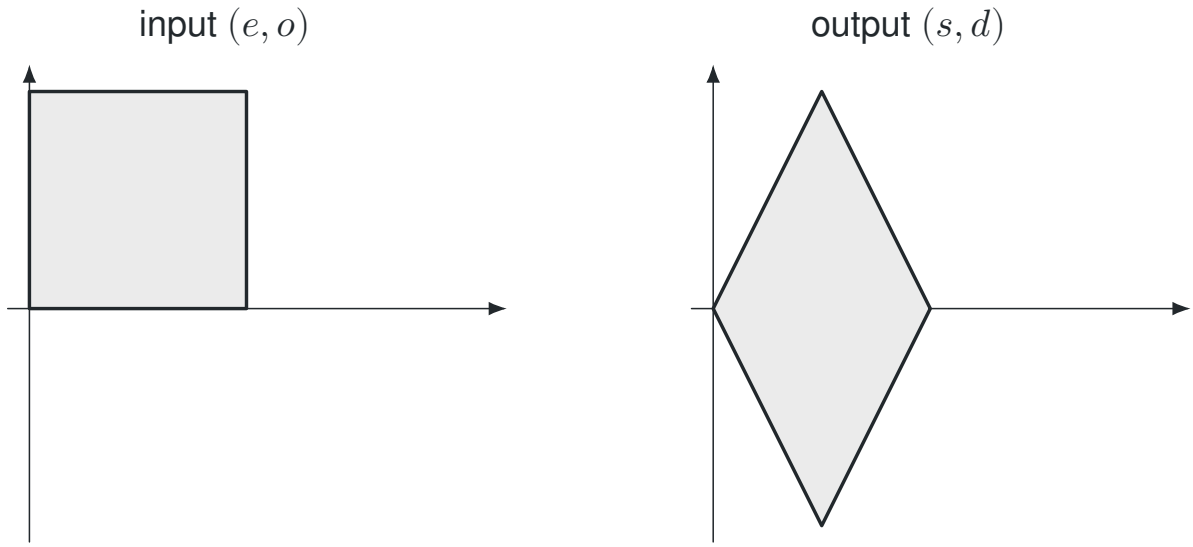
The plot scales both channels by $\sqrt{2}$ so that all displayed ordinates are rational.

The exact energy calculation

The low channel has energy $227/4$, and the detail channel has energy $1/4$. Their sum is 57, exactly the input energy. The normalization is essential: unnormalized sums and differences would multiply the total energy by two.

Why is the first detail channel so small?

The jump starts at sample 6 and ends just before sample 12. Both lie *between* the pairs $(0,1), (2,3), \dots, (14,15)$. Inside every pair the jump contributes either $(0,0)$ or $(3,3)$, so its first-level difference is zero. The small detail values come entirely from the discrete background. This does not mean the edge is absent from the transform. The next split of the low channel compares neighboring pairs, and those comparisons do cross the jump. The next pages expose that contribution explicitly.



> **Read this as:** Haar energy is exact, but a particular detail level is not a universal edge detector. Edge visibility depends on alignment, scale, and the chosen packets.

Plate V.9 / PREDICT–UPDATE / INVERTIBILITY VERSUS ISOMETRY

Lifting preserves information, not energy

Chapter V: Theorem 4.3.

For an even/odd pair (e, o), form the prediction residual $d = o - e$, then update $s = e + d/2$. The inverse reads $e = s - d/2$, followed by $o = d + e$.

The square $[0, 4]^2$ and its exact image under the lifting matrix have the same area. The separate pair $(2, 6)$ illustrates that Euclidean energy need not be preserved.

$$\begin{pmatrix} s \\ d \end{pmatrix} = \begin{pmatrix} 1/2 & 1/2 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} e \\ o \end{pmatrix}, \qquad \begin{pmatrix} e \\ o \end{pmatrix} = \begin{pmatrix} 1 & -1/2 \\ 1 & 1/2 \end{pmatrix} \begin{pmatrix} s \\ d \end{pmatrix}.$$

What determinant one does establish

The matrix is invertible, and in these real coordinates it preserves oriented area. The predict and update operations can be undone in reverse order. Applied to each pair, the construction gives exact finite-signal reconstruction.

What determinant one does not establish

The pair $(2, 6)$ becomes $(4, 4)$. Its squared Euclidean norm changes from 40 to 32. The lifting matrix is not unitary. Energy accounting must therefore use its actual coordinate metric or a separately normalized transform. Invertibility alone cannot replace the Haar energy identity. All values in this example are rational. Integer-to-integer lifting with a rounding rule is a different algorithm. Its inverse and error conventions require their own specification and are not silently inferred from the displayed rational matrix.

> **Read this as:** Perfect reconstruction, determinant one, and norm preservation are different properties. This transform has the first two, not the third.

Plate V.10 / ACTUAL WAVELET PACKETS / FOUR RATIONAL CHANNELS

The second level resolves the hidden change

Chapter V: Theorem 5.1.

Apply Haar analysis to *both* children. A binary address records the chronological low/detail choices, with 0 for low and 1 for detail. Each depth-two channel contains four coefficients.

	coefficient positions within each packet				energy
00	$\frac{1}{2}$	$\frac{5}{2}$	$\frac{13}{2}$	$-\frac{1}{2}$	49
01	$-\frac{1}{4}$	$-\frac{11}{4}$	$-\frac{1}{4}$	$\frac{1}{4}$	$\frac{31}{4}$
10	0	0	0	0	0
11	$-\frac{1}{4}$	$\frac{1}{4}$	$-\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$

$$\sum_{\alpha\in\{0,1\}^2} W_\alpha^* W_\alpha = I_{16}$$

The edge that first-level detail missed

Packet 01 is the detail child of the first low channel. It contains $-11/4$, the large change between neighboring pair averages. Packet 10 vanishes for this particular signal because the first-level differences alternate in canceling pairs. Neither feature is a universal identity for all inputs. The packet energies are

$$49, \qquad 31/4, \qquad 0, \qquad 1/4,$$

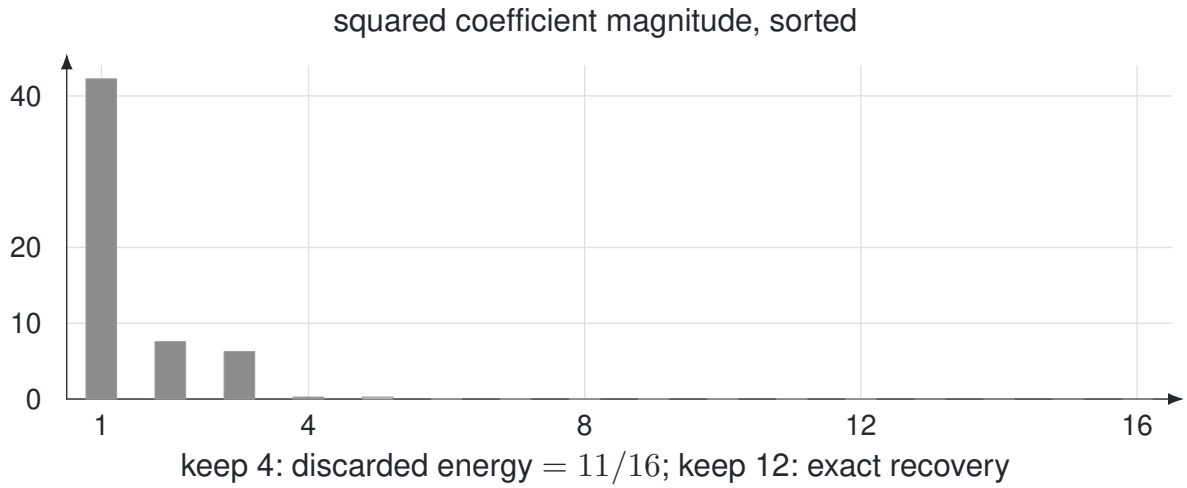
which again sum to 57. Two factors of $1/\sqrt{2}$ explain why the depth-two coefficients are rational halves and quarters.

Coefficients and projectors are different objects

$W_\alpha f$ is the short coefficient vector. The original-space component is $W_\alpha^* W_\alpha f$. Summing these synthesized components, not the short arrays entrywise, reconstructs f:

$$f = \sum_{|\alpha|=2} W_\alpha^* W_\alpha f.$$

The finite verification constructs the actual analysis matrices and checks their product with their adjoints. The chapter's ℓ^2 statement additionally establishes boundedness and the existence of the literal Hilbert adjoints.



> **Read this as:** A packet address specifies an operator word. To add different packets as signals, synthesize them back into the common signal space first.

Plate V.11 / SPARSITY / AN EXACT ERROR LEDGER

Deleting coefficients is the approximation step

Chapter V: Section 10.

The complete depth-two transform is exact. Approximation begins only when we discard some of its sixteen coefficients. Order them by squared magnitude, with a deterministic address-and-position rule for ties.

Every discarded square has a meaning

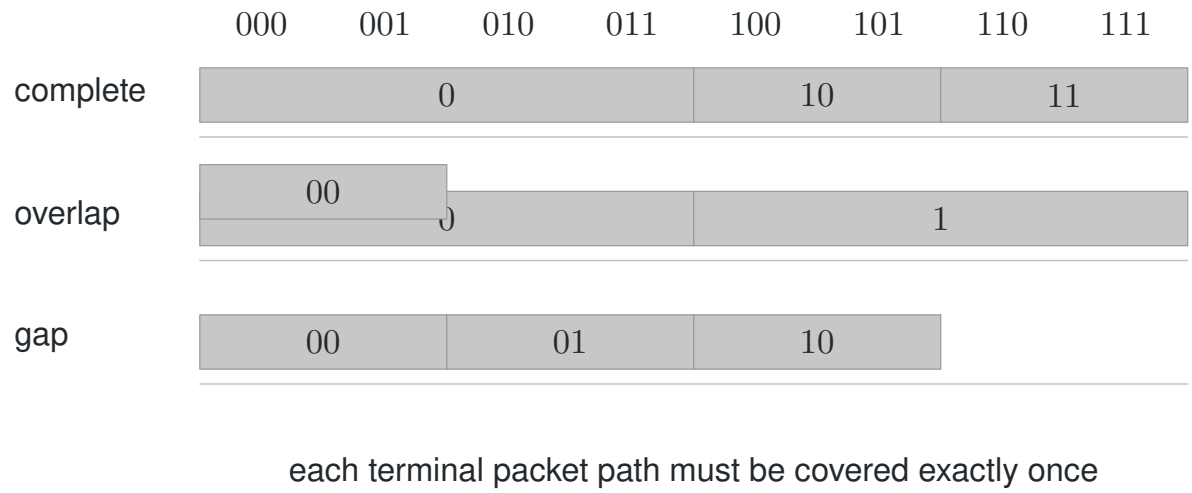
In this fixed orthonormal basis, the squared reconstruction error equals the sum of the squared discarded coefficients. For our running signal:

kept coefficients k	1	2	4	8	12	16
squared error	$59/4$	$115/16$	$11/16$	$1/4$	0	0

The four zero coefficients belong to packet 10, so twelve coefficients suffice for exact reconstruction here. This is a property of the selected signal and basis, not a guarantee that all edge signals need only twelve coefficients.

Do not compare incompatible budgets

A cutoff m in a one-dimensional signed Fourier spectrum means $2m + 1$ bins, including zero. A budget of k largest coefficients is a different rule. Real Fourier synthesis may also require conjugate-pair closure. Neither count alone equals a bit-storage budget once amplitudes, phases, indices, or a selected tree must be encoded. The manuscript's Fourier-versus-Haar experiment is a finite comparison, not a proof that one basis dominates every signal class. Here we isolate the part that can be checked exactly: reconstruction error within one fixed finite basis.



> **Read this as:** Changing coordinates creates no error. Throwing away coefficients does, and orthogonality makes that error exactly accountable.

Plate V.12 / COMPLETE PRUNINGS / NO GAPS AND NO DOUBLE COUNTING

A mixed-depth basis must cover every branch

Chapter V: Definition 11.1, Theorem 11.2.

A complete pruning chooses nodes of a finite refinement tree so that every root-to-terminal path meets exactly one selected node. The horizontal positions below are *terminal packet addresses*, not time intervals in the original signal.

Three candidate selections

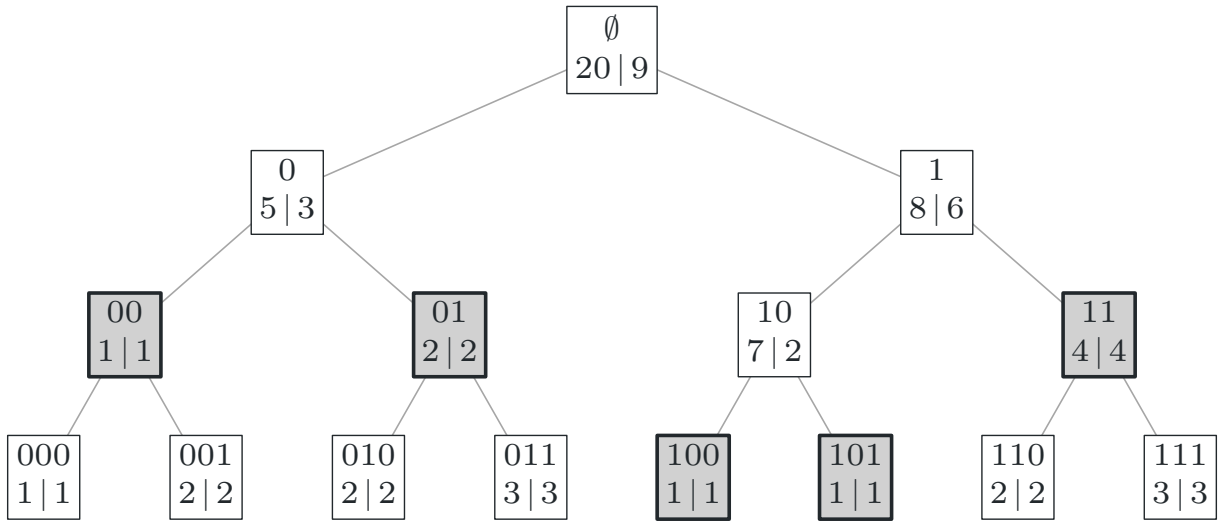
The complete selection $\{0, 10, 11\}$ covers every terminal branch once. The selection $\{0, 00, 1\}$ covers the 00 branch twice: it is not an antichain. The selection $\{00, 01, 10\}$ misses the 11 branch entirely. For actual Haar packets, set $P_v = W_v^* W_v$. Parent-to-child conservation gives

$$P_v = P_{v0} + P_{v1}.$$

Replacing unselected parents by their children until the complete pruning is reached proves $\sum_{v \in \Lambda} P_v = I$. This is why the coefficients at different depths still form an exact coordinate system.

An exhaustive finite check

At depth three the pruning count obeys $a_0 = 1$ and $a_{d+1} = 1 + a_d^2$, giving $1, 2, 5, 26$. The supplied suite checks all 26 covering conditions and all 26 actual 16×16 projector-sum identities. These finite checks illustrate, but do not replace, the universal tree theorem.



> **Read this as:** Mixed depth is allowed. Missing a terminal path or selecting an ancestor and its descendant is not.

Plate V.13 / ADDITIVE COSTS / EXACT DYNAMIC PROGRAMMING

Solve every alternative without searching every alternative

Chapter V: Theorem 11.3, Theorem 11.4.

Give every node the rational stop cost shown below. A node may either stop and pay its own cost, or refine and pay the already optimized costs of its children. The shaded nodes form the selected complete pruning.

node labels: stop cost c_v | optimal subtree cost $V(v)$

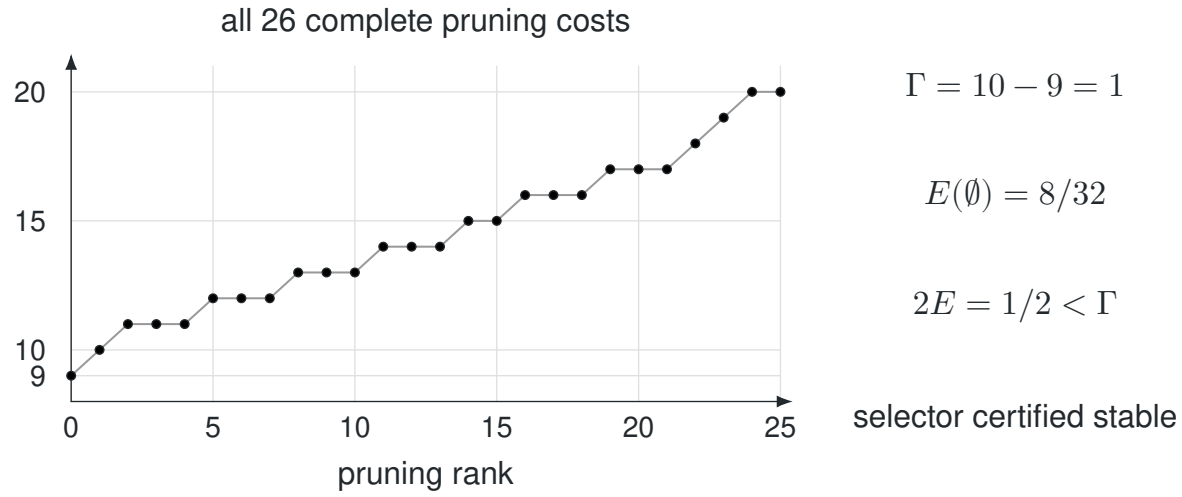
$$V(v) = \min\{c_v,\ V(v0) + V(v1)\}, \qquad V(v) = c_v \text{ at a terminal node.}$$

Read the calculation from the bottom upward

At 10, the children cost $1 + 1 = 2$, better than stopping for 7. At 11, stopping costs 4, better than $2 + 3 = 5$. The right subtree therefore costs 6, better than its stop cost 8. The left subtree costs $1 + 2 = 3$, better than 5. At the root, $3 + 6 = 9$ beats 20. The unique optimum is

$$\Lambda_* = \{00, 01, 100, 101, 11\}, \qquad J(\Lambda_*) = 9.$$

All 26 complete prunings are separately enumerated and give the same minimum. At equality, the rule stops, making the selector deterministic. A singleton tree needs no comparison. The costs here are supplied numbers. The theorem optimizes that stated additive objective. It does not prove those numbers encode the best denoising criterion. Coupled costs that cannot be written as a sum of selected-node costs need a different optimizer.



> **Read this as:** Global optimality follows from the exact stop-or-refine decomposition of a complete pruning, not from a greedy assumption.

Plate V.14 / A GLOBAL MARGIN / NOT A LOCAL HEURISTIC

How far can the costs move before the tree changes?

Chapter V: Theorem 11.3, Corollary 11.5.

The best pruning on the previous page costs 9. The cheapest competitor costs 10. Its exact global gap is therefore $\Gamma = 1$. The plate lists every complete-pruning cost in sorted order, giving each pruning its own horizontal rank.

Propagate an error budget as carefully as a cost

Suppose every node cost changes by at most $\varepsilon_v = 1/32$. A pruning may select as many as eight leaves, so its total cost can change by at most $8/32 = 1/4$. The recursive envelope proves this without guessing which pruning will be selected:

$$E(v) = \max\{\varepsilon_v,\ E(v0) + E(v1)\}, \qquad E(\emptyset) = \tfrac{1}{4}.$$

For any competitor Λ, the changed cost difference is bounded below by

$$J'(\Lambda) - J'(\Lambda_*) \geq \Gamma - 2E(\emptyset) = \tfrac{1}{2} > 0.$$

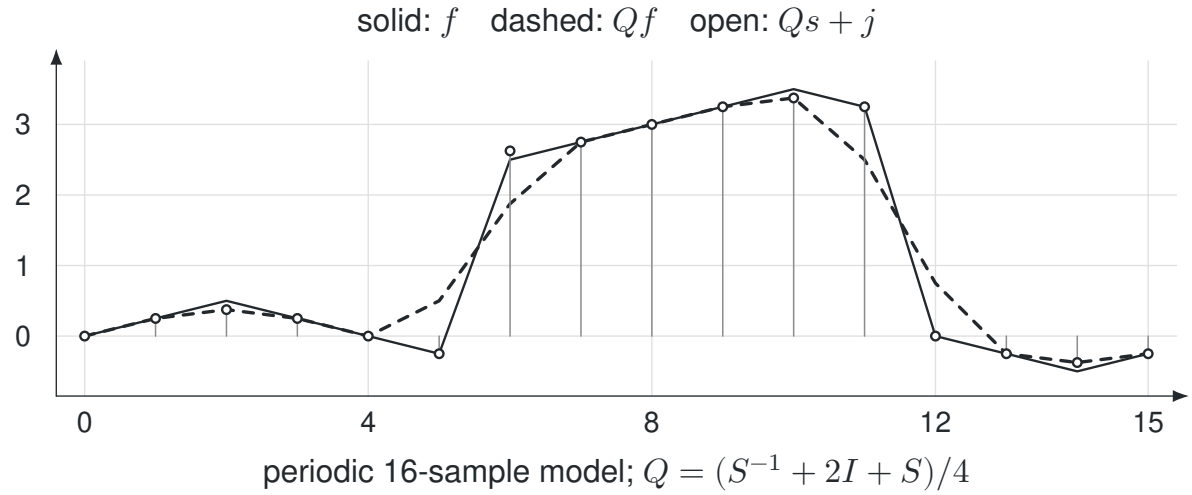
Thus the optimum is unchanged for *every* permitted simultaneous perturbation, not just a sampled noise realization. The envelope is over all feasible prunings, not just the five nodes in the current optimum.

Strict inequality has content

If two competing costs are 9 and 10, moving them to 9.5 and 9.5 removes uniqueness. Equality in $2E = \Gamma$ is therefore not a unique-selector certificate. For ordinary probability, the random node costs and the joint good event must be measurable. Separate nodewise probability bounds do not automatically give the probability of that joint event.

> **Read this as:** The exact selector is stable because its global gap exceeds the total worst-case movement of both competing costs.

Plate V.15 / AN EXACT IDENTITY / A CONDITIONAL INPUT



Retain the jump and approximate the other packet

Chapter V: Theorem 6.1, Corollary 6.2.

Return to the running signal $f = s + j$. For a concrete finite calculation, use the periodic three-tap smoother

$$(Qx)[n] = \tfrac{1}{4}x[n-1] + \tfrac{1}{2}x[n] + \tfrac{1}{4}x[n+1], \qquad n \in \mathbb{Z}/16\mathbb{Z}.$$

The plots compare smoothing the full signal with retaining its supplied jump packet. Every plotted sample is a rational number computed from the displayed formula.

The cancellation is the theorem

Define $\tilde{f} = Qs + j$. Then, sample by sample,

$$\boxed{f - \tilde{f} = s - Qs.}$$

By contrast, linearity gives

$$f - Qf = (s - Qs) + (j - Qj).$$

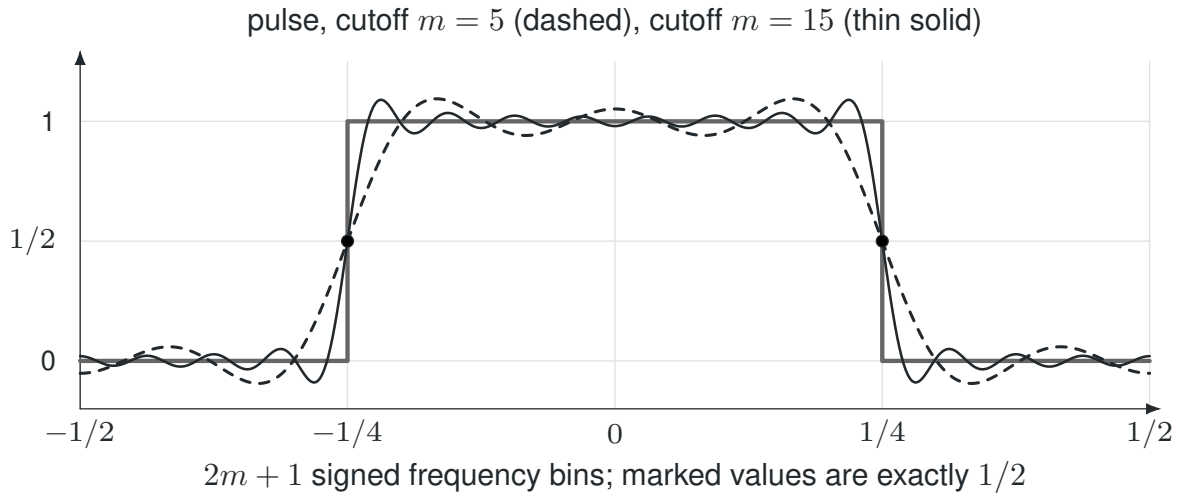
The second error includes a new term caused by smoothing the discontinuity. In this finite example that term is concentrated near the two jump boundaries. The identity itself requires no linearity of the approximation applied to s. Linearity is used only in the comparison with Qf.

The input is not discovered by subtraction

The data here include the correct j. Replacing it with a wrong $\hat{j}$ retains the error $j - \hat{j}$, even when s is approximated perfectly. Multiple amplitudes and overlapping shapes are allowed if their full sum is supplied, but the identity does not estimate that sum from observations. Our finite periodic smoother is an illustration, not a new continuum approximation theorem. Its chosen boundary convention is part of the experiment.

> **Read this as:** Known-edge reconstruction removes the jump from the approximation problem. It does not remove the need to identify the jump.

Plate V.16 / A CONTINUOUS PULSE / EXACT ENDPOINT VALUES



Why a Fourier cutoff cannot reproduce this jump pointwise

Chapter V: Section 6, Section 8.

Use a separate period-one example on $[-1/2, 1/2)$:

$$j(t) = \mathbf{1}_{\{|t|<1/4\}}, \qquad S_m j(t) = \tfrac{1}{2} + \frac{2}{\pi}\sum_{n=1}^{m} \frac{\sin(\pi n/2)}{n}\cos(2\pi n t).$$

This is the exact finite Fourier formula. The drawn curves sample it numerically. The endpoint calculation below is symbolic.

One value is fixed at every cutoff

At $t = \pm 1/4$, every summand vanishes because $\sin(\pi n/2)\cos(\pi n/2) = 0$ for integer n. Hence

$$S_m j(\pm 1/4) = \tfrac{1}{2} \qquad \text{for every } m \geq 0.$$

A larger cutoff resolves a narrower transition, but it does not make the finite trigonometric polynomial discontinuous. The two displayed cutoffs retain 11 and 31 signed frequency bins, respectively, not five and fifteen coefficients.

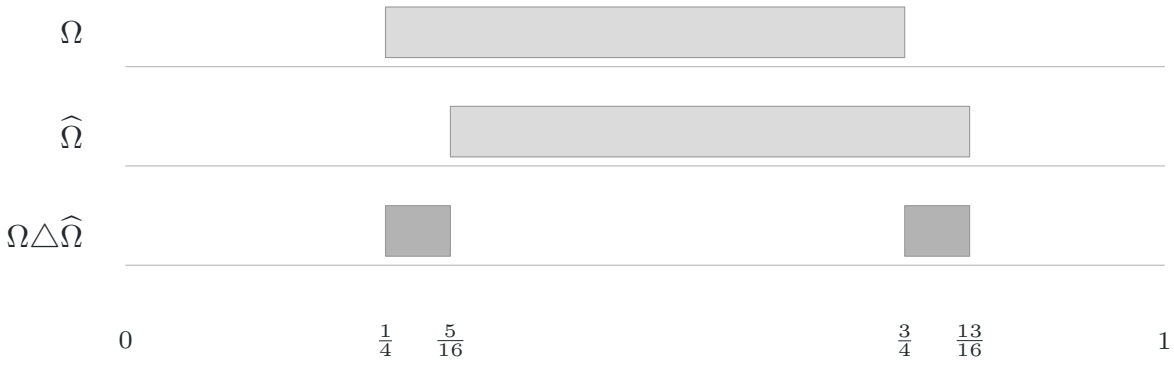
An exact known-packet comparison

Take $s(t) = \frac{1}{4}\cos(2\pi t) + \frac{1}{10}\cos(6\pi t)$. For $m \geq 3$ this smooth packet is already in the retained Fourier span. Thus $S_m s + j = s + j$ exactly in this special model, whereas $S_m(s + j)$ still replaces the pulse by $S_m j$. The values assigned at the two endpoints matter for pointwise error, but do not affect an L^p norm for finite p. The illustrated ringing is not a root enclosure or an asymptotic error certificate.

> **Read this as:** Increasing spectral resolution and retaining a known discontinuity are different operations, with different pointwise consequences.

Plate V.17 / MASK GEOMETRY / TRANSLATION BY ONE SIXTEENTH

Small location errors, different norms



Chapter V: Theorem 7.1.

In Lebesgue measure on the line, let

$$\Omega = [\tfrac{1}{4}, \tfrac{3}{4}], \qquad \widehat{\Omega} = [\tfrac{5}{16}, \tfrac{13}{16}], \qquad a = \hat{a} = 3.$$

The two intervals have the same length. Their disagreement consists of one missed strip and one extra strip, each of width $1/16$.

$$\delta = 1/16, \qquad \mu(\Omega \triangle \widehat{\Omega}) = 2\delta = 1/8$$

$$\|j - \hat{j}\|_1 = 3/8, \qquad \|j - \hat{j}\|_2^2 = 9/8, \qquad \|j - \hat{j}\|_\infty = 3$$

$$|\Omega \triangle \widehat{\Omega}| = \tfrac{1}{8}, \qquad j - \hat{j} = 3(\mathbf{1}_\Omega - \mathbf{1}_{\widehat{\Omega}}).$$

error measure	L^1 norm	squared L^2 norm	L^∞ norm
exact value	$3/8$	$9/8$	3

Area shrinks while the missed jump keeps its height

For a translation by δ with $0 < |\delta| < 1/2$, the symmetric difference has measure $2|\delta|$. At finite p,

$$\|j - \hat{j}\|_p = 3(2|\delta|)^{1/p}.$$

It tends to zero as the displacement tends to zero. The essential supremum stays 3 for every nonzero displacement, because the error reaches height 3 on a set of positive measure. At exactly zero displacement all norms vanish. A nonempty disagreement set of measure zero would be different: it can affect the pointwise supremum while leaving the essential norm unchanged. This is why the chapter distinguishes the two statements.

> **Read this as:** A shrinking boundary strip can give small integrated error and still contain a full-height jump error.

Plate V.18 / COUNTING MEASURE / AN EXACT FINITE BUDGET

Separate amplitude error from mask error

Chapter V: Theorem 7.1.

On the 16 sample addresses, let $\Omega = \{6, \dots, 11\}$ and $\widehat{\Omega} = \{7, \dots, 12\}$. Use true amplitude $a = 3$ and estimate $\hat{a} = 5/2$. There are six true samples, five overlapping samples, and two disagreement samples.

$$a = 3, \quad \hat{a} = 5/2, \quad |\Omega| = 6, \quad |\Omega \triangle \widehat{\Omega}| = 2$$

	4	5	6	7	8	9	10	11	12	13	14
j	0	0	3	3	3	3	3	3	0	0	0
$\hat{j}$	0	0	0	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{5}{2}$	0	0
$j - \hat{j}$	0	0	3	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{5}{2}$	0	0

$$\|j - \hat{j}\|_1 = 3 + 5(1/2) + 5/2 = 8$$

The residual splits exactly as

$$3\mathbf{1}_{\Omega} - \tfrac{5}{2}\mathbf{1}_{\widehat{\Omega}} = \tfrac{1}{2}\mathbf{1}_{\Omega} + \tfrac{5}{2}(\mathbf{1}_{\Omega} - \mathbf{1}_{\widehat{\Omega}}).$$

The missed sample has error 3, the five shared samples have error $1/2$, and the extra sample has error $-5/2$. With *counting measure*,

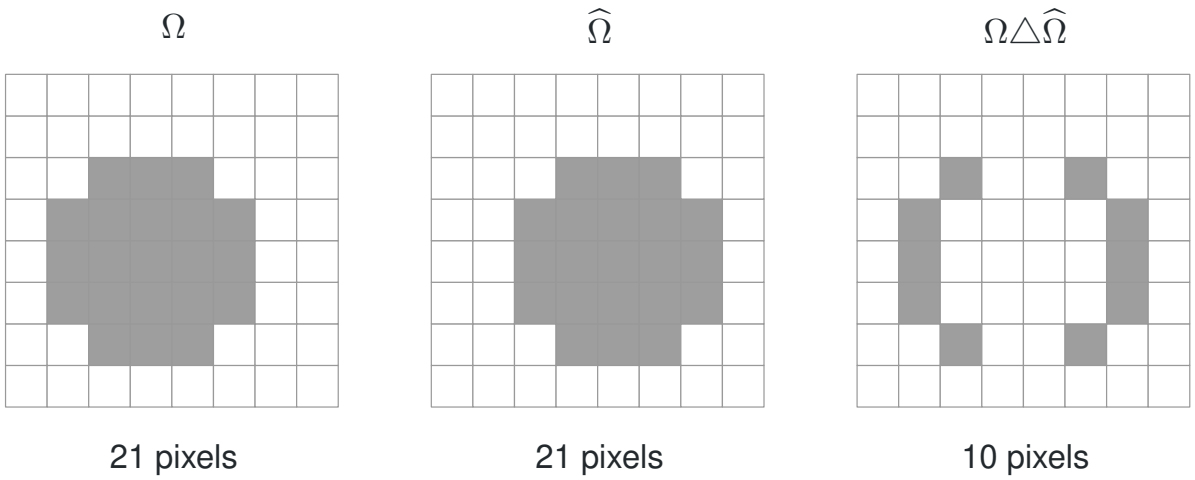
$$\|j - \hat{j}\|_1 = 8, \qquad \|j - \hat{j}\|_2^2 = \tfrac{33}{2}, \qquad \|j - \hat{j}\|_\infty = 3.$$

Read the theorem as a budget, not an equality claim

Here the L^1 bound is attained:

$$|3 - \tfrac{5}{2}|\,|\Omega| + \tfrac{5}{2}|\Omega \triangle \widehat{\Omega}| = \tfrac{1}{2} \cdot 6 + \tfrac{5}{2} \cdot 2 = 8.$$

The L^2 triangle bound is $\frac{1}{2}\sqrt{6} + \frac{5}{2}\sqrt{2}$, and need not be sharp. A background estimate adds another term $\|s - \hat{s}\|_p$. Cancellation between terms can make the total smaller than the bound. Normalized RMSE divides the L^2 norm by $\sqrt{16}$. A boundary-band RMSE uses the band size instead. Changing that denominator changes the reported quantity.



> **Read this as:** Mask error, amplitude error, and background error are separate mathematical inputs. A single reconstruction score conceals that separation.

Plate V.19 / A FINITE IMAGE / AN AMBIGUOUS OBSERVATION

Geometry localizes error while data may leave it ambiguous

Chapter V: Section 7, Section 9.

On the integer 8×8 grid, choose the disk-shaped mask $\Omega = \{(i,j) : (i-3)^2 + (j-3)^2 \le 5\}$ and translate it one pixel to the right. Each mask contains 21 pixels. Their symmetric difference contains exactly 10.

A geometric error calculation is not a segmentation algorithm

For a common amplitude a, the squared counting-measure error is $10a^2$, entirely on the disagreement pixels. The full-image mean squared error is $10a^2/64$. Both are exact, but answer different normalization questions. Now consider the four-sample observation

$$y = (0, \tfrac{3}{2}, 3, 3).$$

It is consistent with either true signal

$$u = (0, 0, 3, 3), \qquad v = (0, 3, 3, 3)$$

under deterministic sup-norm noise at most $3/2$. Indeed $y = (u+v)/2$, and both error norms equal $3/2$. A rule receiving only y and that noise bound cannot be guaranteed to select both distinct true masks correctly.

What additional structure would have to do

A lower noise level, separation, contrast, geometry, or a specified prior can change the identification problem. The example rules out a guarantee at the *stated* noise radius and signal pair, not all recovery results. The manuscript's positive-contrast estimator is deliberately narrower than a universal segmentation method.

> **Read this as:** Exact synthesis can preserve an identified boundary. It cannot decide between two boundaries that the observation model makes indistinguishable.

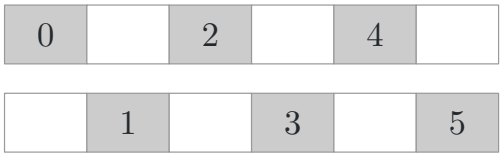


Plate V.20 / POINTWISE SIGNALS VERSUS CAUCHY COEFFICIENTS

Two products, two packet laws

Chapter V: Theorem 12.1.

The word “product” must be typed. Multiplying two signal values at the same time address is not the same operation as multiplying generating series. The distinction changes which packets can interact.

POINTWISE SIGNAL PRODUCT

$$(P_{2,0}x)\,(P_{2,1}y) = 0$$

CAUCHY COEFFICIENT PRODUCT

0	1	2
1	2	0
2	0	1

output label $(i + j) \bmod 3$

$$A = 1 + 2t + 3t^2,\ B = 2 + t^2 : \qquad P_{3,0}(AB) = 2 + 2t^3$$

Pointwise multiplication preserves the same address

For time-residue masks, $(P_{N,i}x)[n](P_{N,j}y)[n] = 0$ when $i \neq j$. Therefore

$$P_{N,k}(x \cdot y) = (P_{N,k}x) \cdot (P_{N,k}y).$$

Here the dot means multiplication at the same sample, not convolution.

Cauchy multiplication adds degrees

For formal series $A(t), B(t)$, the coefficient of t^n is a sum over $a + b = n$. Consequently the output residue is $i + j \pmod N$:

$$P_{N,k}(AB) = \sum_{i+j \equiv k\ (N)} (P_{N,i}A)(P_{N,j}B).$$

For $N = 3$, take $A = 1 + 2t + 3t^2$ and $B = 2 + t^2$. Direct multiplication gives

$$AB = 2 + 4t + 7t^2 + 2t^3 + 3t^4, \qquad P_{3,0}(AB) = 2 + 2t^3.$$

The $2t^3$ term comes from residues $1+2$, not $0+0$. At power zero, the empty product contributes 1 only in residue zero. These are formal coefficient identities and require no convergence assumption.

> **Read this as:** Before applying a packet multiplication rule, specify whether multiplication acts on sample values or on series coefficients.

Plate V.21 / FULL INPUT TUPLES / EXACT CYCLIC INDEXING

Nonlinear neighbors cross channel boundaries

Chapter V: Section 12.

For the periodic running signal define

$$F(x)[n] = x[n] + \tfrac{1}{2}x[n]x[n-1].$$

This is nonlinear and not a convolution operator. Nevertheless its two-channel representation is exact, provided the neighbor comes from the correct channel and index.

$$F(x)[n] = x[n] + \tfrac{1}{2}x[n]x[n-1]$$

$$F_0[n] = e[n] + \tfrac{1}{2}e[n]o[n-1] \qquad F_1[n] = o[n] + \tfrac{1}{2}o[n]e[n]$$

$$e[1] = 1/2, \quad o[0] = 1/4 \qquad o[1] = 1/4, \quad e[1] = 1/2$$

$$F(x)[2] = 9/16 \qquad F(x)[3] = 5/16$$

phase wrap changes the neighbor address; it does not remove the mixed term

Put $e[q] = x[2q]$ and $o[q] = x[2q+1]$, with channel indices taken modulo eight. Then

$$F(x)[2q] = e[q] + \tfrac{1}{2}e[q]o[q-1],$$
$$F(x)[2q+1] = o[q] + \tfrac{1}{2}o[q]e[q].$$

The even output needs the *previous* odd sample. The odd output needs the current even sample. This is the same carry in the address system that appeared in the one-sample delay matrix.

Check two actual outputs

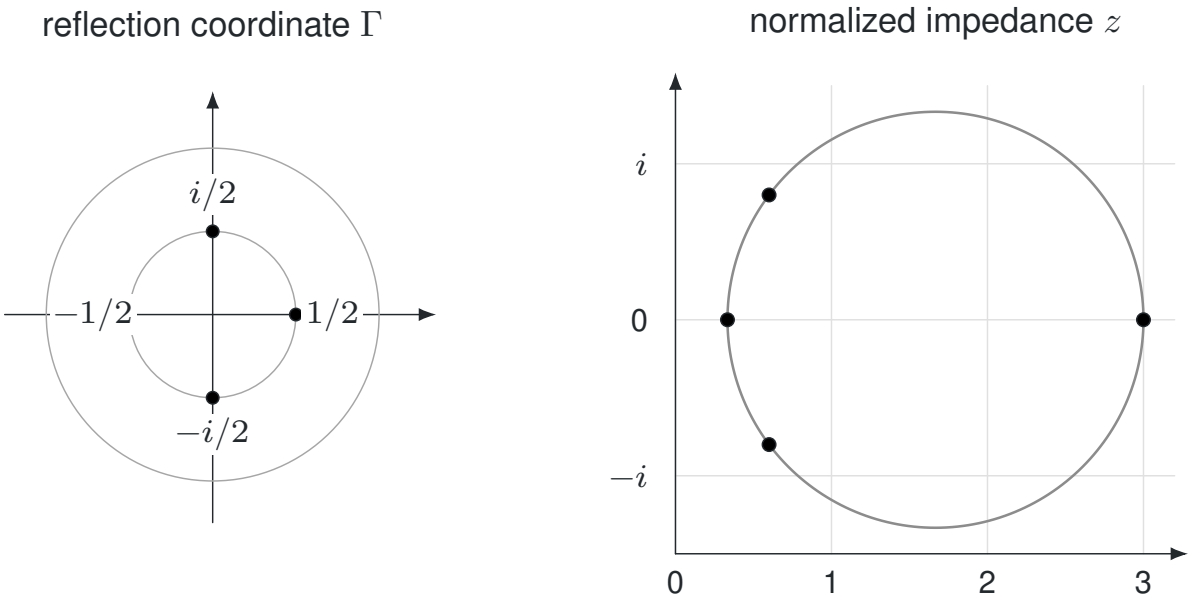
The running values are $x[1] = 1/4$, $x[2] = 1/2$, and $x[3] = 1/4$, so

$$F(x)[2] = \tfrac{1}{2} + \tfrac{1}{2}\tfrac{1}{2}\tfrac{1}{4} = \tfrac{9}{16}, \qquad F(x)[3] = \tfrac{1}{4} + \tfrac{1}{2}\tfrac{1}{4}\tfrac{1}{2} = \tfrac{5}{16}.$$

Applying the same formula independently within each decimated array would use the wrong neighbors. Keeping the full channel tuple avoids that loss of information. The supplied suite compares every output sample in the two implementations using exact rational arithmetic. No convergence, contraction, or approximation property follows merely from writing these exact coordinates. Those require hypotheses on the nonlinear map and the problem being solved.

> **Read this as:** Exact packet coordinates remain available for nonlinear maps. They do not turn cross-channel interactions into independent channel problems.

Plate V.22 / THE CAYLEY CHART / EXACT QUARTER TURNS



One reflection circle, four very different impedances

Chapter V: Theorem 13.2.

Use normalized impedance z and reflection coefficient Γ:

$$\Gamma = \frac{z-1}{z+1}, \qquad z = \frac{1+\Gamma}{1-\Gamma}.$$

The circle $|\Gamma| = 1/2$ is a constant-mismatch orbit. Its four quarter-turn points map to the exact impedances shown below.

$$3, \quad \tfrac{3}{5} + \tfrac{4}{5}i, \quad \tfrac{1}{3}, \quad \tfrac{3}{5} - \tfrac{4}{5}i$$

Γ	$1/2$	$i/2$	$-1/2$	$-i/2$
z	3	$3/5 + 4i/5$	$1/3$	$3/5 - 4i/5$

The coordinates preserve structure, not Euclidean distances

A quarter turn is a rotation in the reflection disk. After pulling back, it is a Möbius map, not a Euclidean rotation of the impedance plane. Equal reflection magnitudes need not give equal impedance magnitudes. The opposite points $1/2$ and $-1/2$ become 3 and $1/3$. The continuous impedance locus is the circle $(\operatorname{Re} z - 5/3)^2 + (\operatorname{Im} z)^2 = 16/9$, also drawn in the plate. Finite passive impedances with $\operatorname{Re} z \geq 0$ map to the closed disk except $\Gamma = 1$. That missing point is obtained only by adjoining impedance infinity. The interior maps to the open right half-plane. The classical Smith grid supplies the geometry. The cyclic labels specify exact rotations on it. Neither a new physical law nor a new optimal sampling theorem is implied by this coordinate description.

> **Read this as:** A simple action in one chart can be nonlinear in another. Conjugacy preserves the action law, not the apparent shape of a displacement.

Plate V.23 / HOMOGENEOUS COORDINATES / NO DIVISION BY ZERO

A pole is a chart boundary, not a broken group action

Chapter V: Theorem 13.2, Corollary 13.3.

Represent impedance by a nonzero pair $[u : v]$, where $[cu : cv] = [u : v]$ for $c \neq 0$. A finite impedance is $[z : 1]$. Infinity is $[1 : 0]$. For a nonzero reflection multiplier w, use

$$A(w) = \frac{1}{2}\begin{pmatrix} 1+w & 1-w \\ 1-w & 1+w \end{pmatrix}.$$

$$A(i) = \tfrac{1}{2}\begin{pmatrix} 1+i & 1-i \\ 1-i & 1+i \end{pmatrix}$$

$z = 0$	$z = -i$	$z = \infty$	$z = i$
$\Gamma = -1$	$\Gamma = -i$	$\Gamma = 1$	$\Gamma = i$

$A(i)^4 = I$: the fourth step returns to $[0 : 1]$

The action is defined before a ratio is taken

The determinant is w, so the matrix cannot send a nonzero pair to zero. Direct multiplication gives

$$A(w)A(w') = A(ww'), \qquad A(1) = I.$$

For $w = i$, the orbit through zero is

$$[0 : 1] \longmapsto [-i : 1] \longmapsto [1 : 0] \longmapsto [i : 1] \longmapsto [0 : 1].$$

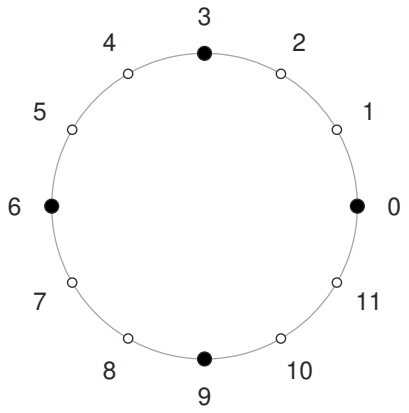
The third point is a legitimate projective point, even though a finite impedance formula has a zero denominator there. The second iterate is $A(-1)$, which swaps the two coordinates. Thus a half turn exchanges 0 and ∞ and sends each finite nonzero z to $1/z$. The matched point $\Gamma = 0$, equivalently $z = 1$, is fixed by every phase multiplier. It is not part of the boundary orbit above. The exact checks test homogeneous pairs and their rescaling equivalence, rather than introducing an artificial complex value for $1/0$.

> **Read this as:** Compute with homogeneous pairs first. A denominator becomes a chart-selection issue rather than an exception to the cyclic action.

Plate V.24 / DYADIC–ODD FACTORIZATION / TWELVE ADDRESSES

Residue labels are not impedance averages

Chapter V: Proposition 14.1.



At phase order $12 = 4 \cdot 3$, the map

$$k \longmapsto (k \bmod 4,\ k \bmod 3)$$

is a bijection from twelve residue addresses to the 4×3 grid. Every cell below contains its unique original address.

	0	1	2
0	0	4	8
1	9	1	5
2	6	10	2
3	3	7	11

row $j \bmod 4$, column $j \bmod 3$

filled: the four coarse rays; open: the eight new rays

The factorization is an intersection of conditions

For integer sample addresses, including negative ones,

$$P_{12,k} = P_{4,k \bmod 4}\, P_{3,k \bmod 3}.$$

The product on the right is composition of two residue masks: both congruences must hold. Coprimality makes their intersection a single class modulo twelve. It is not a formula for multiplying or adding impedances.

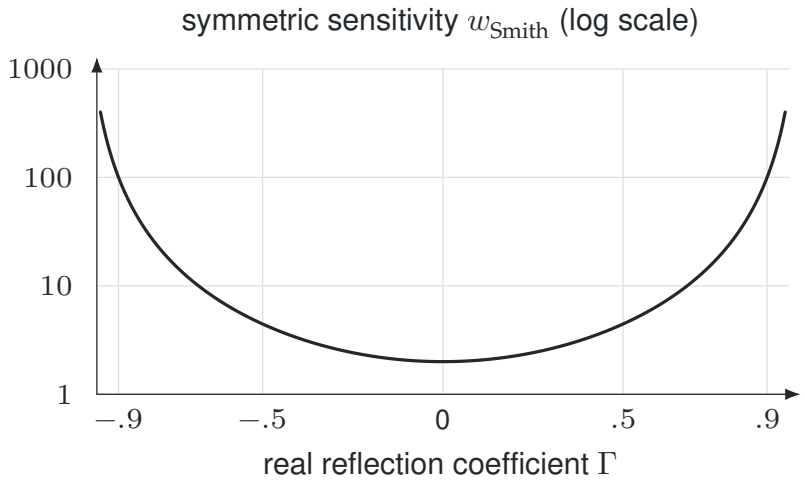
Nested samples and nested projectors are different statements

The four coarse reflection rays occur at indices $0, 3, 6, 9$ of the twelve-ray grid. Thus the geometric sample set is nested. Separately, a coarse coefficient projector is the sum of its fine descendants in a common coefficient space. There is no corresponding rule saying that a coarse impedance is the average of its descendants. The inverse Cayley map is nonlinear. Even opposite reflection points have impedances 3 and $1/3$ in the preceding example. Their average $5/3$ is not the impedance 1 of their averaged reflection coefficient zero.

> **Read this as:** CRT factors addresses. Refinement conserves coefficient packets. Neither operation authorizes linear averaging through a nonlinear chart.

Plate V.25 / LOCAL DERIVATIVES / FINITE INCREMENTS

Sensitivity grows before the pole is reached



Chapter V: Section 14.

Away from $\Gamma = 1$, the inverse Cayley map satisfies

$$\frac{dz}{d\Gamma} = \frac{2}{(1-\Gamma)^2}.$$

Along the real axis, three exact derivatives already show the scale change:

$$\Gamma = \tfrac{1}{2} : 8, \qquad \Gamma = \tfrac{9}{10} : 200, \qquad \Gamma = \tfrac{99}{100} : 20000.$$

Γ	$\lvert dz/d\Gamma \rvert$
$1/2$	8
$9/10$	200
$99/100$	20000

$$\Delta z = 20/9 \neq 2$$

A differential is not the full finite-error formula

For a finite increment ε, with both denominators nonzero,

$$z(\Gamma+\varepsilon) - z(\Gamma) = \frac{2\varepsilon}{(1-\Gamma-\varepsilon)(1-\Gamma)}.$$

At $\Gamma = 9/10$ and $\varepsilon = 1/100$, the actual increment is $20/9$, while derivative times increment is 2. Both are calculated exactly. Their difference comes from using a differential in place of a finite increment. The derivative gives a first order approximation.

What a proposed weight can and cannot certify

Impedance is sensitive near $\Gamma = 1$, and admittance near $\Gamma = -1$. The symmetric weight

$$w(\Gamma) = |1-\Gamma|^{-2} + |1+\Gamma|^{-2}$$

reflects both chart sensitivities. Its growth motivates denser sampling near the endpoints, but does not establish an optimal grid, interpolation rule, or measurement allocation. A finite-error estimate must also control how close the perturbed point comes to either pole.

Read this as: Use the exact finite difference for an error budget. A large derivative diagnoses conditioning. Choosing an optimal algorithm requires further input.

Plate V.26 / EVIDENCE GUIDE / THE FORMAL CONTRACT IS UNCHANGED

What the reader can now verify

Chapter V: Section 21 (formal correspondence), Section E15.

Three worked structures, three distinct kinds of conclusion

Structure	What is established in the original worked layer
Finite signal	Exact signed addressing, filter transfer, Haar reconstruction and energy, sparse coefficient error, and full-tuple nonlinear evaluation.
Finite packet tree	All 26 complete prunings, actual projector sums, the unique cost-9 optimum, and a strict perturbation-margin certificate.
Reflection orbit	Exact rational-complex coordinates, a pole-safe projective action, CRT labels, and finite sensitivity calculations.

What each evidence layer means

Manuscript theorems. The Part I formal correspondence maps twenty theorem-like statements to 225 supporting Lean targets in 23 proof modules. Its compiler and axiom records provide the retained execution evidence. The formal companion gives their scope and reproduction instructions. The additional Part II developments remain outside this twenty-result map.

Recorded exact examples. The symbolic visual suite was rerun for the recorded monograph review. All 181 rational, algebraic, symbolic, and exhaustive finite checks passed. Seven deliberately false assertions were rejected. Numerical samples draw the continuous Fourier and sensitivity curves. They are not promoted to interval enclosures or universal error bounds.

Recorded executions. The recorded checker passed 20 exact tests containing 305,933 assertions and passed 16 verifier tests, including positive and negative controls. The numerical audit of the expanded source passed 11,052 finite checks, mixing exact and numerical calculations. The new extension examples separately passed 38 grouped exact checks and four false controls. These counts measure different operations and are not combined as theorem counts.

Reproducibility. The package preserves the original sources and their reports. Run `python3 build.py` here for an isolated PDF build. The extension finite checker is `checks/verify_extension_examples.py`. Its contract and raw execution manifest are included. The original visual checker requires the listed optional dependencies. PDF assembly does not run Lean or either mathematical checker.

The remaining boundaries are not decorative disclaimers

Known-edge synthesis requires the correct packet. A finite cost optimum depends on the supplied objective. An infinite packet tree, a universal segmentation procedure, minimax recovery rates, and optimal Smith sampling require additional theorems. The core's broad edge-recovery problems are not resolved by these finite examples. Plate V.27 introduces the additional separated-jump recovery results and their explicit hypotheses. The 16-sample running signal is not the 1024-sample manuscript experiment. The 26-pruning example is not its 458,330-pruning benchmark. Their smaller sizes allow every relevant number to be inspected exactly.

> **Read this as:** Coordinates, approximation, identification, optimization, and physical interpretation are separate layers. The examples make their interfaces visible without erasing their hypotheses.

Plate V.27 / PART II / REPRESENTATION BECOMES CONDITIONAL RECOVERY

What the extended developments add

Chapter V: Section 21 (formal correspondence), Section E1, Section E15.

The first twenty-six pages follow the corrected twenty-result formal core. The traditional chapter's second part restores the broader mathematical developments of the earlier expanded manuscript. The next thirteen worked pages make their additional hypotheses and conclusions visible.

Four transitions, with the missing input made explicit

Transition	Additional input	Resulting control
Residues to lattices	A finite-index sublattice and one representative per coset	Exact addresses in several dimensions
Invertibility to stability	Positive lower frame bound and bounded perturbation	Quantified coefficient and reconstruction error
Known jumps to recovery	Separated jumps, sampling, a Lipschitz background, and a strict contrast gap	Exact jump cells and bounded location/amplitude error
Recovered packets to approximation	A bounded linear approximation operator and its norm	A complete two-term error estimate

The two parts have different formal evidence

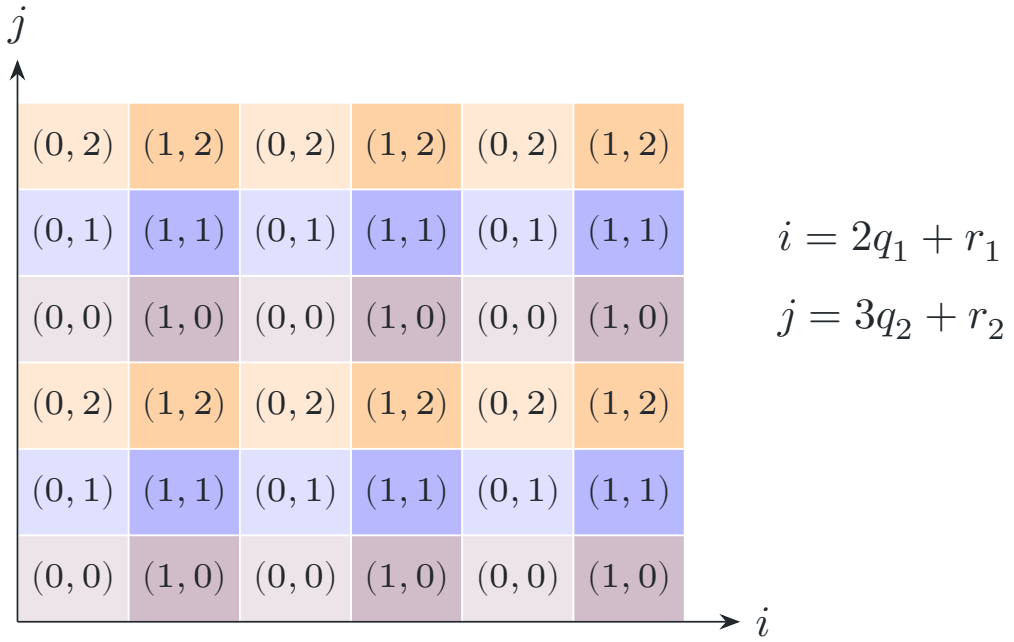
The inherited Lean map covers the twenty designated results of Part I through its 225 supporting targets. The additional traditional proofs in Part II are not silently included in that map. The following pages give mathematical explanations and exact worked specializations of those developments, with a separate checker for the finite examples. The original manuscript's broad edge-recovery questions remain broader than separated one-dimensional jumps. Conditions such as one jump per sample cell, an available wavelet support, and a positive detection margin do real work. In particular, the ambiguous observation on Plate V.19 still rules out an unrestricted recovery guarantee at its stated noise radius.

How to read the extension

Plates V.28–V.30 extend coordinates and stability. Plates V.31–V.34 identify what a singular packet contains and measure its error. Plates V.35–V.39 give three detection mechanisms. Plate V.40 closes the route by combining packet accuracy with a specified approximation operator.

> **Read this as:** A positive recovery theorem can coexist with an impossibility example. Their sampling models, noise bounds, and signal classes decide which conclusion applies.

Plate V.28 / LATTICE COORDINATES / A RECTANGULAR EXAMPLE



Six image phases are six exact address classes

Chapter V: Theorem E3.2, Theorem E3.5, Remark E2.2.

Take $L = 2\mathbb{Z} \times 3\mathbb{Z}$ inside $\mathbb{Z}^2$, with representatives

$$R = \{0, 1\} \times \{0, 1, 2\}.$$

Every address has a unique expression $(i, j) = (r_1, r_2) + (2q_1, 3q_2)$. The six channels are $x_r(2q_1, 3q_2) = x(r_1 + 2q_1, r_2 + 3q_2)$.

Each cell shows its residue label. Colors identify six disjoint classes. They do not average neighboring image pixels.

A negative address is still unique

The point $(-1, 7)$ has representative $(1, 1)$ and lattice displacement $(-2, 6)$, hence channel index $(-1, 2)$. Floor division gives the correct answer in both coordinates. For finite p, the channel norm uses the sum of the pth powers. At $p = \infty$, it uses their maximum. Both equal the norm on the original lattice because the cosets partition all addresses. In ℓ^∞, this coordinate identity does not imply that translates of an impulse are dense: their closure is only c_0.

Refinement partitions a class again

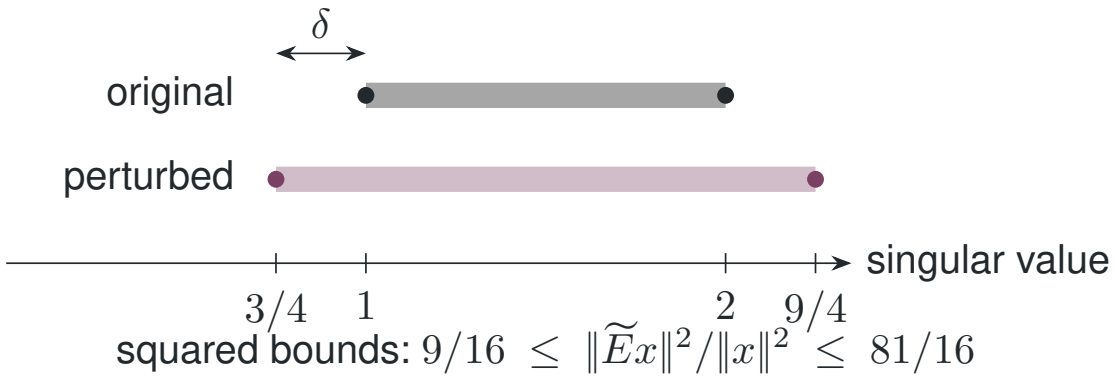
For $L' = 4\mathbb{Z} \times 6\mathbb{Z} \subset L$, the coarse representative $(1, 2)$ has fine representatives

$$(1, 2),\ (3, 2),\ (1, 5),\ (3, 5).$$

Their original-lattice masks sum to the coarse mask. As on Plate V.4, decimated arrays are interleaved, not added entrywise.

> **Read this as:** Dimension changes the address tuple. Unique coset decomposition still supplies exact synthesis and the correct norm identity.

Plate V.29 / FRAME STABILITY / AN EXACT TWO-CHANNEL BANK



A positive singular-value gap survives perturbation

Chapter V: Theorem E5.2, Theorem E5.7, Corollary E5.6.

Consider the constant analysis bank

$$E = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}, \qquad E^*E = \operatorname{diag}(1, 4).$$

It has frame bounds $A = 1$, $B = 4$. For every perturbation with operator norm at most $\delta = 1/4$, the squared-norm bounds remain at least $(1 - 1/4)^2 = 9/16$ and at most $(2 + 1/4)^2 = 81/16$.

Both bounds can be attained

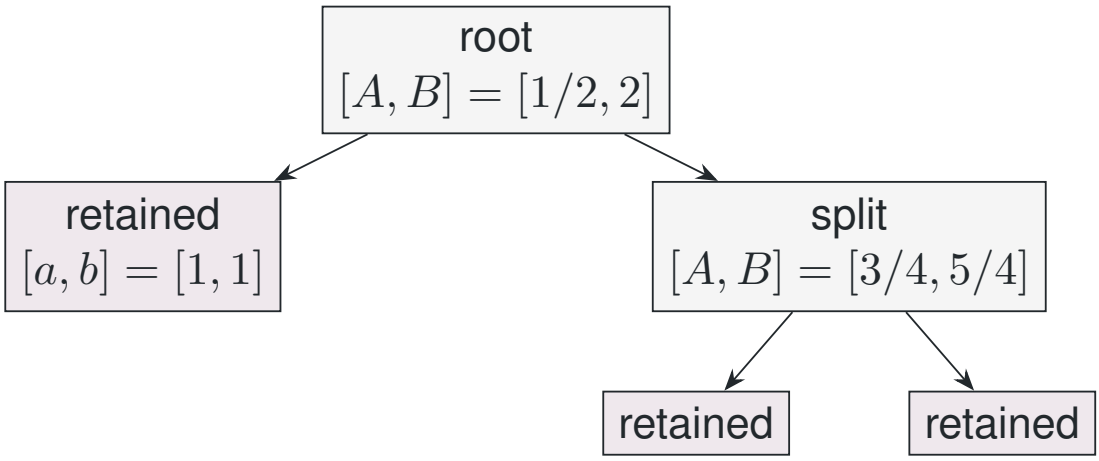
Choose $\Delta E = \operatorname{diag}(-1/4, 1/4)$. Then $\widetilde{E} = \operatorname{diag}(3/4, 9/4)$ has precisely those two frame bounds. Its inverse has operator norm $4/3$. A coefficient error $\nu = (3/4, 0)$ therefore produces signal error $(1, 0)$, attaining the noise bound. The strict condition $\delta < \sqrt{A}$ prevents the lower bound from vanishing. At $\delta = 1$, the perturbation $\operatorname{diag}(-1, 0)$ destroys the first channel entirely.

An inverse and an approximate inverse answer different questions

If the original synthesis $R = \operatorname{diag}(1, 1/2)$ is retained after this perturbation, then

$$R\widetilde{E} - I = \operatorname{diag}(-1/4, 1/8).$$

Its defect norm is $1/4$. Every input has relative reconstruction error at most that value, with equality on the first coordinate. For frequency-dependent banks the theorem uses an essential supremum on the unit circle, not a few sampled frequencies.



> **Read this as:** A lower singular-value gap quantifies stable recovery. A reconstruction defect quantifies the error of the actual synthesis bank being used.

Plate V.30 / LOCAL FRAME CONSTANTS / A MIXED-DEPTH CERTIFICATE

Nonunitary tree bounds propagate along branches

Chapter V: Proposition E6.4.

Suppose the root split has nonnegative squared-norm bounds $A = 1/2$ and $B = 2$. Retain the left child. Split the right child with bounds $3/4$ and $5/4$, then retain both grandchildren.

Start with one at every retained node

The left subtree has bounds $a_0 = b_0 = 1$. The right subtree has $a_1 = 3/4$ and $b_1 = 5/4$. The recursive certificate gives

$$a_{\mathrm{root}} = \tfrac{1}{2}\min\{1, \tfrac{3}{4}\} = \tfrac{3}{8}, \qquad b_{\mathrm{root}} = 2\max\{1, \tfrac{5}{4}\} = \tfrac{5}{2}.$$

Consequently the total leaf coefficient energy lies between $3/8$ and $5/2$ times the root energy. These are guaranteed bounds. No assertion that every admissible collection of local maps attains both constants is needed.

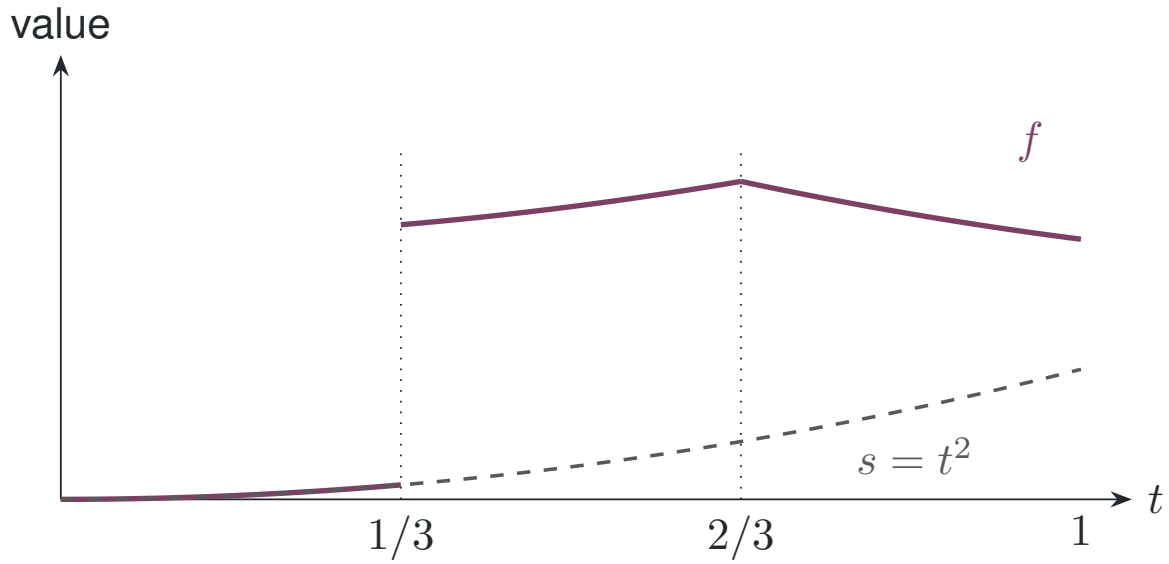
Why a minimum and maximum appear

After the root split, its energy may distribute unevenly between the two children. The lower estimate must survive the least favorable child lower bound. The upper estimate must survive the largest child upper bound. Replacing these by an unweighted average would presume an energy distribution that the hypotheses do not supply. When all local maps are unitary, every factor is one and the recursion recovers exact energy conservation. For general local maps, a positive lower bound alone establishes injectivity and stable inversion on the range. It does not by itself assert surjectivity onto every possible leaf tuple.

> **Read this as:** Exact tree coverage and good conditioning are separate inputs. The first chooses a coordinate route. The second bounds what that route does to norms.

Plate V.31 / TRACE DATA / A STEP AND A RAMP

Derivative jumps have their own packets



Chapter V: Theorem E7.2, Corollary E7.3.

On $[0,1]$, let $H_\tau = \mathbf{1}_{[\tau,1]}$ and take

$$f(t) = t^2 + 2H_{1/3}(t) - 3(t-2/3)_+.$$

The function has a value jump 2 at $1/3$ and a first-derivative jump -3 at $2/3$. Its packet and remainder are

$$j_f(t) = 2\phi_{0,1/3}(t) - 3\phi_{1,2/3}(t), \qquad s_f(t) = t^2.$$

The displayed curves are exact polynomial pieces. The solid jump is not connected across its discontinuity. The dashed curve is the global smooth remainder.

The normalization makes the trace coefficient literal

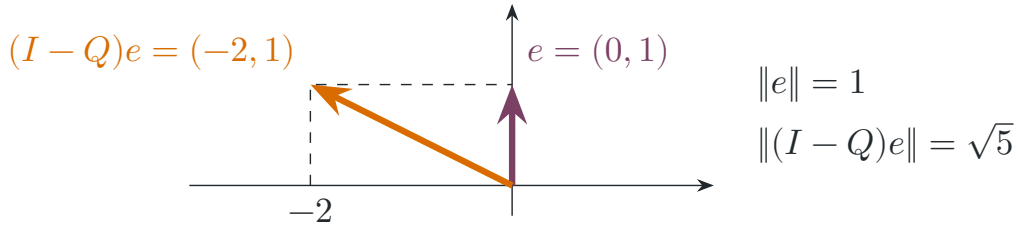
The general packet is $\phi_{m,\tau}(t) = (t-\tau)_+^m/m!$. Its derivative of order m has a unit trace jump, while its other classical trace jumps vanish. Thus its multiplier is exactly the jump being removed, with no hidden factorial. Here the remainder has matching value and first-derivative traces and belongs to $W^{2,p}(0,1)$ for every $1 \le p \le \infty$. Its second weak derivative is 2. The singular packet accounts for the distributional boundary terms that would otherwise arise at the breakpoints.

What the general theorem requires

Each piece must lie in the stated Sobolev class and possess the specified one-sided traces. Subtracting the finite trace packet then joins those pieces into a global Sobolev remainder. This is a theorem about finitely many declared breakpoints, not a representation of every possible singular measure or arbitrary image boundary.

> **Read this as:** A value jump uses a step. A slope jump uses a ramp. The derivative order determines the packet and its normalization.

Plate V.32 / ESTIMATED PACKETS / AN EXACT AMPLIFICATION EXAMPLE



The approximation operator also acts on packet error

Chapter V: Theorem E7.8.

Let Q be a bounded *linear* operator and set $e = j - \hat{j}$. Substituting $f = s + j$ into $\hat{f} = Q(f - \hat{j}) + \hat{j}$ gives

$$f - \hat{f} = (I - Q)s + (I - Q)e.$$

The second term includes the action of Q on the packet error. Linearity is required for this split.

An oblique projection can increase the error

In $\mathbb{R}^2$, choose

$$Q = \begin{pmatrix} 1 & 2 \\ 0 & 0 \end{pmatrix}, \qquad s = (1,0), \qquad e = (0,1).$$

Then $Q^2 = Q$ and $Qs = s$, but $(I - Q)e = (-2, 1)$. The smooth error is zero while the unit packet error becomes a reconstruction error of norm $\sqrt{5}$. For a fully specified realization, take $j = e$ and $\hat{j} = 0$. Then $f = (1, 1)$, $\hat{f} = Qf = (3, 0)$, and their difference is exactly $(-2, 1)$.

Use the actual operator bound

The estimate that always holds in this setting is

$$\|f - \hat{f}\| \le \|s - Qs\| + (1 + \|Q\|)\|e\|.$$

Here $\|Q\| = \sqrt{5}$, so the bound is conservative. For an orthogonal projection, $\|I - Q\| \le 1$ gives a sharper estimate. The operator's geometry determines which bound can be used.

> **Read this as:** Recovering the packet and approximating the background are separate tasks, but the chosen approximation operator couples their final errors.

Plate V.33 / REGION VALUES / EVERY MISCLASSIFICATION HAS A WEIGHT

An overlap matrix is an exact error ledger

Chapter V: Theorem E8.1, Theorem E8.4.

Let two piecewise-constant signals have region values $a = (0, 2, 5)$ and $b = (0, 2, 5)$ on a counting-measure domain of twelve samples. Suppose their overlap counts are

$$M = \begin{pmatrix} 3 & 1 & 0 \\ 0 & 2 & 1 \\ 1 & 0 & 4 \end{pmatrix}.$$

The row totals $(4, 3, 5)$ are the true region sizes. The column totals are also $(4, 3, 5)$, although three samples are assigned to the wrong values.

	$b_0 = 0$	$b_1 = 2$	$b_2 = 5$
$a_0 = 0$	3	1	0
$a_1 = 2$	0	2	1
$a_2 = 5$	1	0	4

off-diagonal squared error

$$1 \cdot 2^2 + 1 \cdot 3^2 + 1 \cdot 5^2$$

$$= 38$$

Equal error counts need not mean equal reconstruction error

The three off-diagonal entries contribute one sample each. Their value differences have magnitudes 2, 3, and 5, so

$$\|j - \hat{j}\|_1 = 2 + 3 + 5 = 10, \qquad \|j - \hat{j}\|_2^2 = 4 + 9 + 25 = 38.$$

The counting-measure supremum error is 5. The full-domain mean squared error is $38/12 = 19/6$. A mismatch fraction of $3/12$ reports a different statistic and omits all three amplitude weights.

The formula requires partitions

For measurable partitions (E_i) and (F_j), with $M_{ij} = \mu(E_i \cap F_j)$,

$$\|j - \hat{j}\|_p^p = \sum_{i,j} |a_i - b_j|^p M_{ij}, \qquad 1 \le p < \infty.$$

Each location belongs to exactly one intersection. Overlapping indicator packets that are summed at the same location must first be converted to their actual combined value regions before this partition formula is applied.

> **Read this as:** Geometry supplies the overlap counts. Signal values supply the weights. Their combination gives the norm relevant to reconstruction.

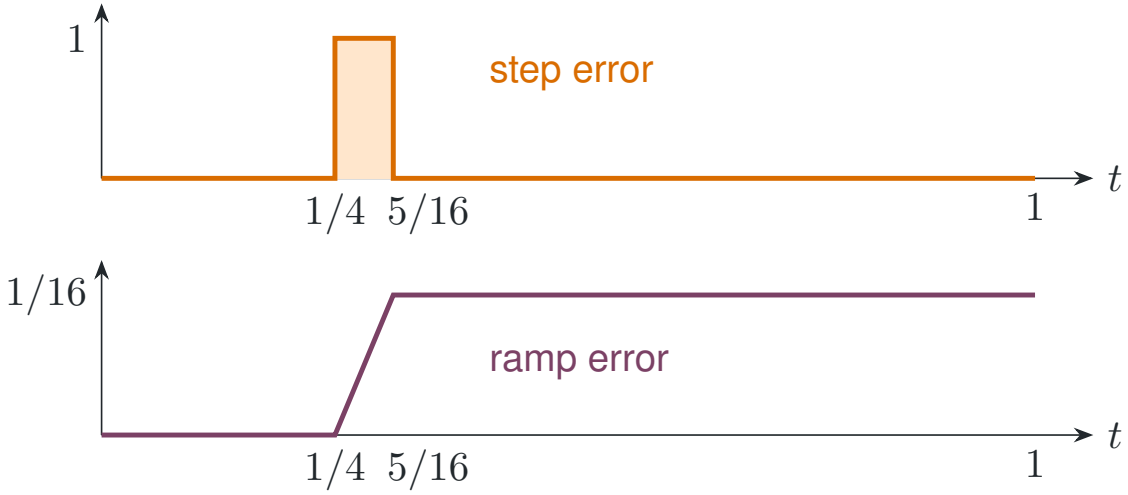


Plate V.34 / LOCATION STABILITY / A ONE-SIXTEENTH DISPLACEMENT

A shifted step and a shifted ramp have different moduli

Chapter V: Corollary E8.2, Theorem E8.3, Theorem E8.7.

Set $\tau = 1/4$, $\hat{\tau} = 5/16$, and $\delta = 1/16$. A unit step differs only on the interval between its two locations:

$$\|H_\tau - H_{\hat{\tau}}\|_2 = \sqrt{\delta} = \tfrac{1}{4}, \qquad \|H_\tau - H_{\hat{\tau}}\|_\infty = 1.$$

For a ramp, the error height shrinks too

Write $r_\tau(t) = (t - \tau)_+$. The difference grows linearly from zero to δ on $[\tau, \hat{\tau}]$ and stays at δ on $[\hat{\tau}, 1]$. Direct integration gives

$$\|r_\tau - r_{\hat{\tau}}\|_2^2 = \frac{\delta^3}{3} + (1 - \hat{\tau})\delta^2 = \frac{17}{6144} < \frac{1}{256} = \delta^2.$$

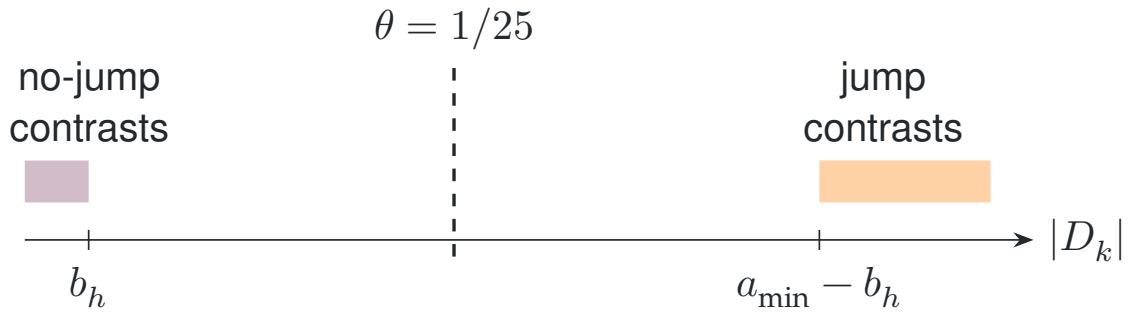
Thus the L^2 ramp error is at most δ, and its supremum error is exactly δ. Positive-order truncated powers are Lipschitz in location, with the order-dependent constants supplied by the theorem.

The geometric analogue needs a tube hypothesis

If $E \triangle F \subseteq N_\delta(\partial E)$ and the tube measure is bounded by $C\delta$ for the stated range $0 < \delta < \delta_0$, then an equal-amplitude packet has finite-p error at most $|a|(C\delta)^{1/p}$. A mere visual impression that two boundaries are close does not establish the inclusion or the tube estimate.

> **Read this as:** A displaced value jump keeps its full height on a smaller set. A displaced derivative-jump packet also decreases in height.

Plate V.35 / DETERMINISTIC RECOVERY / A NUMERICAL CERTIFICATE



A strict contrast gap locates every separated jump cell

Chapter V: Lemma E9.1, Theorem E9.2, Example E9.7.

Assume a real signal is a Lipschitz background plus jumps. No jump occurs at a sample point, and each grid cell contains at most one jump. With spacing h, background constant M, and sample noise bounded by ε, write

$$b_h = Mh + 2\varepsilon.$$

A no-jump contrast has magnitude at most b_h. A jump contrast differs from its true amplitude by at most b_h.

Use the manuscript's exact numerical inputs

For $h = 1/256$, $M = 1/2$, $\varepsilon = 1/500$, and $a_{\min} = 2/25$,

$$b_h = \frac{381}{64000} < \frac{3}{500}, \qquad 2b_h < \frac{2}{25}.$$

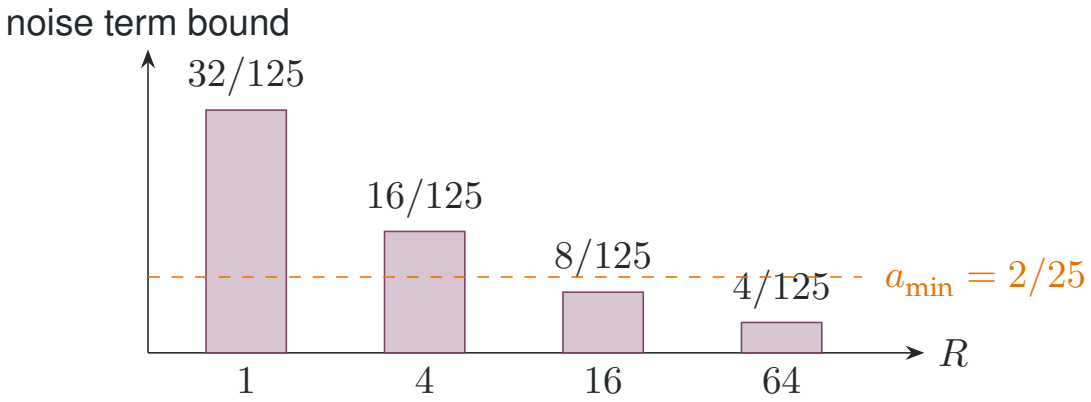
The threshold $\theta = 1/25$ lies strictly between b_h and $a_{\min} - b_h$. Thresholding $|y_{k+1} - y_k|$ therefore identifies exactly the jump-containing cells. Their midpoints locate each jump within $1/512$, and each estimated amplitude differs by at most $381/64000$.

The recovered object is a cell, then an estimate

The theorem does not claim the exact real-valued breakpoint from a finite grid. It supplies the correct cell and a controlled representative of that cell. For real jumps, the amplitude error is too small to reverse the sign. Two opposite jumps in one cell could cancel in the contrast, which is why the separation assumption cannot be dropped. For Q jumps the finite-p packet bound contains both Qb_h and the location term $(\frac{h}{2}\sum_q |a_q|^p)^{1/p}$. A growing number of jumps or shrinking separation requires its own analysis.

> **Read this as:** Exact detection means exact cell identification under a strict margin. Location and amplitude remain quantitative estimates with explicit errors.

Plate V.36 / SUBGAUSSIAN RECOVERY / A CONSERVATIVE SAMPLE BUDGET



Repeated observations shrink the noise side of the gap

Chapter V: Theorem E9.8, Corollary E9.9, Corollary E9.11.

Suppose all noise observations are independent and centered, with moment-generating bound $\mathbb{E}e^{\lambda\eta} \le e^{\sigma^2\lambda^2/2}$. Averaging R observations at each of $n+1$ sample sites replaces σ by $\sigma/\sqrt{R}$. A sufficient recovery condition is

$$a_{\min} > 2Mh + \frac{4\sigma}{\sqrt{R}}\sqrt{\log(2n/\delta)}.$$

The probability of simultaneous recovery is then at least $1-\delta$, subject to the same separated-jump sampling model.

One explicit conservative choice

Take $n = 256$, $M = 1/2$, $\sigma = 1/50$, $\delta = 1/20$, and $a_{\min} = 2/25$. Since $\log(10240) < 10 < (16/5)^2$, choosing $R = 16$ makes the right-hand side strictly less than

$$\frac{1}{256} + \frac{1}{50}\frac{16}{5} = \frac{2173}{32000} < \frac{2}{25}.$$

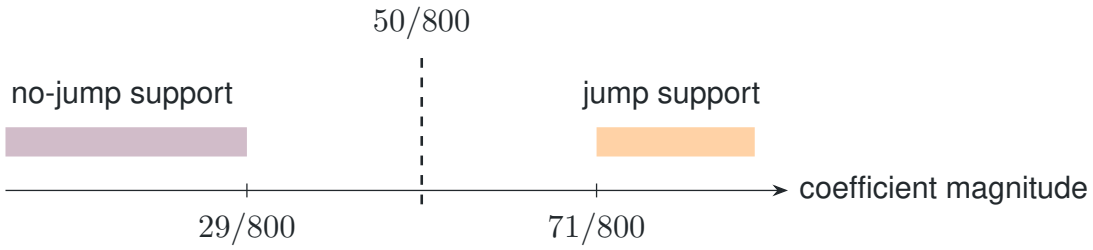
Thus sixteen independent observations per sample site suffice for this bound. It is a sufficient budget, not a claim of optimal sample complexity. The exact checker certifies $e^{10} > 10240$ using a rational Taylor partial sum, so the displayed logarithm bound is not based on rounded numerical logarithms.

Dependence between adjacent contrasts is allowed

Neighboring differences share one sample. The proof does not require those differences to be independent: it bounds each tail and applies a union bound across all cells. Independence of the underlying sample noises supplies the stated sub-Gaussian difference proxy. For a fixed separated signal model, a noise scale satisfying $\sigma_n\sqrt{\log n} \to 0$ gives the stated recovery consistency in probability. A fixed positive noise scale with one observation per site does not satisfy that condition.

Read this as: More grid points and more repeated observations affect different terms. Finer spacing reduces background variation. Averaging reduces noise.

Plate V.37 / SCALE SEPARATION / A QUANTIFIED THRESHOLD



Haar sees a jump only through its position in the support

Chapter V: Theorem E10.1, Theorem E10.2, Corollary E10.3.

Use a normalized Haar wavelet on an available interval of length L on the real line, positive on its left half and negative on its right half. Here H_τ is the half-line step $\mathbf{1}_{[\tau,\infty)}$, so there is no artificial second endpoint jump. If u is the relative jump position in the support, then

$$|\langle aH_\tau, \psi\rangle| = |a|\sqrt{L}\min\{u, 1-u\}.$$

The coefficient vanishes when the jump lies exactly at a support boundary.

A worked gap with all three contributions

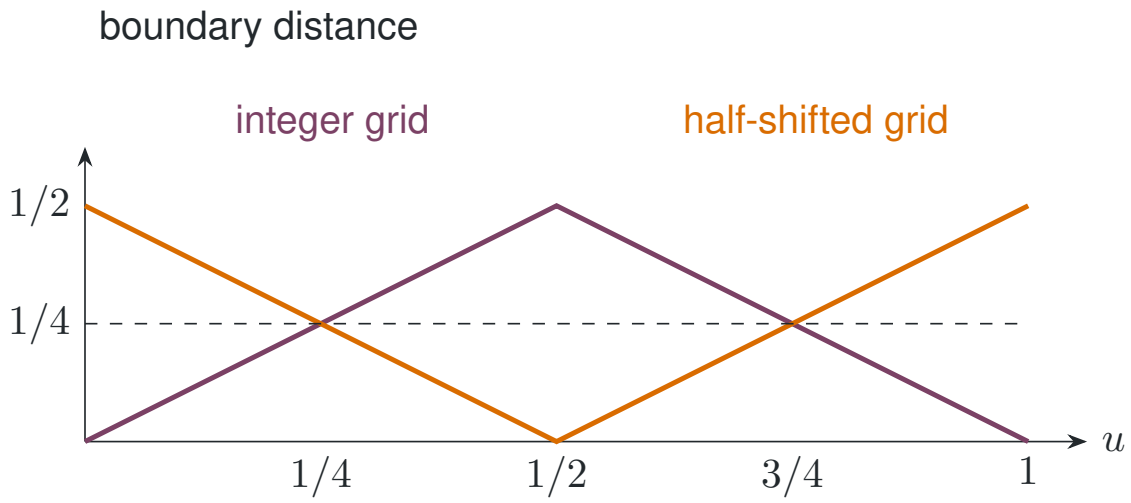
Take $L = 1/4$, $M = 1$, noise bound $\varepsilon = 1/100$, jump size $|a| = 1$, and relative boundary distance at least $\rho = 1/4$. The smooth and noise contributions together are bounded by

$$\frac{M}{4}L^{3/2} + \varepsilon\sqrt{L} = \frac{1}{32} + \frac{1}{200} = \frac{29}{800}.$$

The jump contributes at least $|a|\rho\sqrt{L} = 1/8$. The observed coefficient therefore has magnitude at least $71/800$. The threshold $1/16 = 50/800$ separates every such jump support from every support containing no jump.

The available support is part of the hypothesis

A fixed extension is needed if the observation domain ends inside a desired wavelet support. Also, the selected support must contain only the specified jump. An unmodeled second jump can reinforce or cancel the coefficient.



> **Read this as:** Scale determines the smooth contribution, but alignment determines the jump contribution. A detection guarantee needs both.

Plate V.38 / HAAR SUPPORT GEOMETRY / A QUARTER-CELL GUARANTEE

Two half-shifted grids remove exact alignment failure

Chapter V: Theorem E10.4, Corollary E10.5.

Normalize the support length to $L = 1$. The first grid has boundaries at integers. The second has boundaries at half-integers. For a point at position u modulo one, consider its distance to the nearest boundary of each grid.

At least one distance is one quarter or larger

If $1/4 \le u \le 3/4$, the original cell works. Outside that range, a shifted cell works. At $u = 1/8$, the original margin is $1/8$ but the shifted cell $[-1/2, 1/2)$ gives margin $3/8$. At $u = 1/4$, both margins equal $1/4$, showing that the uniform constant cannot be increased for these two grids. Restoring L, every jump has a support with boundary distance at least $L/4$ in one grid. If L is smaller than the minimum jump separation, that support contains no other jump.

Insert the geometric guarantee into the analytic estimate

The alignment-independent gap condition is

$$\frac{|a|}{4} > 2\varepsilon + \frac{M}{2}L.$$

For the numbers on Plate V.37, the right side is $1/50 + 1/8 = 29/200$, strictly below $1/4$. Hence one of the two grids supplies a detectable support for every jump, regardless of its position relative to the original grid. This certifies a useful support per jump. It does not by itself specify a unique rule for merging duplicate detections from two grids into exact breakpoint estimates.

> **Read this as:** A second grid repairs a geometric blind spot. The contrast inequality and separation hypotheses still supply the recovery guarantee.

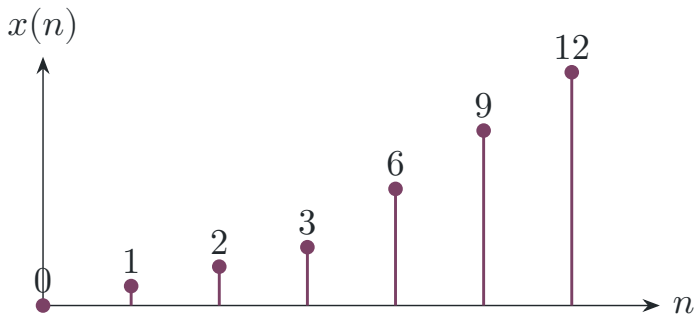


Plate V.39 / BOUNDARY STENCILS / SIGNAL RESPONSE AND NOISE GAIN

Higher differences annihilate polynomial interiors

Chapter V: Theorem E10.6, Proposition E10.7, Corollary E10.8.

Let $x(n) = n + 2(n-3)_+$ on the integer line. Its slope changes from one to three at the breakpoint 3. The second forward difference is

$$\Delta^2 x(n) = x(n+2) - 2x(n+1) + x(n).$$

$\Delta^2 x(2) = 2$

all other displayed second differences vanish

An exact small stencil calculation

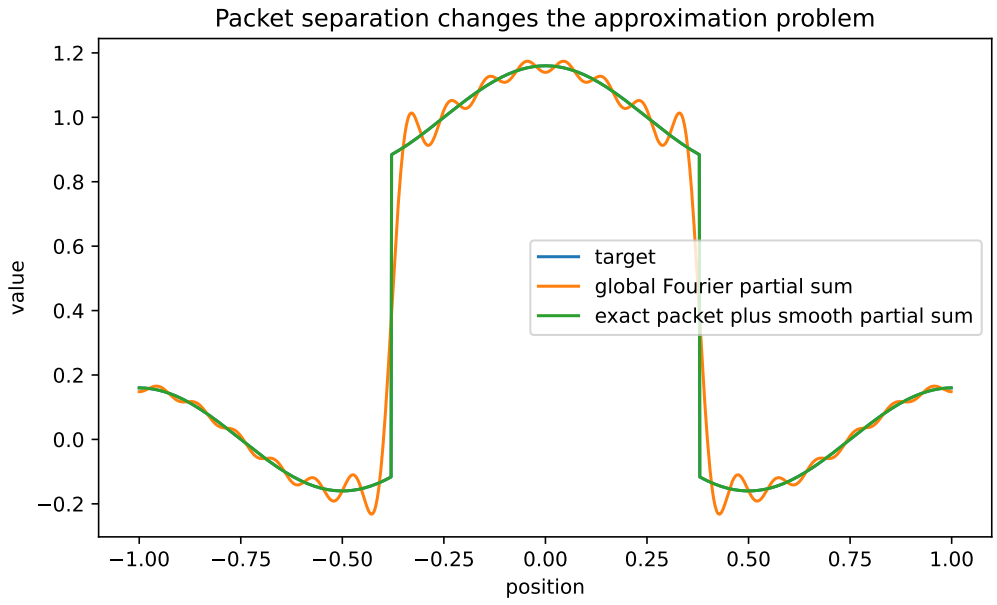
The values at $n = 0, \dots, 6$ are $(0, 1, 2, 3, 6, 9, 12)$. The second differences at $n = 0, \dots, 4$ are $(0, 0, 2, 0, 0)$. The only nonzero stencil straddles the slope change. For a piecewise polynomial of degree at most d, Δ^{d+1} vanishes whenever its complete stencil lies inside one polynomial piece. Candidate responses are confined to at most $d+1$ starting addresses before each breakpoint. They are boundary bands, not necessarily exact breakpoint locations.

Differencing also acts on noise

The absolute binomial coefficients of Δ^m sum to 2^m. With $\|\eta\|_\infty \le 1/16$, second-difference noise is bounded by $4/16 = 1/4$. The true response 2 remains at least $7/4$, while all responses away from the breakpoint band remain at most $1/4$. Threshold one separates them. The general robust-band statement assumes that each breakpoint has at least one sufficiently large true response. A breakpoint can fail that assumption through its amplitude or local configuration. Annihilation away from boundaries does not prove a lower bound at every boundary.

> **Read this as:** A vanishing interior response is structural. Reliable detection also requires the boundary response to exceed the amplified noise.

Plate V.40 / THE TWO ERRORS / A COMPLETE READING CONTRACT



Conditional Gibbs control closes the reconstruction estimate

Chapter V: Theorem E11.2, Theorem E11.3.

The exact retained-packet approximation shares the same discontinuity as its target. If $f = s + j$ and $Q_m s \to s$ uniformly, then

$$\|f - (Q_m s + j)\|_\infty = \|s - Q_m s\|_\infty \longrightarrow 0.$$

The approximants themselves may be discontinuous. There is no conflict with the failure of continuous Fourier polynomials to converge uniformly to a jump.

Preserved vector figure from the expanded source. It illustrates the choice of approximation target. It is not an independent universal recovery certificate.

Estimated packets need the operator norm too

If the bounded linear operators satisfy $\sup_m \|Q_m\|_{L^p \to L^p} \le C_Q$, then

$$\|f - \hat{f}_m\|_p \le \|s - Q_m s\|_p + (1 + C_Q)\|j - \hat{j}_m\|_p.$$

For an orthogonal L^2 projection one may use $\|I - Q_m\| \le 1$, sharpening the packet multiplier to one. Such a bound must be justified in the norm actually being used. In particular, uniform boundedness of Fourier partial sums in the supremum norm is not supplied by this theorem.

What the complete guide establishes

Plates V.1–V.26 preserve the original worked layer. Plates V.27–V.40 explain the additional traditional developments, outside the inherited twenty-result Lean map. The new exact examples have their own finite arithmetic record. They do not extend the formal coverage merely by appearing beside formally mapped results. The final package keeps recorded computations and inherited compiler reports attached to their stated scope. The symbolic visual suite was rerun, with 181 checks passed and seven invalid controls rejected. Lean compiler evidence remains inherited. No fresh Lean run is claimed.

Read this as: A complete error claim specifies the signal class, the recovered packet, the approximation operator, and the norm. Each term can then be improved and checked on its own terms.

CHAPTER VI

Transfer Semigroups and Memory

Probabilistic refinement, fractional operators, and exact hidden-state elimination

Static descriptions now become evolution and conditioning problems.

Evolution, probability and conditioning share a transfer language. Eliminating hidden states produces memory terms whose hypotheses remain part of the model.

IN THIS CHAPTER

Mathematical text 511

Visual studies 616

Formal companion 1992

Sources and references 2678

Scope

Finite-state, common-gap and fixed-partition restrictions remain explicit. Completion, uniform refinement control and stable infinite latent-packet closure remain open. Floating residuals are not interval certificates.

The next chapter treats quantum seeds, operator grammars and finite effective dynamics.

How to use this volume

Part I. The thirty-three-result formal core, including nonnormal memory and canonical finite holomorphic naturality.

Part II. The complete strengthened mathematical development: bounded refinement towers, Bayesian information, Hermite transfer, quantitative memory compression, and competing risks.

Part III. Complementary results, exact examples, and the boundedoperator reciprocal calculus received from Chapter IV.

Part IV. Forty-two visual pages work through exact finite models, analytical examples, and the boundaries of the formal contract.

Reading this chapter

This chapter studies transfer semigroups in three complementary settings. Part I establishes the finite formal core. Part II develops bounded refinement towers, probabilistic conditioning and analytical realizations. Part III gives additional results on product-topology limits, reversible coarse dynamics, filtering, perturbation and operator substitution. Their hypotheses distinguish the constructions even where the underlying identities overlap.

The formal companion covers exactly the thirty-three scoped results of Part I. Its 341 supporting Lean theorem declarations lie in 47 proof modules. The wider namespace audit includes definitions and generated declarations. Formal coverage does not automatically extend to Parts II or III. The companion supplies the exact targets, assumptions and specialization boundaries.

Part I includes three explicitly open conjectures. Part II supplies bounded or finite theorems for several related questions. It does not settle arbitrary continuum limits, unbounded-generator convergence, general statistical sufficiency, or globally optimal nonnormal model reduction. The reader should keep each result's declared space, topology, positivity, and stability hypotheses. Part I's mass-only Bayesian commutation criterion assumes at least two coarse blocks. Part II's stronger sufficiency convention also preserves within-block conditionals, so its one-block case still requires a constant likelihood.

The worked atlas follows the mathematical development through exact finite models and analytical examples. Calculations illustrate stated ranges and assumptions. Their computational records remain distinct from both the written proofs and the formal declarations.

Read Part I for the common operator language and the exact formal contract. Read Part II for bounded Banach-space development and the broader probabilistic and analytical realizations. Read Part III for product-topology limits, reversible coarse dynamics, prior-restricted and coarse filtering, killed-transfer perturbations, rational realization, and the transferred operator reciprocal family. Section numbers in Part II have prefix E. Those in Part III have prefix R. Original labels and statement locations are mapped in the editable sources.

Contour winding, positive memory decay, finite moment closure and eventual absorption each require the hypotheses stated with their results. When the spaces vary along a refinement system, summability must be read in the specified ambient setting.

Part I The formal core

Projector-Resolved Seed Calculus VI

Transfer Semigroups: Stochastic, Bayesian, Fractional, and PDE Realizations

Overview

This chapter develops the transfer-semigroup realization of the projector-resolved seed calculus. A seed is propagated by a one-parameter semigroup, a Markov kernel, a normalized Bayesian transfer, a fractional spectral power, a Green operator, or a potential-weighted Feynman–Kac operator. Exact packet projectors resolve every transfer into input-output blocks, and the semigroup law becomes block convolution over intermediate packets. Coarse and fine generators are compared by a refinement defect. A Duhamel identity proves that this generator-level defect is exactly the source of the corresponding semigroup defect and gives a quantitative stability bound. In the stochastic realization, point-mass seeds generate random walks and continuous-time Markov evolution. Exact lumpability is the vanishing of the same refinement defect. Conditional expectation is treated as a weighted orthogonal packet projector, with nested partitions producing martingale-difference packets. Bayesian conditioning is a normalized nonlinear operator. Its independent-data composition law, packet-evidence decomposition, stability bound, conjugate updates, and continuous likelihood flow are proved explicitly. The Bayesian refinement conjecture is resolved in finite dimensions: for strictly positive likelihoods and at least two coarse packets, exact commutation for every prior is equivalent to blockwise-constant likelihoods up to global scale, and every failure factors through an explicit information-loss packet. Fractional powers are constructed packetwise through the spectral projectors of a positive operator, and the square-root semigroup is recovered by subordination. The fractional-naturality conjecture is also resolved for bounded nonnegative self-adjoint refinement systems: the fractional intertwining defect has an exact resolvent integral, a gap-free Hölder certificate, a sharper common-gap estimate, and a Duhamel semigroup bound. Green kernels, finitedifference Poisson problems, and second-order low-mode convergence provide the PDE realization. A finite-state Feynman–Kac formula is proved by path enumeration. Exact Schur–Feshbach elimination shows that discarded latent packets return as a frequency-dependent self-energy and, in time coordinates, as a memory kernel. Survival and hazard functions are generated by transient semigroups. Nineteen code-generated figures, machine-readable results, the original thirty-seven automated tests, and seventeen added boundary-case checks accompany the text. The saved Lean verification covers all 33 scoped theorem-like results in Appendix A. Finite-dimensional theorems, classical infinite-dimensional extensions, numerical certificates, and open continuum claims are kept separate.

Scope and claim boundary. The chapter proves the stated finite-dimensional semigroup, packet, Markov, Bayesian, conditional-expectation, fractional spectral, Green-kernel, Feynman–Kac, Schur–Feshbach, and survival identities. It also proves quantitative refinement-defect formulas under explicit norm hypotheses, including exact transfer of a bounded generator defect to every fractional power $0 < \alpha < 1$ for bounded nonnegative self-adjoint generators. It does not claim that an arbitrary infinite-dimensional operator generates a semigroup, that every stochastic process admits a finite packet representation, that every posterior family is conjugate, that finite Bayesian sufficiency automatically extends to infinite disintegrations, or that every PDE continuum limit follows from a finite test. Domain, closability, sectoriality, measurability, tightness, and compactness hypotheses remain necessary in their respective infinite-dimensional settings. Classical sources are retained in the separate end-of-series reference ledger rather than reproduced in this chapter.

1 The transfer-semigroup realization

Let X be a finite-dimensional real or complex vector space, let $A \in \mathrm{End}(X)$, and let $s \in X$ be a primitive seed. The basic continuous transfer is

$$T(t) = e^{tA}, \qquad t \geq 0,$$

while a positive operator L is more naturally written

$$H(t) = e^{-tL}.$$

Both satisfy the semigroup law. The sign convention changes with the domain: Markov generators and evolution equations are usually written with e^{tA}. Positive diffusion and elliptic operators are usually written with e^{-tL}.

The common operator chain is

$$\boxed{\text{seed} \longrightarrow \text{transfer} \longrightarrow \text{project} \longrightarrow \text{condition} \longrightarrow \text{refine} \longrightarrow \text{complete} \longrightarrow \text{reconstruct.}}$$

Definition 1.1 (Transfer-semigroup seed system)**.** A finite transfer-semigroup seed system is a tuple

$$\mathfrak{S} = (X, s, A, \{P_\alpha\}_{\alpha \in I}, \tau),$$

where X is the state space, s is the seed, A is a transfer generator, the P_α are pairwise orthogonal idempotents summing to the identity, and τ specifies the topology in which a completion or limit is interpreted.

Theorem 1.2 (Finite semigroup law)**.** *For every matrix A and all $s, t \in \mathbb{R}$,*

$$\boxed{e^{(s+t)A} = e^{sA} e^{tA}.}$$

Moreover, $T(0) = I$ and $T'(t) = AT(t) = T(t)A$.

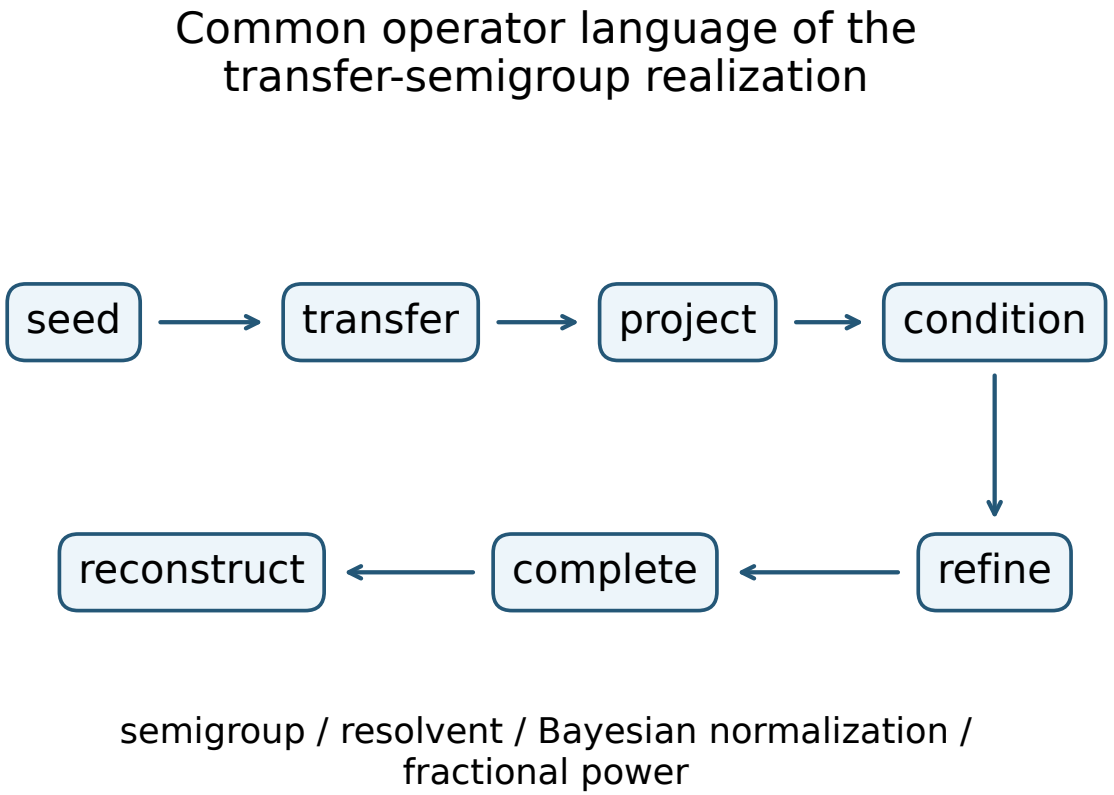


Figure 1. The common operator language used throughout the chapter. Semigroups, resolvents, normalized Bayesian maps, and fractional powers are distinct realizations of the same transfer stage.

Proof. Both exponentials are absolutely convergent matrix power series. Since every power of A commutes with every other power, the Cauchy product gives

$$e^{sA}e^{tA} = \sum_{m,n\geq 0} \frac{s^m t^n}{m!n!} A^{m+n} = \sum_{r\geq 0} \frac{(s+t)^r}{r!} A^r.$$

Termwise differentiation is valid in finite dimension and gives the derivative identities. □

Boundary 1.3 (Infinite-dimensional generators). For an unbounded operator, writing e^{tA} is not a definition unless a semigroup-generation theorem applies. The finite matrix identities in this chapter remain algebraically correct models, but a continuum realization must state the operator domain, closure, growth bound, and topology of convergence.

2 Packet blocks of a semigroup

The central idea

A packet block remembers both the origin and the destination. Composition must sum over every intermediate packet, because an unobserved intermediate coordinate can carry a real contribution. The original formulas below express this bookkeeping exactly.

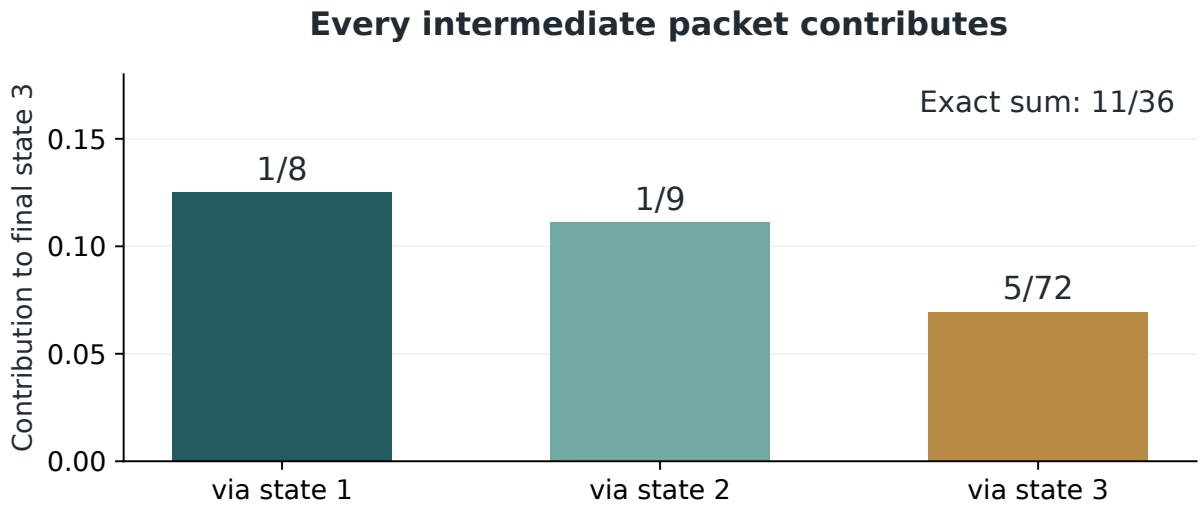

Figure 2. Two rational transfer steps resolved through all three intermediate states. The displayed products are computed exactly before plotting. This finite illustration explains the intermediate-packet sum.

Let

$$P_\alpha P_\beta = \delta_{\alpha\beta} P_\alpha, \qquad \sum_{\alpha\in I} P_\alpha = I.$$

For any operator B, define

$$B_{\beta\alpha} = P_\beta B P_\alpha.$$

Then

$$B = \sum_{\alpha,\beta} B_{\beta\alpha}.$$

For the semigroup, write

$$T_{\beta\alpha}(t) = P_\beta e^{tA} P_\alpha.$$

Theorem 2.1 (Packet semigroup convolution)**.** *For every s, t and every pair of packets α, β,*

$$\boxed{T_{\beta\alpha}(s+t) = \sum_{\gamma \in I} T_{\beta\gamma}(s) T_{\gamma\alpha}(t).}$$

Thus the semigroup law becomes ordinary matrix multiplication in the packet indices.

Proof. Insert the resolution of the identity between the two semigroup factors:

$$\begin{aligned} P_\beta e^{(s+t)A} P_\alpha &= P_\beta e^{sA} \left(\sum_\gamma P_\gamma \right) e^{tA} P_\alpha \\ &= \sum_\gamma (P_\beta e^{sA} P_\gamma)(P_\gamma e^{tA} P_\alpha). \end{aligned}$$

□

Corollary 2.2 (Reducing packets)**.** *If $P_\beta A P_\alpha = 0$ for every $\beta \neq \alpha$, then*

$$P_\beta e^{tA} P_\alpha = 0 \quad (\beta \neq \alpha)$$

for every t. Each packet evolves independently under $P_\alpha A P_\alpha$.

Proof. The hypothesis makes A block diagonal. Every power A^m is block diagonal with respect to the same projectors, and therefore so is the exponential series. □

Remark 2.3 (Path expansion). Expanding the exponential and inserting $I = \sum_\alpha P_\alpha$ between every pair of generators gives

$$P_{\alpha_m} A^m P_{\alpha_0} = \sum_{\alpha_1, \dots, \alpha_{m-1}} P_{\alpha_m} A P_{\alpha_{m-1}} \cdots P_{\alpha_1} A P_{\alpha_0}.$$

Every coefficient is therefore a sum over packet-transfer paths. The numerical library verifies that truncating this path series converges to the ordinary matrix exponential.

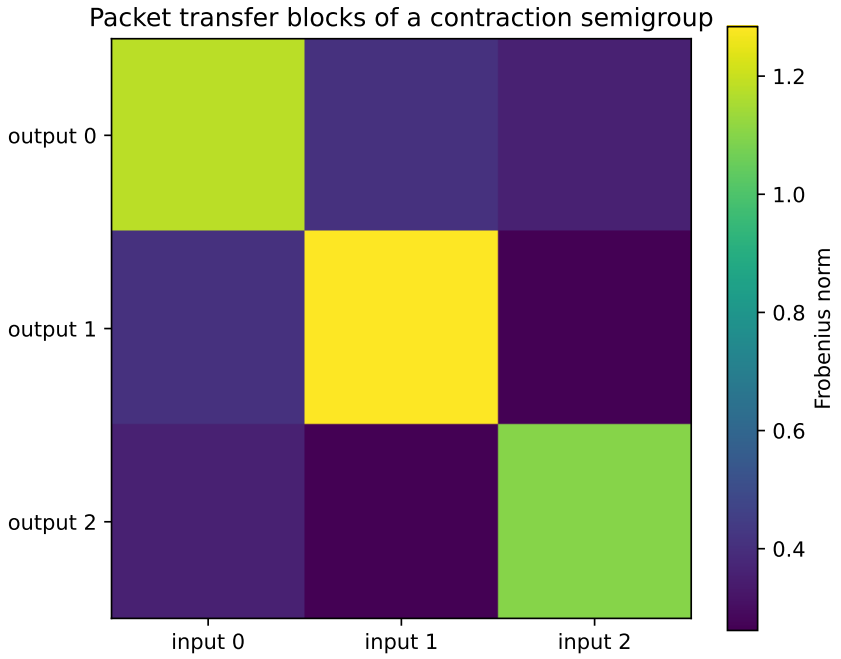

Figure 3. Norms of the packet blocks $P_\beta e^{tA} P_\alpha$. Off-diagonal entries quantify transfer between packets.

3 Refinement defects and the Duhamel identity

How to read the result

Read the generator defect as a mismatch between two declared paths: evolve and then coarsen, or coarsen and then evolve. The Duhamel identity transports that mismatch through time. Its estimate depends on the stated operator norms and growth bounds.

Let X_f and X_c be fine and coarse spaces, with generators A_f and A_c, and let

$$C : X_f \to X_c$$

be a coarsening map. Define the generator-level refinement defect

$$\boxed{\Delta = CA_f - A_c C.}$$

The corresponding semigroup defect is

$$\mathfrak{D}(t) = Ce^{tA_f} - e^{tA_c} C.$$

Theorem 3.1 (Exact Duhamel refinement identity)**.** *For every $t \geq 0$,*

$$\boxed{Ce^{tA_f} - e^{tA_c} C = \int_0^t e^{(t-r)A_c} \Delta e^{rA_f}\, dr.}$$

In particular, $\Delta = 0$ implies exact semigroup intertwining at every time.

Proof. Set

$$F(r) = e^{(t-r)A_c} C e^{rA_f}.$$

Then

$$F'(r) = e^{(t-r)A_c}(CA_f - A_c C)e^{rA_f}.$$

Integrating from 0 to t gives $F(t) - F(0) = Ce^{tA_f} - e^{tA_c}C$ and proves the formula. □

Corollary 3.2 (Norm bound). *Suppose*

$$\|e^{tA_f}\| \le M_f e^{\omega_f t}, \qquad \|e^{tA_c}\| \le M_c e^{\omega_c t}.$$

Then

$$\|\mathfrak{D}(t)\| \le M_f M_c \|\Delta\| \int_0^t e^{\omega_c(t-r)} e^{\omega_f r}\, dr.$$

For contraction semigroups,

$$\boxed{\|\mathfrak{D}(t)\| \le t\,\|\Delta\|\,.}$$

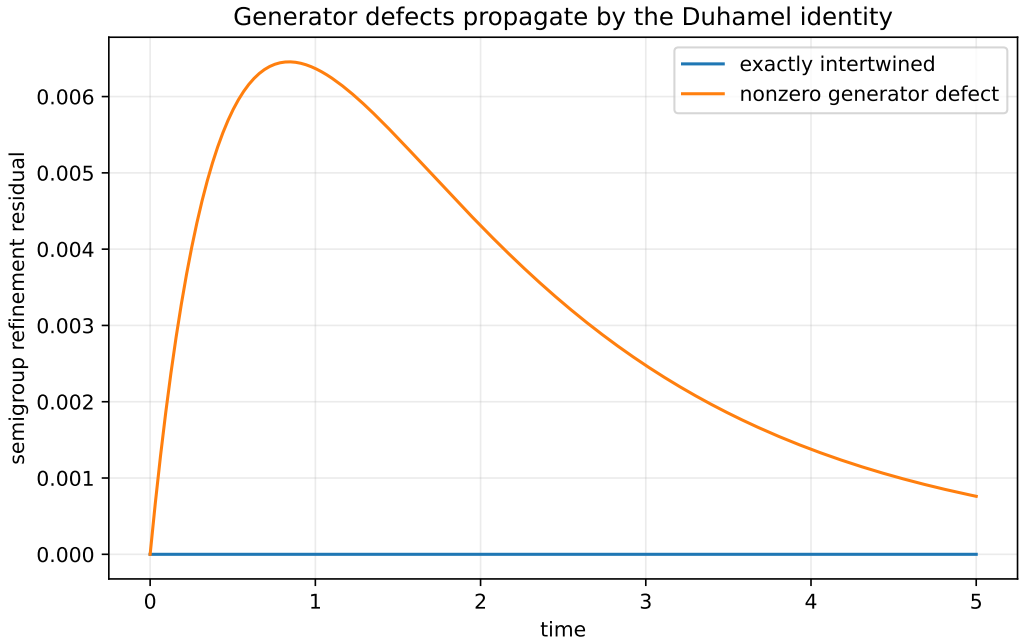

Figure 4. Exact generator intertwining gives a vanishing semigroup defect. A controlled perturbation produces a nonzero defect propagated by the Duhamel identity.

3.1 Resolvent form

For z in the common resolvent set, let

$$R_f(z) = (zI - A_f)^{-1}, \qquad R_c(z) = (zI - A_c)^{-1}.$$

Theorem 3.3 (Resolvent refinement identity)**.**

$$\boxed{CR_f(z) - R_c(z)C = R_c(z)\Delta R_f(z).}$$

Proof. Multiply the left side by $zI - A_c$ on the left and $zI - A_f$ on the right. The result is

$$(zI - A_c)C - C(zI - A_f) = CA_f - A_cC = \Delta.$$

Multiplication by the two resolvents recovers the stated identity. □

4 Markov seeds and stochastic transfer

Use column probability vectors. A finite continuous-time Markov generator Q has nonnegative off-diagonal entries and column sums zero. The stochastic semigroup is

$$K(t) = e^{tQ}.$$

Theorem 4.1 (Finite Markov semigroup)**.** *If Q has nonnegative off-diagonal entries and column sums zero, then e^{tQ} has nonnegative entries and column sums one for every $t \geq 0$.*

Proof. Choose $\lambda \geq \max_i(-Q_{ii})$. Then $B = Q + \lambda I$ has nonnegative entries, so e^{tB} is entrywise nonnegative by its power series. Hence

$$e^{tQ} = e^{-\lambda t}e^{tB}$$

is nonnegative. Since $1^TQ = 0$, differentiation gives

$$\frac{d}{dt}1^Te^{tQ} = 1^TQe^{tQ} = 0,$$

so $1^Te^{tQ} = 1^T$. □

Example 4.2 (Symmetric random walk)**.** Starting from δ_0 and applying the transfer

$$T = \frac{1}{2}(S + S^{-1})$$

for n steps gives

$$\mathbb{P}(X_n = k) = 2^{-n}\binom{n}{(n+k)/2}$$

when $k \equiv n \pmod 2$, and zero otherwise. Hence

$$\mathbb{E}[X_n] = 0, \qquad \mathrm{Var}(X_n) = n.$$

The parity packet is exact: all mass remains in the one residue class permitted by n.

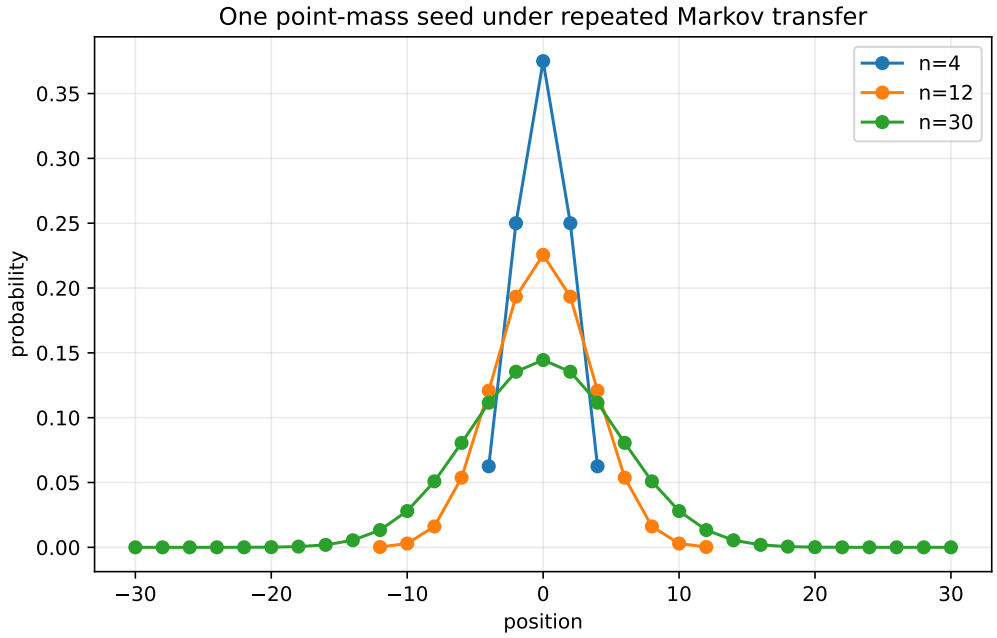

Figure 5. The point mass δ_0 propagated by repeated symmetric random-walk transfer.

5 Markov lumping as exact refinement

Let K be a column-stochastic fine transition matrix, let C aggregate fine states into coarse packets, and let $\bar{K}$ be a coarse transition matrix. Define

$$\Delta = CK - \bar{K}C.$$

Theorem 5.1 (Exact lumpability). *If $\Delta = 0$, then*

$$\boxed{CK^n = \bar{K}^n C}$$

for every $n \geq 0$. Thus fine evolution followed by coarse reconstruction equals coarse evolution from the beginning.

Proof. The result is immediate for $n = 0$. If $CK^n = \bar{K}^n C$, then

$$CK^{n+1} = \bar{K}^n CK = \bar{K}^{n+1} C.$$

□

Theorem 5.2 (Finite-horizon defect formula). *For arbitrary $\Delta = CK - \bar{K}C$,*

$$\boxed{CK^n - \bar{K}^n C = \sum_{j=0}^{n-1} \bar{K}^{n-1-j} \Delta K^j.}$$

If K and $\bar{K}$ are contractions in the chosen norm, then

$$\left\|CK^n - \bar{K}^n C\right\| \le n \left\|\Delta\right\|.$$

Proof. The identity follows by telescoping:

$$\bar{K}^{n-1-j} C K^{j+1} - \bar{K}^{n-j} C K^j = \bar{K}^{n-1-j}(CK - \bar{K}C)K^j.$$

Summing from $j = 0$ to $n - 1$ leaves $CK^n - \bar{K}^n C$. The norm bound follows termwise. □

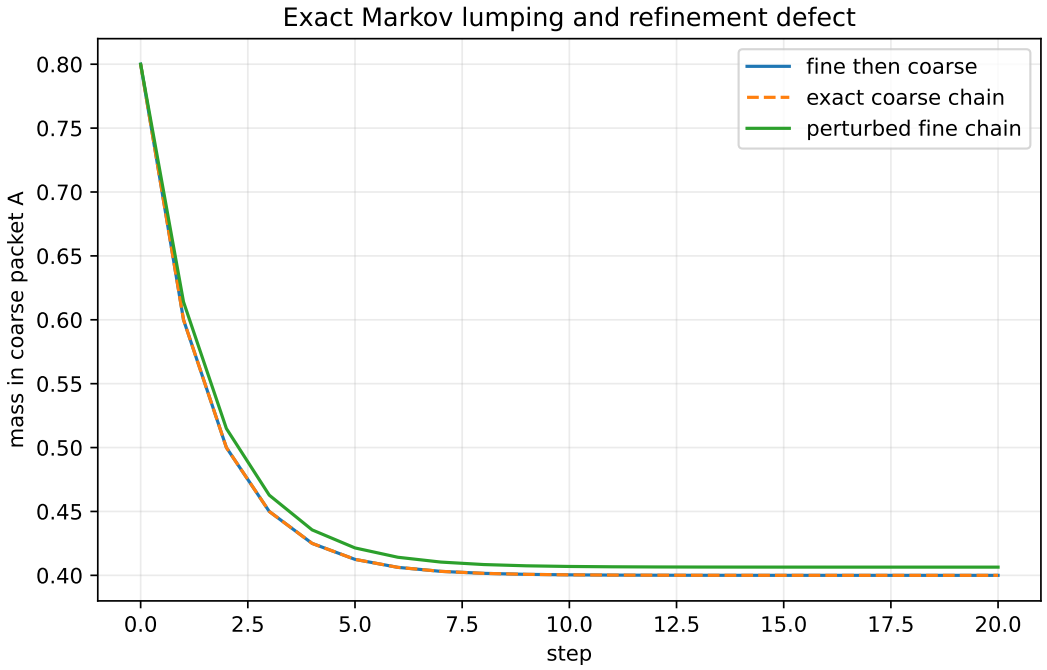

Figure 6. Exact lumping agrees at every horizon. A small generator-level or one-step defect creates a controlled coarse discrepancy.

6 Conditional expectation as a stochastic projector

A route through this section

Conditional expectation is a projector in a weighted Hilbert space. Nested partitions therefore split information into orthogonal increments. Keep the underlying measure fixed while reading the projector identities. A change of measure is a different operation.

Let $\Omega = \{1, \dots, n\}$ carry strictly positive probabilities π_i, and let $\mathcal{Q} = \{B_1, \dots, B_m\}$ be a partition. Define

$$(P_{\mathcal{Q}} f)_i = \frac{\sum_{j \in B(i)} \pi_j f_j}{\sum_{j \in B(i)} \pi_j},$$

where $B(i)$ is the block containing i.

Theorem 6.1 (Finite conditional-expectation projector)**.** *With the weighted inner product*

$$\langle f, g\rangle_\pi = \sum_i \pi_i f_i \overline{g_i},$$

the operator $P_{\mathcal{Q}}$ satisfies

$$P_{\mathcal{Q}}^2 = P_{\mathcal{Q}}, \qquad \langle P_{\mathcal{Q}} f, g\rangle_\pi = \langle f, P_{\mathcal{Q}} g\rangle_\pi.$$

Its range is the space of functions constant on each partition block.

Proof. After one application, the result is constant on every block, so applying the same block average again changes nothing. Weighted self-adjointness follows by expanding both inner products block by block. Both equal

$$\sum_{B\in\mathcal{Q}} \frac{1}{\pi(B)} \left(\sum_{i\in B} \pi_i f_i\right) \overline{\left(\sum_{j\in B} \pi_j g_j\right)}.$$

□

Theorem 6.2 (Tower law and martingale packets)**.** *If $\mathcal{Q}_c$ is coarser than $\mathcal{Q}_f$, then*

$$\boxed{P_c P_f = P_f P_c = P_c.}$$

For a nested tower $P_0 \le P_1 \le \cdots \le P_r$, define

$$D_0 = P_0, \qquad D_j = P_j - P_{j-1}.$$

Then

$$D_i D_j = \delta_{ij} D_j, \qquad P_r = \sum_{j=0}^{r} D_j.$$

Proof. A coarse-block average of a fine-block average is the coarse-block average, and a fine-block average of a coarse-constant function leaves it unchanged. The difference identities follow from $P_i P_j = P_{\min(i,j)}$. □

Classical Input 6.3 (Gaussian chaos realization). For the standard Gaussian measure, the normalized probabilists' Hermite polynomials form orthonormal chaos packets. The Ornstein–Uhlenbeck semigroup acts diagonally:

$$T_t H_n = e^{-nt} H_n.$$

Thus conditional expectation, martingale differences, and Gaussian chaos are all projector realizations of stochastic refinement.

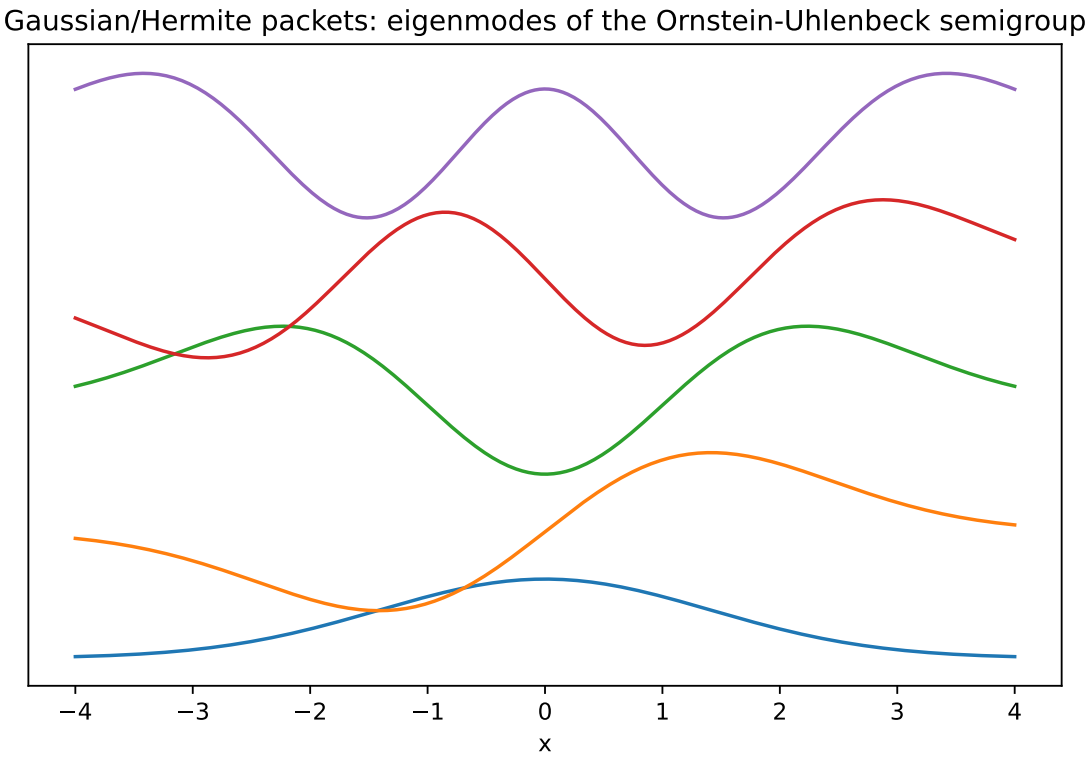

Figure 7. Hermite–Gaussian packets, which diagonalize the Ornstein–Uhlenbeck semigroup. The numerical study checks their Gaussian orthogonality through quadrature. The five displayed modes run from n = 0 at the bottom to n = 4 at the top. Vertical offsets separate the curves.

7 Bayesian conditioning as a normalized nonlinear operator

Let $p = (p_i)$ be a probability vector and let $\lambda = (\lambda_i)$ be a nonnegative likelihood with positive evidence

$$Z_\lambda(p) = \sum_i \lambda_i p_i.$$

Define

$$\boxed{\mathcal{B}_\lambda(p) = \frac{\lambda \odot p}{Z_\lambda(p)}.}$$

This map is nonlinear solely because of its scalar reconstruction factor.

Theorem 7.1 (Independent-likelihood composition)**.** *For nonnegative likelihoods λ and μ, assume $Z_\lambda(p) > 0$ and $Z_{\lambda\odot\mu}(p) > 0$. Equivalently, both successive updates have positive evidence. Then*

$$\boxed{\mathcal{B}_\mu(\mathcal{B}_\lambda(p)) = \mathcal{B}_{\lambda\odot\mu}(p).}$$

Proof. The first normalization appears in both numerator and denominator of the second update and cancels:

$$\frac{\mu_i(\lambda_i p_i/Z_\lambda)}{\sum_j \mu_j\lambda_j p_j/Z_\lambda} = \frac{\mu_i\lambda_i p_i}{\sum_j \mu_j\lambda_j p_j}.$$

□

7.1 Packet evidence and reconstruction

Let the state indices be partitioned into packets I_α. Define

$$Z_\alpha = \sum_{i\in I_\alpha} \lambda_i p_i, \qquad m_\alpha = \frac{Z_\alpha}{\sum_\beta Z_\beta}, \qquad q_{\alpha,i} = \begin{cases} \lambda_i p_i/Z_\alpha, & Z_\alpha > 0,\ i \in I_\alpha, \\ 0, & \text{otherwise.} \end{cases}$$

Theorem 7.2 (Bayesian packet reconstruction)**.**

$$\boxed{\mathcal{B}_\lambda(p) = \sum_\alpha m_\alpha q_\alpha.}$$

Only packets with positive evidence carry a conditional probability vector. A zero-evidence packet has zero posterior mass and contributes the zero vector. The nonlinear coupling between packets occurs only through the total evidence used to normalize the packet evidences.

Proof. If $Z_\alpha = 0$, nonnegativity implies $\lambda_i p_i = 0$ for every $i \in I_\alpha$, so the reconstruction identity holds with both sides zero. For $Z_\alpha > 0$ and $i \in I_\alpha$,

$$m_\alpha q_{\alpha,i} = \frac{Z_\alpha}{Z}\frac{\lambda_i p_i}{Z_\alpha} = \frac{\lambda_i p_i}{Z}.$$

The packet supports are disjoint, so summing reconstructs the full posterior. □

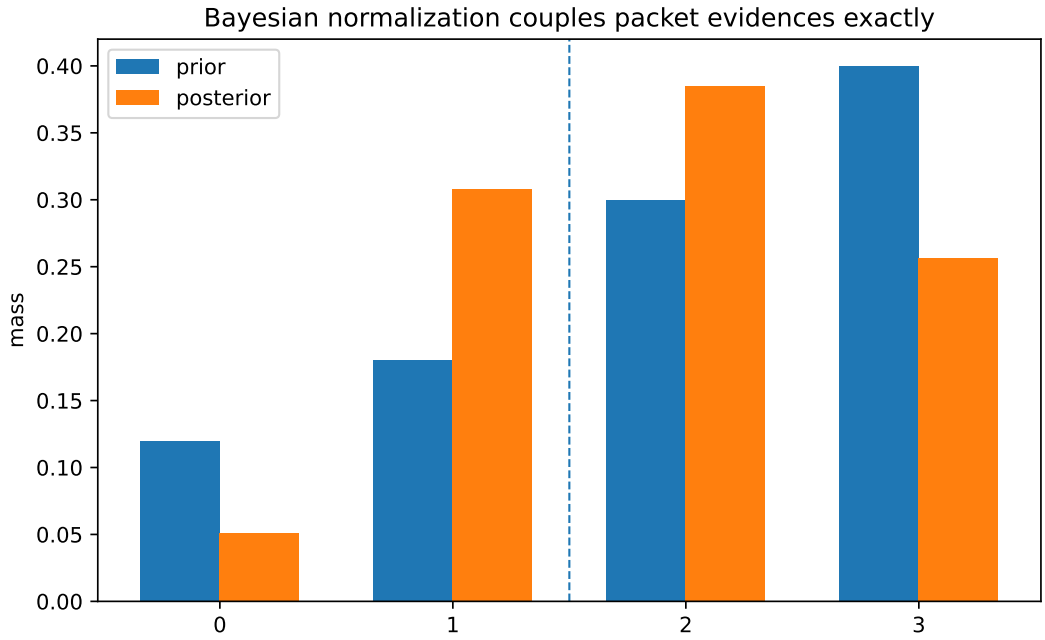

Figure 8. A finite prior and posterior split into two state packets. Evidence changes both the local packet shape and the global packet mass.

Theorem 7.3 (Likelihood perturbation bound). *Let p be fixed and let $\lambda, \mu \geq 0$ have positive evidences Z_λ, Z_μ. Then*

$$\boxed{\left\|\mathcal{B}_\lambda(p) - \mathcal{B}_\mu(p)\right\|_1 \leq \frac{2\sum_i |\lambda_i - \mu_i| p_i}{\min(Z_\lambda, Z_\mu)}.}$$

Proof. Add and subtract $\mu \odot p / Z_\lambda$ and use the triangle inequality:

$$\left\|\frac{\lambda \odot p}{Z_\lambda} - \frac{\mu \odot p}{Z_\mu}\right\|_1 \leq \frac{\|(\lambda - \mu) \odot p\|_1}{Z_\lambda} + \|\mu \odot p\|_1 \left|\frac{1}{Z_\lambda} - \frac{1}{Z_\mu}\right|.$$

The second term equals $|Z_\lambda - Z_\mu| / Z_\lambda$ and is bounded by the same weighted L^1 difference divided by Z_λ. Interchanging λ and μ gives the minimum-evidence form. □

8 Exact Bayesian refinement and information-loss packets

How to read the result

The all-prior criterion here tests coarse posterior masses for every prior and assumes at least two coarse blocks. Part II uses a stronger convention that also preserves each conditional distribution inside a block. These are different contracts, so the one-block boundary must be read with its own definition.

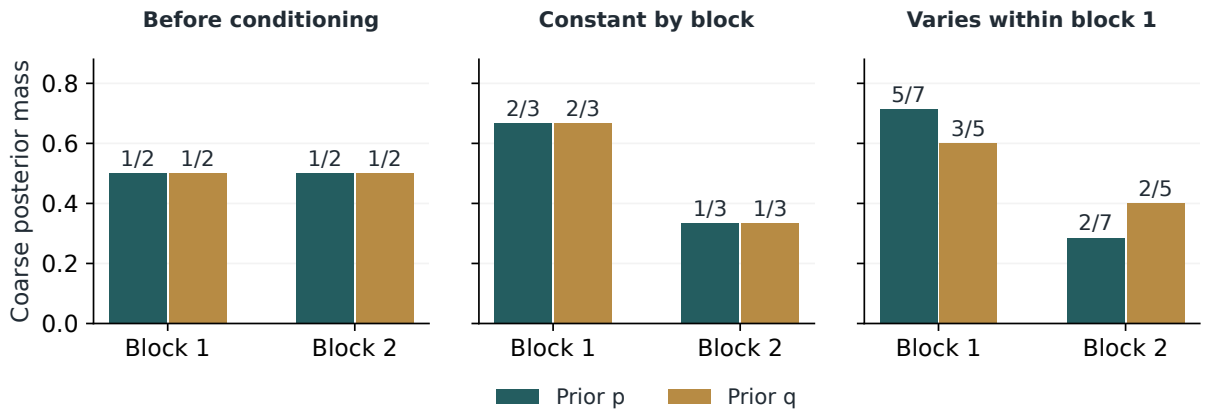

Figure 9. Two rational priors with the same two coarse masses. A blockwise constant likelihood gives the same coarse update, while a likelihood varying within a block separates the posteriors. The exact fractions are calculated before plotting.

Let the fine state set I be partitioned into nonempty coarse packets I_a, $a \in A$. The coarsening map on probability vectors is

$$(C_\pi p)_a = P_a = \sum_{i \in I_a} p_i.$$

For a fine likelihood $\lambda = (\lambda_i)_{i \in I}$ and a prior p, define the effective coarse likelihood

$$r_a(p) = \frac{\sum_{i \in I_a} \lambda_i p_i}{P_a} \qquad (P_a > 0).$$

Its value on a zero-mass packet is irrelevant and may be set to zero.

Theorem 8.1 (Exact effective-likelihood factorization). *Whenever the fine evidence is positive,*

$$\boxed{C_\pi \mathcal{B}_\lambda(p) = \mathcal{B}_{r(p)}(C_\pi p).}$$

Thus the only fine information needed for the coarse posterior, beyond the coarse prior masses, is the vector of conditional packet evidences $r(p)$.

Proof. For $P = C_\pi p$ and $Z = \sum_i \lambda_i p_i = \sum_a P_a r_a(p)$,

$$\left(C_\pi \mathcal{B}_\lambda(p)\right)_a = \frac{\sum_{i \in I_a} \lambda_i p_i}{Z} = \frac{P_a r_a(p)}{\sum_b P_b r_b(p)} = \left(\mathcal{B}_{r(p)}(P)\right)_a.$$

□

The next result gives the exact necessary and sufficient condition for a coarse likelihood to work for every prior.

Theorem 8.2 (Bayesian refinement criterion)**.** *Assume that the partition contains at least two coarse packets and that the fine and coarse likelihoods are strictly positive. The identity*

$$\boxed{C_\pi \mathcal{B}_\lambda(p) = \mathcal{B}_{\bar\lambda}(C_\pi p)}$$

holds for every fine prior p if and only if there exists one scalar $c > 0$ such that

$$\boxed{\lambda_i = c\,\bar\lambda_a \qquad (i \in I_a).}$$

Equivalently, the likelihood is constant on each coarse packet, with the coarse values determined up to the globally invisible Bayesian scaling c.

Proof. If $\lambda_i = c\bar\lambda_a$ on I_a, then $P_a r_a(p) = c\bar\lambda_a P_a$ for every prior, including zero-mass packets, and the preceding theorem gives the desired identity because Bayesian normalization removes the common scalar c.

Conversely, fix two fine states $i, i' \in I_a$ and one state $j \in I_b$ in another coarse packet. Vary the distribution of a fixed coarse mass inside I_a between i and i' while leaving every coarse packet mass unchanged. The right side depends only on those coarse masses and is therefore unchanged. The left-side posterior mass of packet a depends on the conditional average of λ_i and $\lambda_{i'}$. It can be independent of that variation only if $\lambda_i = \lambda_{i'}$. Hence λ is constant on every packet. Write the value on I_a as λ_a.

Now use priors supported on one state of packet a and one state of packet b. Equality of the two coarse posterior odds gives

$$\frac{\lambda_a}{\lambda_b} = \frac{\bar\lambda_a}{\bar\lambda_b}.$$

This holds for every pair of coarse packets, so $\lambda_a = c\bar\lambda_a$ for one common $c > 0$. □

Remark 8.3 (The one-packet boundary). If the coarse partition has only one packet, every posterior coarsens to the scalar 1, so commutation is automatic and no within-packet likelihood information can be identified. The nontrivial criterion begins with at least two coarse packets.

When sufficiency fails, the defect still has an exact finite factorization. Fix a declared coarse likelihood $\bar\lambda$, put

$$P = C_\pi p, \qquad \delta(p) = r(p) - \bar\lambda, \qquad \bar b = \mathcal{B}_{\bar\lambda}(P), \qquad Z_r = \langle r(p), P\rangle.$$

Theorem 8.4 (Bayesian information-loss packet)**.** *Assume nonnegative fine and declared coarse likelihoods, with both $Z_r > 0$ and $Z_{\bar\lambda} > 0$. The coarsening defect is*

$$\boxed{C_\pi \mathcal{B}_\lambda(p) - \mathcal{B}_{\bar\lambda}(P) = \frac{1}{Z_r}\left(\operatorname{diag}(P) - \bar b P^{\mathsf T}\right)\delta(p).}$$

The factor matrix annihilates $\bar{\lambda}$. This records the common-scale null direction at the declared coarse likelihood. The full exact defect remains homogeneous under simultaneous likelihood rescaling because the numerator and evidence denominator scale together. Moreover,

$$\boxed{\left\|C_\pi \mathcal{B}_\lambda(p) - \mathcal{B}_{\bar{\lambda}}(P)\right\|_1 \le \frac{2\sum_a P_a|\delta_a(p)|}{\min\{Z_r, Z_{\bar{\lambda}}\}}}$$

and

$$\sum_a P_a|\delta_a(p)| \le \sum_i p_i \left|\lambda_i - \bar{\lambda}_{\pi(i)}\right|.$$

Proof. The effective-likelihood theorem reduces the defect to

$$\mathcal{B}_{\bar{\lambda}+\delta}(P) - \mathcal{B}_{\bar{\lambda}}(P).$$

Since $Z_r = Z_{\bar{\lambda}} + P^\mathsf{T}\delta$, direct subtraction gives

$$\frac{1}{Z_r}\left(\operatorname{diag}(P) - \bar{b}P^\mathsf{T}\right)\delta.$$

Also,

$$\left(\operatorname{diag}(P) - \bar{b}P^\mathsf{T}\right)\bar{\lambda} = P \odot \bar{\lambda} - \bar{b}Z_{\bar{\lambda}} = 0.$$

The first norm bound is the likelihood perturbation theorem applied on the coarse simplex. For a zero-mass packet, both sides of the following estimate vanish. For $P_a > 0$,

$$P_a|\delta_a| = P_a\left|\sum_{i\in I_a}\frac{p_i}{P_a}(\lambda_i - \bar{\lambda}_a)\right| \le \sum_{i\in I_a} p_i|\lambda_i - \bar{\lambda}_a|,$$

and summing over a proves the second inequality. □

Corollary 8.5 (Nested Bayesian packet tower)**.** *Consider a nested finite packet tower with strictly positive likelihoods at every level. At each adjacent coarsening with at least two coarse packets, commutation for every prior is equivalent to the fine likelihood being blockwise proportional to the declared coarse likelihood, with one common positive proportionality factor. An adjacent coarsening to a single packet commutes automatically and imposes no such condition. Under these conditions, all composite coarsening squares commute.*

Proof. At each adjacent coarsening with at least two coarse packets, apply the refinement criterion. For a single coarse packet, both normalized posteriors equal 1. Composition of these commuting squares gives the full tower statement. □

Corollary 8.6 (Canonical coarsest likelihood-resolving partition)**.** *For a finite family of likelihoods $\{\lambda^{(y)}\}_{y\in Y}$, define*

$$i \sim j \iff \lambda_i^{(y)} = \lambda_j^{(y)} \text{ for every } y \in Y.$$

The equivalence classes form the unique coarsest likelihood-resolving partition: every likelihood is constant on each packet. Every update therefore closes on this partition whenever its evidence is positive. If all likelihoods are strictly positive and there are at least two profile classes, this is also the unique coarsest nontrivial partition on

which every update closes for every prior. The one-packet partition always closes, independently of the profiles, and is excluded from this last assertion.

Proof. Equality of likelihood profiles is an equivalence relation. Its classes are likelihood-resolving by definition, and every likelihood-resolving partition refines them. Exact closure follows by summing the weighted masses in each fiber, including zero-mass fibers. Under strict positivity, the refinement criterion implies that every nontrivial all-prior closed partition is likelihood-resolving. When every profile is identical, all partitions close. There need not be a unique coarsest nontrivial partition. □

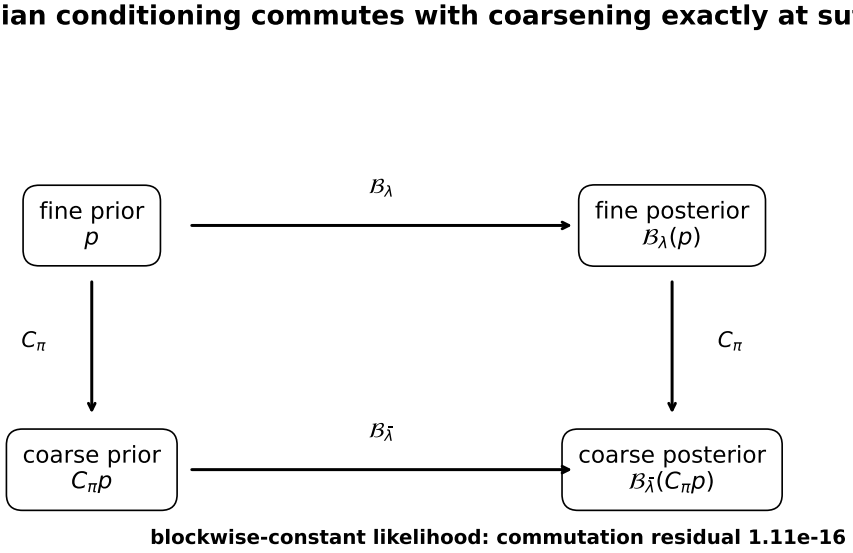

Figure 10. For strictly positive likelihoods and at least two coarse packets, the Bayesian refinement square commutes for every prior exactly when the likelihood is constant on each coarsening fiber, up to one global scale.

Numerical Certificate 8.7 (Bayesian refinement). For the finite test partition $\{0,1\} \sqcup \{2,3\}$, a blockwise-constant likelihood gave commutation residual 1.11×10^{-16}. A nonconstant likelihood produced an exact defect-factorization residual 7.29×10^{-17}. Its measured L^1 defect was 4.8787×10^{-2}, below the certified bound 1.1016×10^{-1}. Two priors with identical coarse masses but different hidden within-packet shapes produced coarse posteriors differing by 1.2400×10^{-1}, which is a direct necessity witness.

Boundary 8.8 (Finite exact theorem). The conjectured Bayesian refinement law is therefore resolved for finite packet systems and arbitrary priors. Infinite-dimensional disintegration, posterior consistency, and stability of data-dependent partitions require their own measure-theoretic and asymptotic hypotheses.

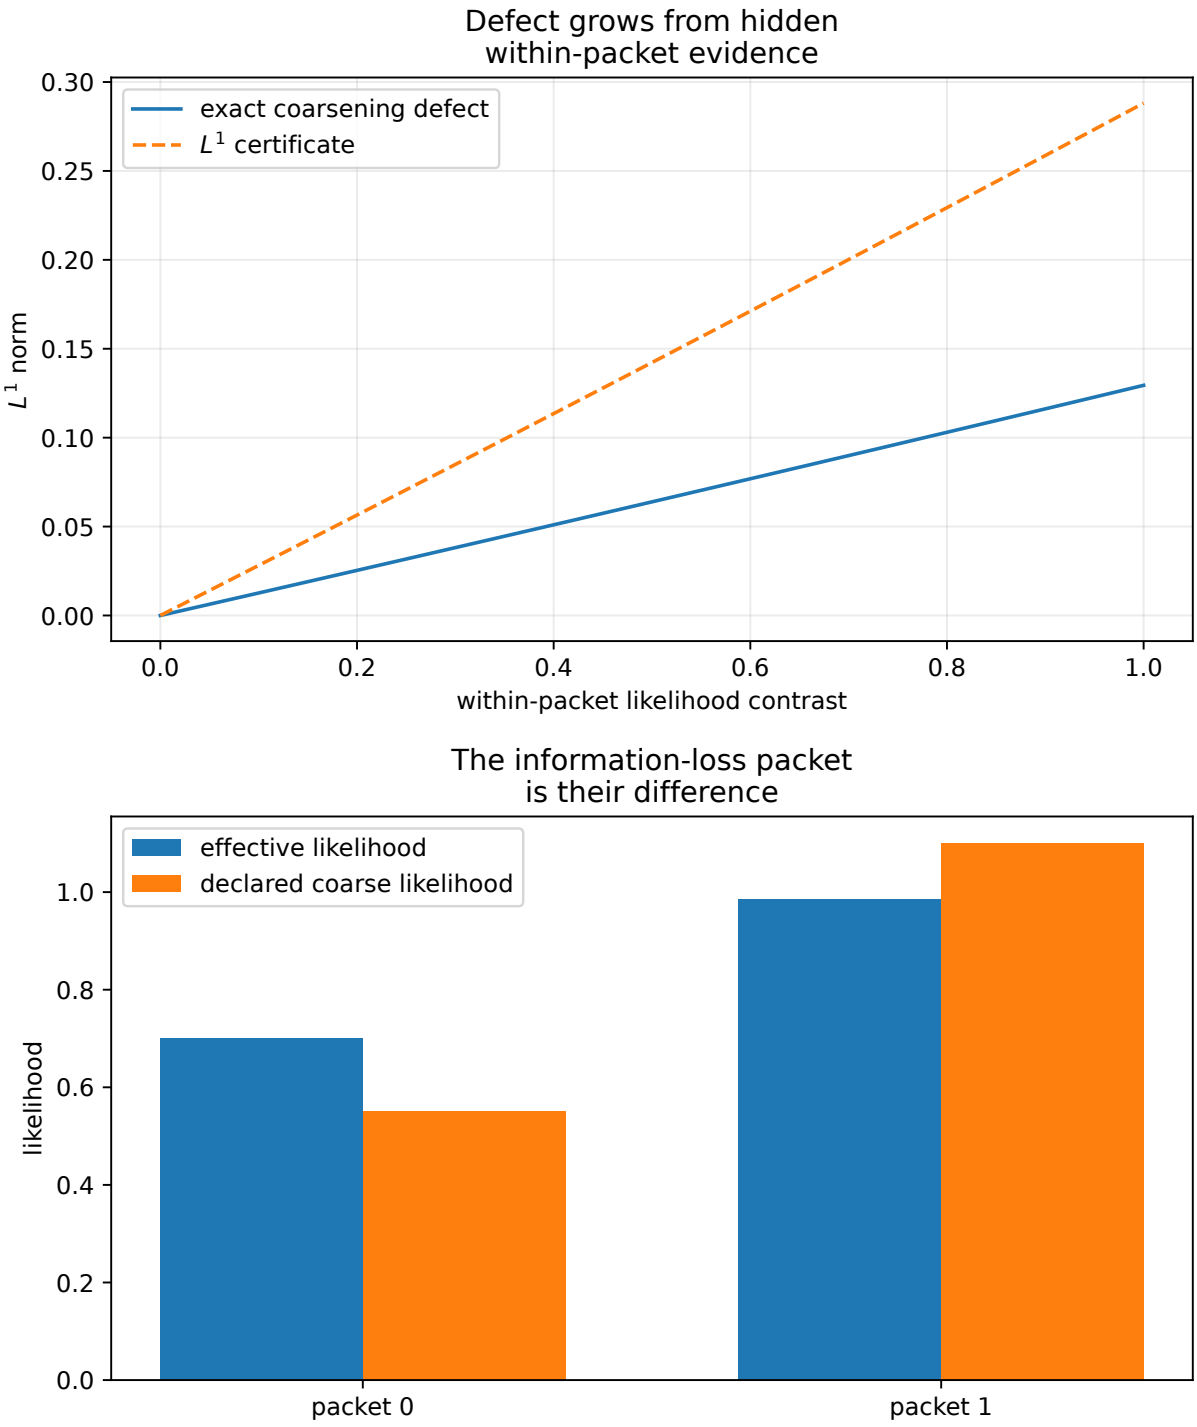

Figure 11. When packet sufficiency fails, the exact defect factors through the difference between the conditional effective likelihood and the declared coarse likelihood.

9 Bayesian flows, conjugacy, and hidden states

Fix a score vector g. The likelihood flow is

$$\lambda_i(t) = e^{tg_i},$$

and the Bayesian flow is

$$\Phi_t(p)_i = \frac{e^{tg_i}p_i}{\sum_j e^{tg_j}p_j}.$$

Theorem 9.1 (Bayesian nonlinear semigroup)**.**

$$\boxed{\Phi_{s+t} = \Phi_s \circ \Phi_t.}$$

Its generator is the centered multiplicative field

$$\boxed{\frac{d}{dt}p_i(t) = (g_i - \langle g, p(t)\rangle)p_i(t).}$$

Proof. The semigroup law is the likelihood-composition theorem with $e^{sg}e^{tg} = e^{(s+t)g}$. Differentiating the normalized exponential formula gives

$$\dot{p}_i = g_i p_i - p_i \frac{\sum_j g_j e^{tg_j}p_j(0)}{\sum_j e^{tg_j}p_j(0)}.$$

The quotient is $\langle g, p(t)\rangle$. □

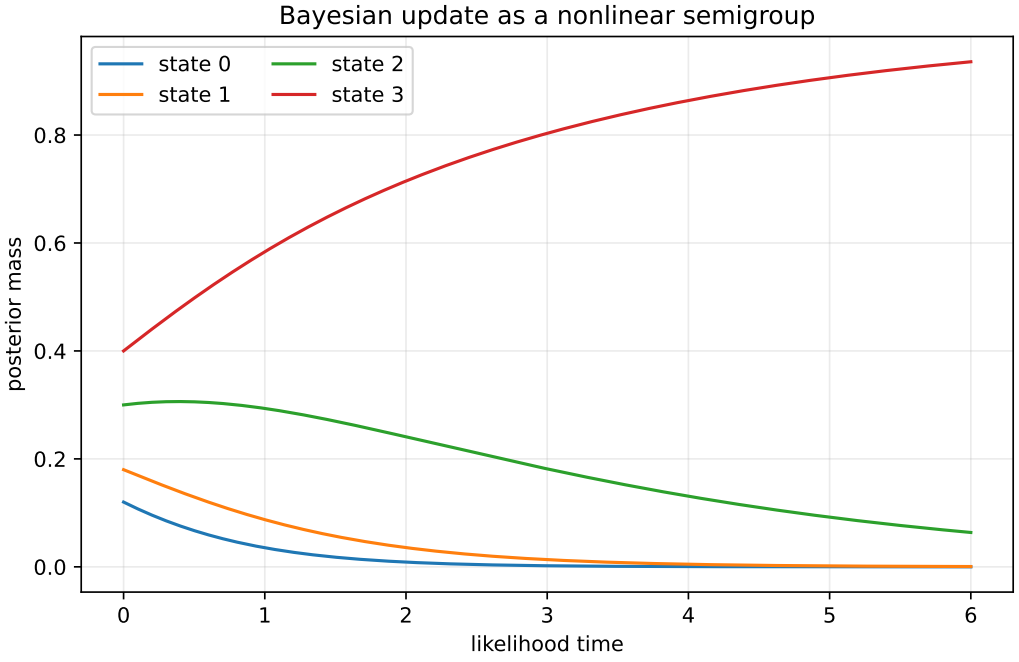

Figure 12. Continuous likelihood accumulation produces a nonlinear semigroup on the probability simplex.

Example 9.2 (Beta–Binomial conjugate packet)**.** A Beta(a, b) prior and s successes in n trials produce

$$\text{Beta}(a + s, b + n - s).$$

The prior exponents are additive packets: the likelihood increments them by $(s, n-s)$. In the numerical example,

$$(a, b) = (2, 3), \quad (s, n) = (7, 10),$$

so the posterior is Beta$(9, 6)$ with mean 0.6.

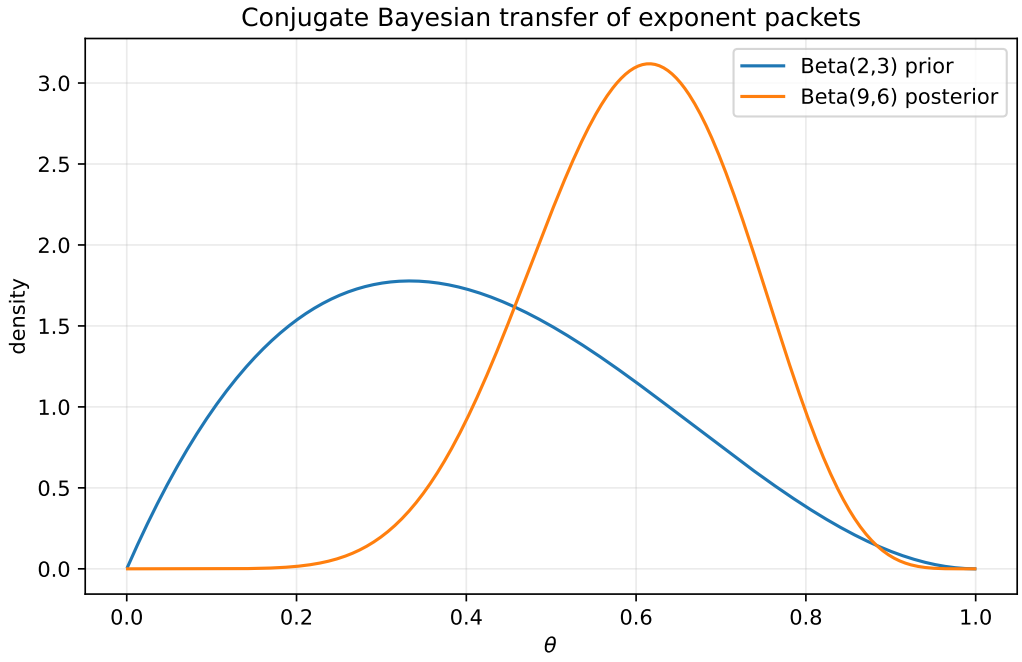

Figure 13. A conjugate Bayesian update viewed as exact transfer of exponent packets.

9.1 Hidden Markov filtering

Let K be column stochastic and let $\lambda^{(r)}$ be the likelihood associated with the rth observation. The filter recursion is

$$\hat{p}_r = K p_{r-1}, \qquad p_r = \mathcal{B}_{\lambda^{(r)}}(\hat{p}_r).$$

Proposition 9.3 (Prediction-update reconstruction)**.** *Every hidden Markov filtering step is the composition of a linear Markov transfer and a normalized nonlinear likelihood transfer. Assume a probability initial vector, a column-stochastic transition matrix, and nonnegative likelihoods with positive evidence at every step. Then every p_r is a probability vector.*

Proof. Column stochasticity gives $\hat{p}_r \geq 0$ and $1^T \hat{p}_r = 1$. Bayesian normalization then gives $p_r \geq 0$ and $1^T p_r = 1$. □

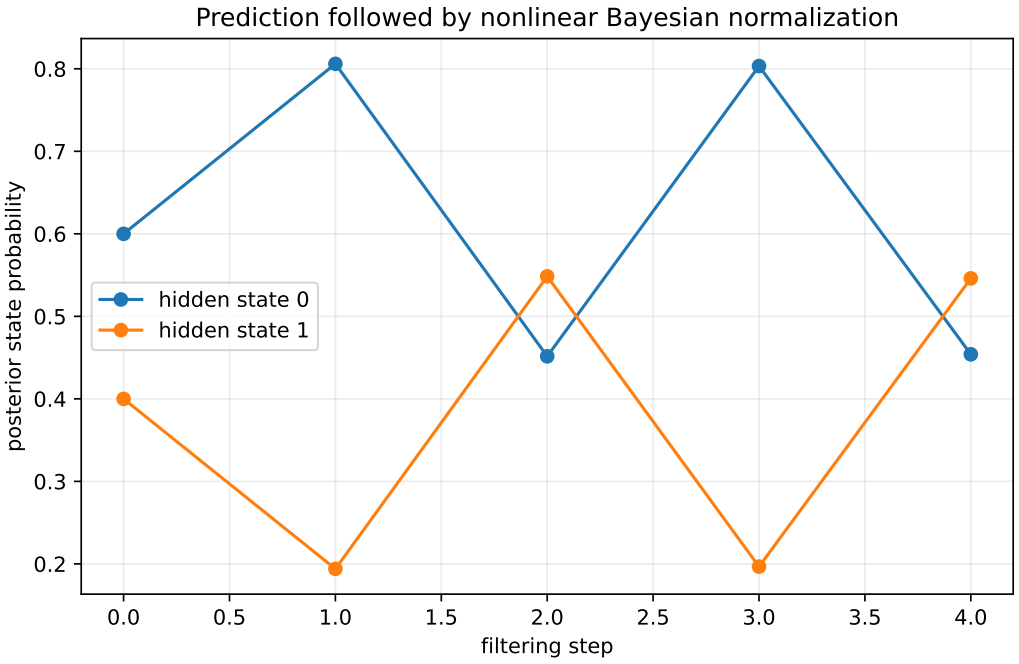

Figure 14. A hidden Markov filter alternates a linear prediction semigroup with nonlinear Bayesian normalization.

10 Fractional powers as spectral packet transfer

A route through this section

First identify the positive operator and its spectral packets. Then distinguish an exact spectral identity from a bound for a refinement mismatch. The gap-free certificate and the common-gap estimate have different hypotheses and different strengths.

Let $L = L^* \geq 0$ on a finite-dimensional Hilbert space. Its spectral resolution is

$$L = \sum_j \lambda_j P_j.$$

For $\alpha > 0$, define

$$\boxed{L^\alpha = \sum_j \lambda_j^\alpha P_j.}$$

The associated fractional semigroup is

$$T_\alpha(t) = e^{-tL^\alpha} = \sum_j e^{-t\lambda_j^\alpha} P_j.$$

Theorem 10.1 (Fractional packet calculus). *For $\alpha, \beta > 0$,*

$$L^\alpha L^\beta = L^{\alpha+\beta},$$

and for $s, t \geq 0$,

$$\boxed{T_\alpha(s)T_\alpha(t) = T_\alpha(s+t).}$$

Every spectral packet P_j reduces L^α and $T_\alpha(t)$.

Proof. All statements hold coefficientwise on the mutually orthogonal spectral projectors. For example,

$$L^\alpha L^\beta = \sum_{j,k} \lambda_j^\alpha \lambda_k^\beta P_j P_k = \sum_j \lambda_j^{\alpha+\beta} P_j.$$

□

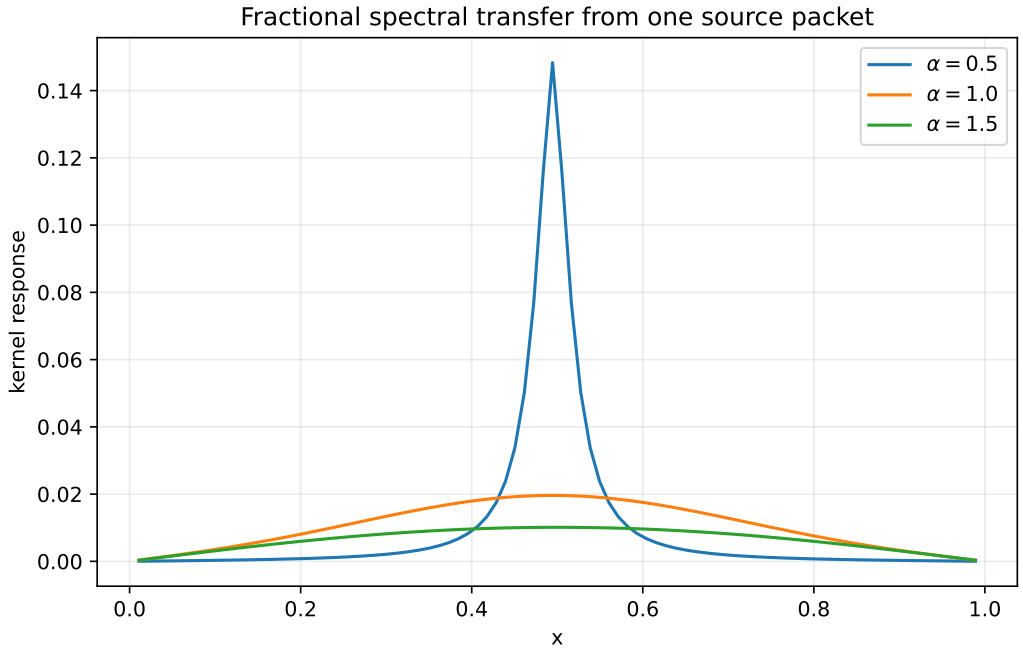

Figure 15. Different spectral exponents produce different transfer profiles from the same point seed.

10.1 Square-root subordination

Theorem 10.2 (Poisson subordination). *For $t > 0$ and $L \geq 0$,*

$$\boxed{e^{-t\sqrt{L}} = \frac{t}{2\sqrt{\pi}} \int_0^\infty s^{-3/2} e^{-t^2/(4s)} e^{-sL}\, ds.}$$

The integral converges in operator norm in finite dimension.

Proof. By the spectral theorem it suffices to prove the scalar identity

$$e^{-t\sqrt{\lambda}} = \frac{t}{2\sqrt{\pi}} \int_0^\infty s^{-3/2} e^{-t^2/(4s) - \lambda s}\, ds$$

for $\lambda \geq 0$. This is the classical Gaussian integral after the substitution $u = t/(2\sqrt{s})$. Applying the identity to every eigenvalue and recombining the spectral projectors proves the operator formula. □

10.2 Fractional naturality under a bounded refinement defect

Let $A \geq 0$ act on a fine Hilbert space, let $B \geq 0$ act on a coarse Hilbert space, and let C be a bounded coarsening map. Set

$$D = CA - BC, \qquad D_\alpha = CA^\alpha - B^\alpha C, \qquad 0 < \alpha < 1.$$

Theorem 10.3 (Fractional intertwining theorem). *For bounded nonnegative self-adjoint A and B,*

$$\boxed{D_\alpha = \frac{\sin(\pi\alpha)}{\pi} \int_0^\infty t^\alpha (tI + B)^{-1} D (tI + A)^{-1}\, dt.}$$

The improper integral converges in operator norm. Moreover,

$$\boxed{\|D_\alpha\| \leq K_\alpha \|C\|^{1-\alpha} \|D\|^\alpha, \qquad K_\alpha = \frac{2^{1-\alpha}\sin(\pi\alpha)}{\pi\alpha(1-\alpha)}.}$$

If $A, B \geq mI$ for some $m > 0$, then the stronger linear estimate holds:

$$\boxed{\|D_\alpha\| \leq \alpha m^{\alpha-1} \|D\|.}$$

In particular, exact generator intertwining $CA = BC$ implies exact fractional intertwining $CA^\alpha = B^\alpha C$.

Proof. For $0 < \alpha < 1$, the Balakrishnan formula gives

$$A^\alpha = \frac{\sin(\pi\alpha)}{\pi} \int_0^\infty t^{\alpha-1} A (tI + A)^{-1}\, dt,$$

and likewise for B. Using

$$A(tI + A)^{-1} = I - t(tI + A)^{-1}$$

and the rectangular resolvent identity

$$(tI + B)^{-1}C - C(tI + A)^{-1} = (tI + B)^{-1}(CA - BC)(tI + A)^{-1},$$

the difference of the two Balakrishnan integrals becomes the displayed resolvent-defect formula.

For small t,

$$\left\| CA(tI + A)^{-1} - B(tI + B)^{-1}C \right\| \leq 2\|C\|,$$

because the two positive resolvent factors are contractions. For large t, the resolvent identity gives the bound $\|D\|/t$. Splitting the integral at

$$r = \frac{\|D\|}{2\|C\|}$$

when C and D are nonzero yields

$$\begin{aligned}\|D_\alpha\| &\le \frac{\sin(\pi\alpha)}{\pi}\left(2\|C\|\int_0^r t^{\alpha-1}\,dt + \|D\|\int_r^\infty t^{\alpha-2}\,dt\right)\\ &= K_\alpha \|C\|^{1-\alpha}\|D\|^\alpha.\end{aligned}$$

The zero cases are immediate.

If $A, B \ge mI$, then both resolvents have norm at most $(t+m)^{-1}$, so

$$\|D_\alpha\| \le \frac{\sin(\pi\alpha)}{\pi}\|D\|\int_0^\infty \frac{t^\alpha}{(t+m)^2}\,dt.$$

After $t = mu$, the beta integral equals

$$m^{\alpha-1}\frac{\alpha\pi}{\sin(\pi\alpha)},$$

which gives the linear estimate. □

Corollary 10.4 (Fractional semigroup refinement)**.** *For $s \ge 0$,*

$$\boxed{Ce^{-sA^\alpha} - e^{-sB^\alpha}C = -\int_0^s e^{-(s-r)B^\alpha} D_\alpha e^{-rA^\alpha}\,dr.}$$

Hence

$$\left\|Ce^{-sA^\alpha} - e^{-sB^\alpha}C\right\| \le s\|D_\alpha\|.$$

Under the common gap $A, B \ge mI$,

$$\boxed{\left\|Ce^{-sA^\alpha} - e^{-sB^\alpha}C\right\| \le se^{-sm^\alpha}\alpha m^{\alpha-1}\|D\|.}$$

Proof. Differentiate

$$r \longmapsto e^{-(s-r)B^\alpha}Ce^{-rA^\alpha}$$

and integrate from 0 to s. Positive fractional semigroups are contractions. Under the gap, the product of their two norm bounds is e^{-sm^α}. □

Corollary 10.5 (Fractional refinement towers)**.** *Let $D_\ell = C_\ell A_{\ell+1} - A_\ell C_\ell$ in a bounded nonnegative self-adjoint tower, with $\sup_\ell \|C_\ell\| \le M$. If*

$$\sum_\ell \|D_\ell\|^\alpha < \infty,$$

then the fractional defects

$$C_\ell A_{\ell+1}^\alpha - A_\ell^\alpha C_\ell$$

have summable operator norms. If the tower has a uniform gap $m > 0$, it is enough that $\sum_\ell \|D_\ell\| < \infty$. On every bounded time interval, the series of corresponding fractional-semigroup defect norms converges uniformly. The maps may have different domain and codomain spaces. No operator sum across unrelated spaces is asserted.

Boundary 10.6 (Unbounded and nonnormal generators). The theorem resolves fractional naturality for bounded nonnegative self-adjoint refinement systems and gives the exact estimate needed for finite discretization towers. For unbounded positive generators, the same resolvent argument requires a declared common-domain condition and a bounded extension of $CA - BC$. Sectorial or nonnormal

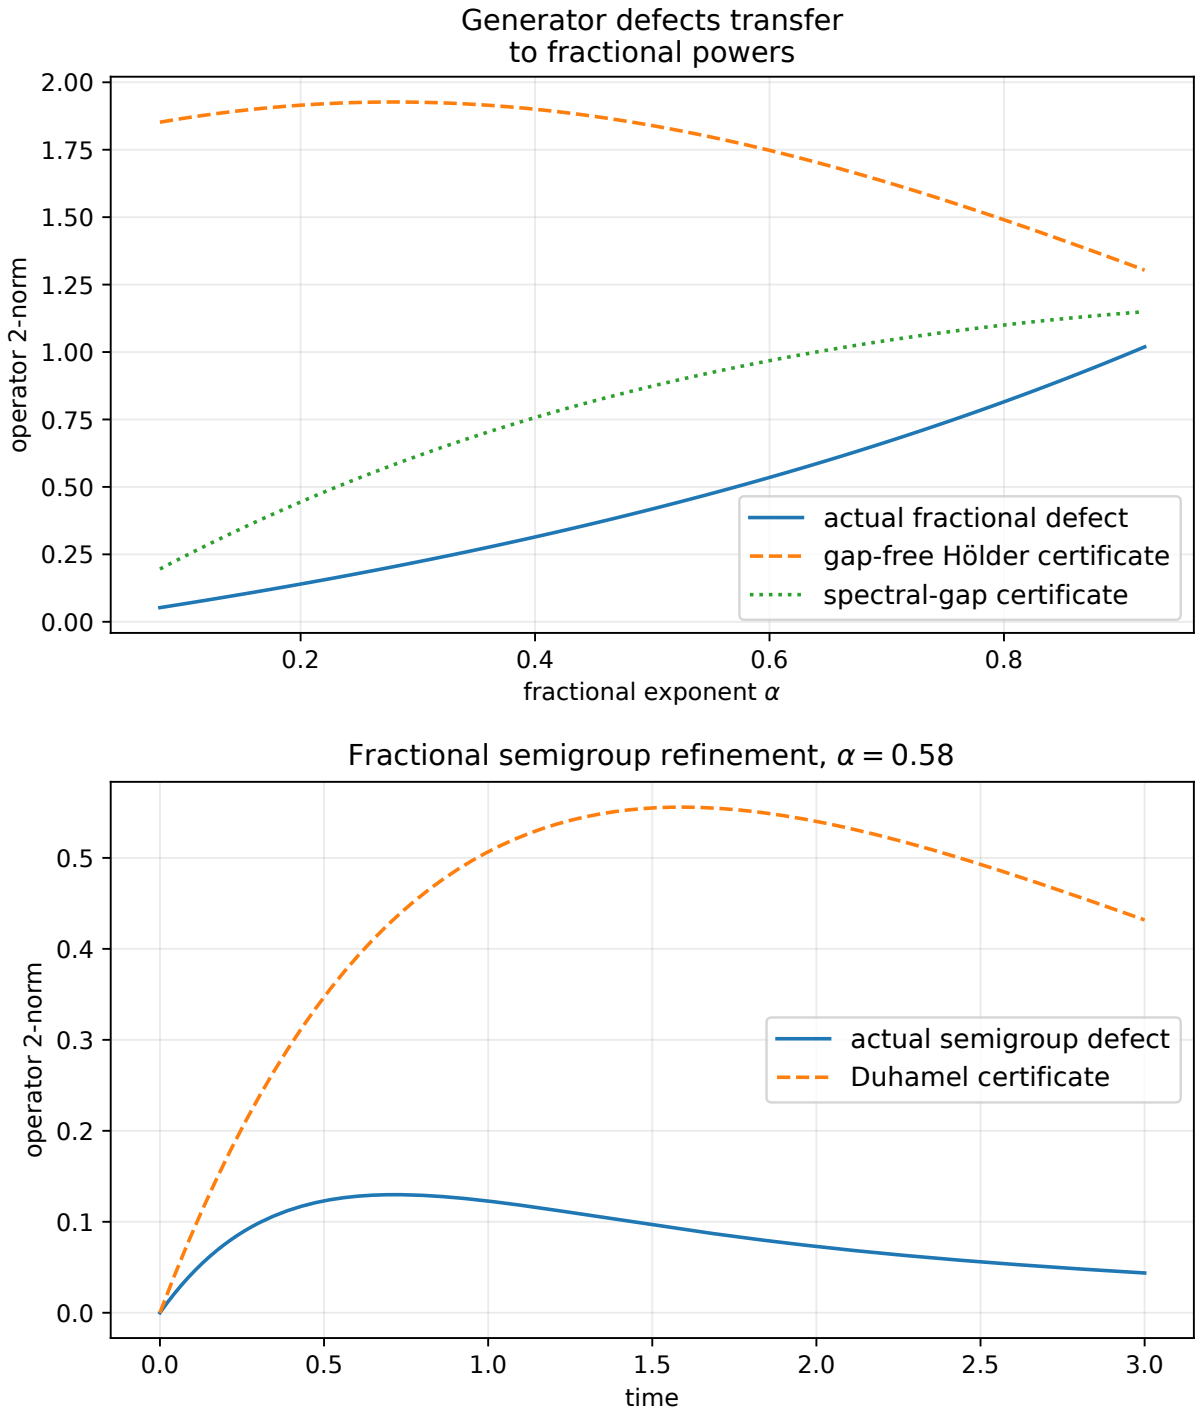

Figure 16. A generator-level refinement defect transfers quantitatively to fractional powers and then to fractional semigroups. The two upper curves are theorem certificates, not fitted error bars.

generators require their own contour calculus and resolvent bounds. Those domain questions are not inferred from the finite certificates.

Boundary 10.7 (Non-self-adjoint fractional powers). The spectral definition above is complete for finite self-adjoint positive operators. Sectorial and nonnormal operators require a resolvent or contour functional calculus. The same packet language can be used only after those analytic hypotheses are established.

11 Green operators and the Poisson seed

On the interval $(0,1)$ with Dirichlet boundary conditions, the Green kernel for $-u'' = f$ is

$$\boxed{G(x,y) = \min(x,y) - xy.}$$

Thus the point source δ_y generates the solution kernel, and a general source is reconstructed by

$$u(x) = \int_0^1 G(x,y) f(y)\, dy.$$

For n interior points with spacing $h = 1/(n+1)$, define

$$L_h = \frac{1}{h^2} \begin{pmatrix} 2 & -1 & & \\ -1 & 2 & \ddots & \\ & \ddots & \ddots & -1 \\ & & -1 & 2 \end{pmatrix}.$$

Theorem 11.1 (Exact discrete Green reconstruction at grid nodes). *Let $x_i = ih$. Then*

$$\boxed{\frac{1}{h}(L_h^{-1})_{ij} = G(x_i, x_j).}$$

Thus the scaled discrete inverse reproduces the continuum Dirichlet Green kernel exactly at the grid nodes.

Proof. The inverse of the unscaled tridiagonal matrix has entries

$$\frac{\min(i,j)(n+1-\max(i,j))}{n+1}.$$

Multiplying by h^2 and then dividing by h gives

$$h \min(i,j) \left(1 - \frac{\max(i,j)}{n+1}\right) = \min(x_i, x_j) - x_i x_j.$$

□

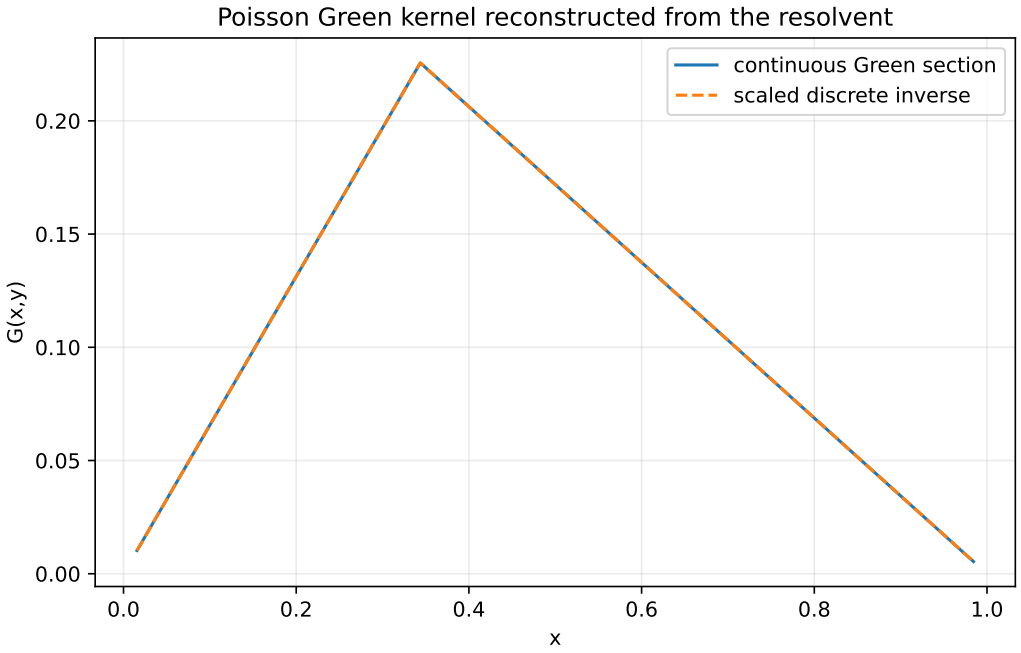

Figure 17. A section of the continuum Green kernel and the scaled discrete inverse. They agree at the grid nodes.

11.1 Low-mode convergence

The kth discrete eigenvalue is

$$\lambda_{k,h} = \frac{4}{h^2}\sin^2\left(\frac{k\pi h}{2}\right),$$

whereas the continuum eigenvalue is $(k\pi)^2$.

Theorem 11.2 (Second-order low-mode convergence). *For fixed k,*

$$\lambda_{k,h} = (k\pi)^2 + O(h^2).$$

More precisely, for sufficiently small h,

$$0 \le (k\pi)^2 - \lambda_{k,h} \le \frac{(k\pi)^4}{12}h^2.$$

Proof. For $x \ge 0$, $0 \le x^2 - \sin^2 x \le x^4/3$. Set $x = k\pi h/2$ and multiply by $4/h^2$. □

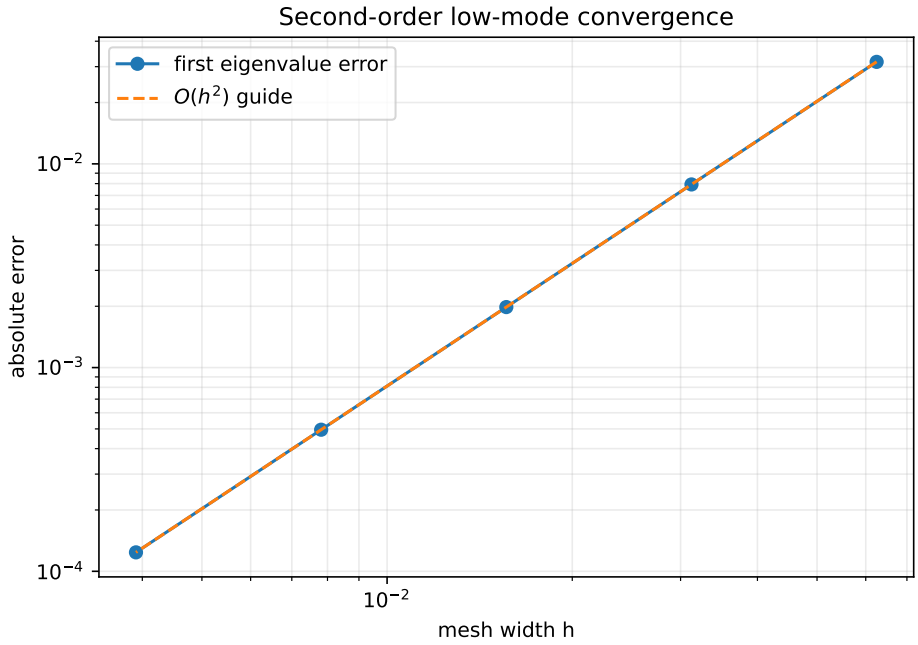

Figure 18. The first finite-difference eigenvalue converges with observed order approximately two.

12 Finite-state Feynman–Kac transfer

Let K be a column-stochastic matrix, let V be a potential on the states, and let f be terminal data. Define

$$M_V = \operatorname{diag}(e^{-V})K^T.$$

The backward Feynman–Kac value after n steps is

$$u_n = M_V^n f.$$

Theorem 12.1 (Discrete Feynman–Kac path formula)**.** *For an initial state i,*

$$\boxed{(u_n)_i = \mathbb{E}_i\left[\exp\left(-\sum_{r=0}^{n-1} V(X_r)\right) f(X_n)\right].}$$

Proof. For $n = 1$,

$$(M_V f)_i = e^{-V(i)} \sum_j K_{ji} f_j,$$

which is the stated expectation. Iterating and expanding the matrix product sums over every path $(i = i_0, i_1, \dots, i_n)$ with probability $\prod_r K_{i_{r+1}, i_r}$ and weight $\prod_r e^{-V(i_r)}$. □

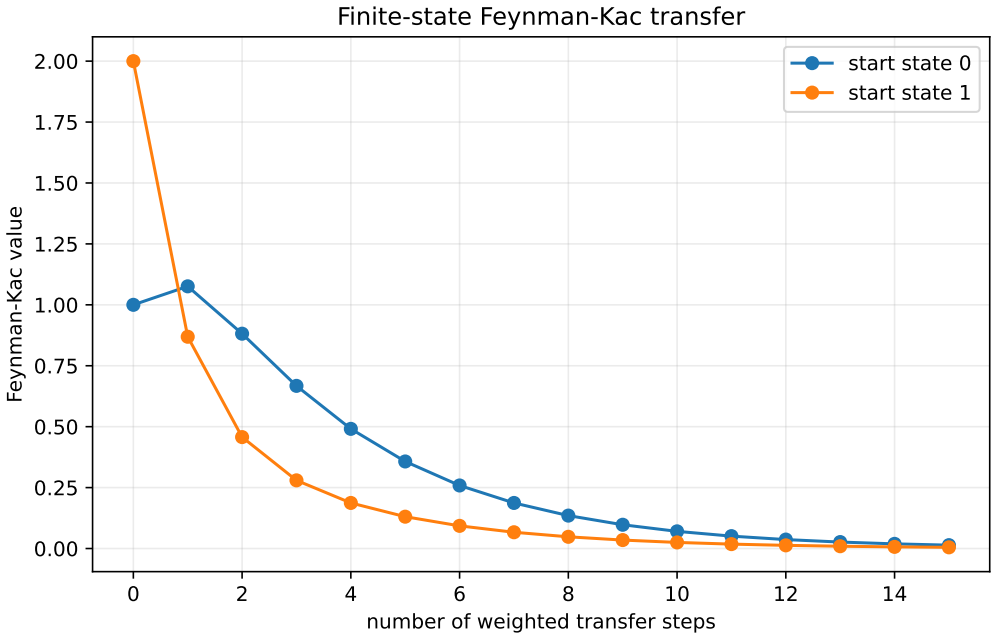

Figure 19. Potential-weighted transfer values computed by the finite Feynman–Kac operator. Exhaustive path enumeration agrees with the matrix formula in the supplied tests.

13 Exact elimination of latent packets

The central idea

Elimination removes hidden coordinates from the displayed state, but their future influence survives. The resolvent stores that influence as a self-energy. The time description stores it as a memory kernel. Both descriptions refer to the same declared block system.

Let $X = PX \oplus QX$ and write

$$A = \begin{pmatrix} A_{PP} & A_{PQ} \\ A_{QP} & A_{QQ} \end{pmatrix}.$$

Theorem 13.1 (Schur–Feshbach projected resolvent). *Assume both $zI - A$ and $zI - A_{QQ}$ are invertible. Define*

$$\boxed{F_P(z) = zI - A_{PP} - A_{PQ}(zI - A_{QQ})^{-1}A_{QP}.}$$

Then

$$\boxed{P(zI - A)^{-1}\big|_{\operatorname{Ran} P} = F_P(z)^{-1}.}$$

Proof. Solve the hidden block equation

$$(zI - A_{QQ})x_Q = A_{QP}x_P + y_Q$$

for x_Q and substitute it into the retained equation. The resulting retained coefficient is $F_P(z)$. Invertibility of the full operator and of the hidden block implies invertibility of this Schur complement. Setting

$y_Q = 0$ gives the stated identity as an operator on $\operatorname{Ran} P$. Equivalently, this is the block inverse formula. □

The self-energy

$$\Sigma_P(z) = A_{PQ}(zI - A_{QQ})^{-1}A_{QP}$$

contains the exact effect of the eliminated packets. A bare truncation A_{PP} discards this term and is generally not exact.

13.1 Time-domain memory

For the homogeneous system $\dot{x} = Ax$, variation of constants gives

$$x_Q(t) = e^{tA_{QQ}}x_Q(0) + \int_0^t e^{(t-r)A_{QQ}}A_{QP}x_P(r)\,dr.$$

Substitution yields

$$\dot{x}_P(t) = A_{PP}x_P(t) + A_{PQ}e^{tA_{QQ}}x_Q(0) + \int_0^t \mathcal{K}(t-r)x_P(r)\,dr,$$

where

$$\boxed{\mathcal{K}(t) = A_{PQ}e^{tA_{QQ}}A_{QP}.}$$

Theorem 13.2 (Memory/self-energy correspondence)**.** *For finite complex block matrices, assume* $\operatorname{Re} z > \operatorname{Re}\lambda$ *for every* $\lambda \in \sigma(A_{QQ})$*. Then the following improper integral is absolutely convergent and*

$$\boxed{\int_0^\infty e^{-zt}\mathcal{K}(t)\,dt = A_{PQ}(zI - A_{QQ})^{-1}A_{QP} = \Sigma_P(z).}$$

Proof. Put $B = A_{QQ}$ and $T_z(t) = e^{-zt}e^{tB} = e^{t(B-zI)}$. The generalized-eigenspace decomposition in finite dimensions writes T_z as a finite sum of constant matrix coefficients times $t^k e^{(\lambda-z)t}$. This follows by expanding the nilpotent part on each generalized eigenspace. Equivalently, apply the decomposition to left multiplication by B on the matrix algebra and evaluate the exponential at I. The strict spectral inequality makes every such term absolutely integrable on $(0,\infty)$ and forces it to tend to zero. Hence T_z is Bochner integrable and $T_z(t) \to 0$, including when B is nonnormal.

Let $J = \int_0^\infty T_z(t)\,dt$. Integrating both derivative identities $T_z' = (B - zI)T_z = T_z(B - zI)$ and using $T_z(0) = I$ gives

$$(zI - B)J = J(zI - B) = I.$$

Thus $J = (zI - B)^{-1}$. Continuous left and right multiplication carry the Bochner integral through the two rectangular transfer blocks, yielding the claim. □

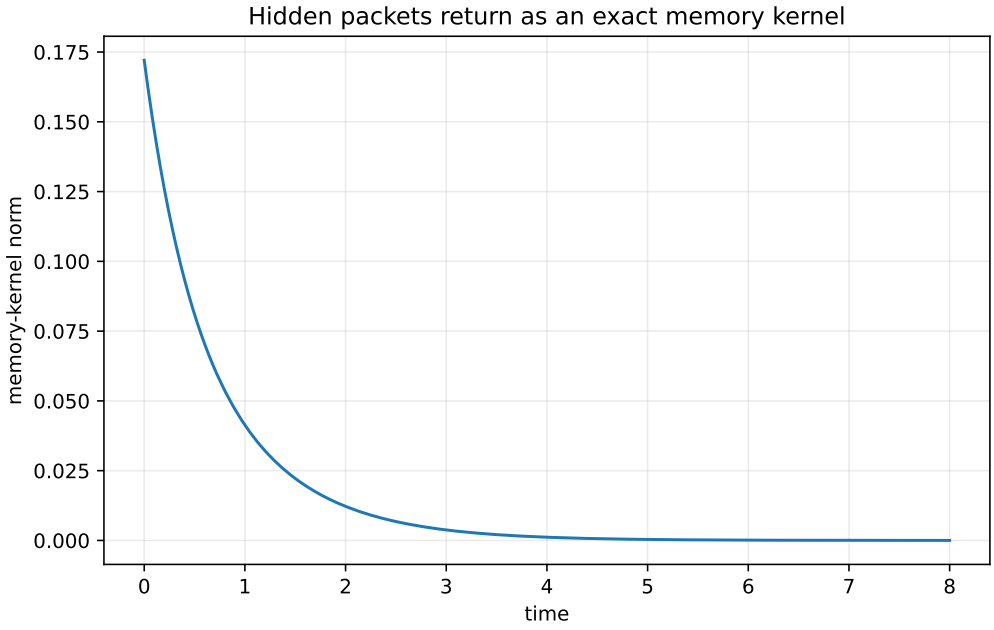

Figure 20. The norm of the exact memory kernel produced by eliminated packets.

14 Survival and hazard semigroups

Let A be a finite subgenerator: its off-diagonal entries are nonnegative and its column sums are nonpositive. These sign conditions alone allow nonabsorbing states. Eventual absorption is a separate hypothesis. Let p_0 be an initial transient-state distribution. Define

$$p(t) = e^{tA}p_0, \qquad S(t) = 1^T p(t).$$

The exit-rate row vector is

$$a^T = -1^T A \geq 0.$$

Theorem 14.1 (Semigroup survival identities). *For $t \geq 0$, the finite-time exit density and, wherever $S(t) > 0$, the hazard are*

$$\boxed{f(t) = a^T e^{tA} p_0 = -S'(t), \qquad h(t) = \frac{f(t)}{S(t)}.}$$

Consequently, S is nonincreasing and

$$S(t) = \exp\left(-\int_0^t h(r)\,dr\right)$$

whenever $S(t) > 0$. The density may be defective: its total mass is $1 - \lim_{t\to\infty} S(t)$. It is a probability density when absorption is eventual, so that this limit is zero.

Proof. Differentiate:

$$S'(t) = 1^T A e^{tA} p_0 = -a^T e^{tA} p_0.$$

The hazard identity is the definition of conditional instantaneous exit rate. Integrating $(\log S)' = -h$ gives the final formula. □

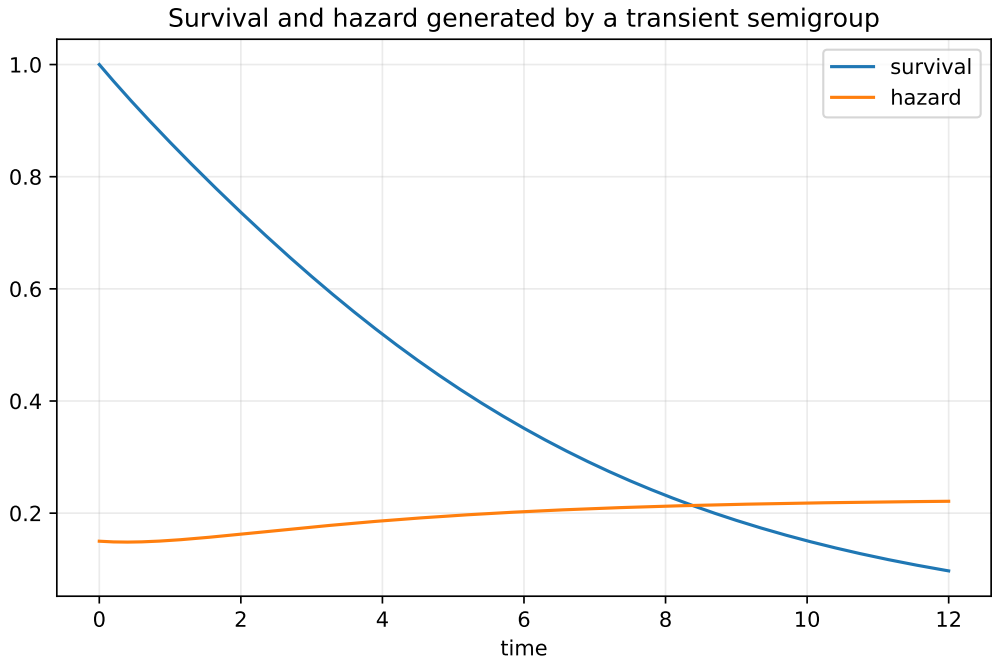

Figure 21. Survival and instantaneous hazard produced by one transient transfer semigroup.

15 One common operator language

The preceding constructions are not identical, but they use the same packet operations. The domain dictionary is summarized in table 1.

Realization	Seed	Transfer	Packet/reconstruction law
Markov	point mass δ_i	K^n or e^{tQ}	state lumping and $CK^n = \bar{K}^n C$
Conditional	random variable	P_Q	nested partitions and tower law
Bayesian	prior p	$\mathcal{B}_\lambda$	packet evidences and normalized synthesis

Table 1. The transfer-semigroup dictionary in the common operator language.

For clarity, the finite-dimensional holomorphic calculus used below has the following canonical definition. For A acting on $\mathbb{C}^d$, its generalized eigenspaces $E_\mu = \ker(A-\mu I)^d$ form a direct-sum decomposition over the eigenvalues. Define the unique linear operator $F(A)$ by

$$F(A)|_{E_\mu} = \sum_{k=0}^{d-1} \frac{F^{(k)}(\mu)}{k!}(A-\mu I)^k\Big|_{E_\mu}.$$

The formula is independent of a basis and of increasing the truncation index: the extra nilpotent powers vanish. It depends only on the finite Taylor jets of F at the spectrum. If F is holomorphic on an open neighborhood U of the spectrum, each eigenvalue admits a radius $r_\mu > 0$ with $\overline{D(\mu, r_\mu)} \subset U$, and Cauchy's formula gives

$$\frac{F^{(k)}(\mu)}{k!} = \frac{1}{2\pi i}\oint_{|z-\mu|=r_\mu} \frac{F(z)}{(z-\mu)^{k+1}}\,dz.$$

Consequently the same canonical operator is obtained from any such local Cauchy circles, even when U is disconnected. This is the standard finite Taylor-jet definition of the holomorphic matrix function.

Theorem 15.1 (Naturality under exact intertwining). *For finite complex matrices, let F be holomorphic on a neighborhood of the union of the spectra of A_f and A_c. Real matrices are treated by complexification. If*

$$CA_f = A_cC,$$

then

$$\boxed{CF(A_f) = F(A_c)C.}$$

In particular, exact generator refinement propagates simultaneously to semigroups, resolvents, integer powers, and analytic transfer functions.

Proof. The intertwining identity implies $C(A_f-\mu I)^k = (A_c-\mu I)^k C$ for every $k \geq 0$. It therefore sends the generalized μ-eigenspace of A_f into that of A_c. Use a common truncation index at least as large as both dimensions in the canonical formula above. Multiplying its finite sum by C now gives the desired identity on every generalized eigenspace. The direct-sum decomposition gives it on the full space. The argument covers nilpotent Jordan parts and uses only local spectral Taylor jets. It does not require one Taylor series to converge on both spectra. The zero-dimensional case is immediate. □

Remark 15.2 (Where nonlinearity enters). Bayesian conditioning does not fit the preceding linear functional calculus because normalization depends on the current state. It nevertheless obeys an exact composition law and has a closed packet reconstruction. Chapter III supplies the general nonlinear coordinate theorem. The Bayesian map is a probabilistic realization.

16 Numerical certificates

The recorded calculations were run on CPU. No GPU timing or performance claim is made. Floating-point residuals are implementation checks and are not substitutes for the symbolic proofs.

Numerical Certificate 16.1 (Test suite). The recorded automated test suite reports the following result:

$$\boxed{54/54 \text{ automated tests.}}$$

Certificate	Value
Packet-block semigroup composition residual	2.554×10^{-15}
Operator reconstruction residual	0
Random-walk mass error	0
Exact Markov generator-lumping defect	5.551×10^{-17}
Exact finite-horizon lumping error	2.220×10^{-16}
Perturbed ten-step lumping error	6.523×10^{-3}
Linear defect bound for that example	2.000×10^{-1}
Bayesian composition residual	5.551×10^{-17}
Bayesian packet reconstruction residual	0
Bayesian refinement commutation residual	1.110×10^{-16}
Bayesian defect-factorization residual	7.286×10^{-17}
Bayesian flow generator residual	1.959×10^{-11}
Conditional-expectation tower residual	0
Hermite Gram residual	9.992×10^{-15}
Fractional semigroup residual	2.082×10^{-17}
Maximum square-root subordination error	1.665×10^{-16}
Exact fractional-naturality residual	0
Fractional-power defect / gap certificate	$0.51059/0.95079$
Fractional-semigroup defect / certificate	$0.12969/0.44480$
Observed low-mode PDE convergence order	1.999854
Feynman–Kac enumeration residual	1.665×10^{-16}
Feshbach projected-resolvent residual	5.551×10^{-17}
Memory Laplace-transform residual	6.939×10^{-18}
Duhamel refinement identity residual	2.108×10^{-16}
Survival monotonicity violation	0
Hidden-Markov normalization error	1.110×10^{-16}

Table 2. Selected results from the machine-readable numerical record.

The tests cover projector reconstruction, packet-block semigroup composition, exact and approximate Markov lumping, Bayesian composition and flow, the exact Bayesian refinement criterion, information-loss factorization, likelihood-profile partitions, conditional-expectation towers, Hermite orthogonality, fractional semigroups, square-root subordination, fractional intertwining and semigroup-defect bounds, discrete Green kernels, PDE convergence, Feynman–Kac enumeration, Schur–Feshbach elimination, memory kernels, refinement defects, hidden Markov filtering, and survival curves.

17 Remaining conjectural extensions

The finite theory closes several operator identities but does not settle the corresponding universal continuum questions.

Conjecture 17.1 (Transfer-semigroup realization)**.** Every sufficiently regular realization of the seed calculus whose transfer stage is local in time admits a closed generator on a completed state space, and the packet analysis maps form a compatible system for its semigroup or evolution family.

Conjecture 17.2 (Uniform refinement control)**.** For a nested family of physically or analytically meaningful discretizations, there exist norms and constants independent of resolution such that

$$\left\|C_\ell e^{tA_{\ell+1}} - e^{tA_\ell} C_\ell\right\| \le M\, t\, \left\|C_\ell A_{\ell+1} - A_\ell C_\ell\right\|$$

on every bounded time interval. Summable generator defects would then produce a coherent inverse-limit evolution.

Conjecture 17.3 (Latent-packet closure)**.** For a stable infinite packet system, exact elimination of unresolved packets produces a causal memory kernel whose Laplace transform is the limiting packet self-energy. A Markovian closure exists precisely when this self-energy is constant, or can be represented by finitely many additional state packets.

Boundary 17.4 (What remains outside Chapter VI)*.* The following issues are not proved here:

1. existence and uniqueness for arbitrary stochastic differential equations;
2. posterior consistency or asymptotic normality in infinite statistical models;
3. domain invariance for unbounded fractional operators;
4. tightness and compactness required for stochastic continuum limits;
5. nonlinear PDE well-posedness beyond the stated finite and linear models;
6. an optimal packet choice for a general Markov, Bayesian, or PDE problem.

These belong to later realization-specific work or to external analytic theory.

18 Computational implementation

The accompanying Python package implements the formulas and finite models used in the chapter.

```
projector_transfer_semigroups
```

The computational organization mirrors the chapter:

`packets.py`	projectors, blocks, reconstruction, block composition
`semigroup.py`	matrix semigroups, defects, Feshbach operators, memory
`markov.py`	random walks, exact lumping, survival
`bayes.py`	normalized updates, packet evidence, conjugacy, flows, HMM
`conditional.py`	conditional expectation and Gaussian chaos
`fractional.py`	spectral powers, subordination, and fractional refinement certificates
`pde.py`	Dirichlet Laplacians, Green kernels, eigenvalue error
`feynman_kac.py`	weighted transfer and exhaustive path enumeration.

18.1 Representative algorithms

Listing 1. Normalized finite Bayesian update.

```
def bayes_update(prior, likelihood):
    p = normalize(prior)
    evidence = likelihood @ p
    if evidence <= 0:
        raise ValueError("positive evidence required")
    return likelihood * p / evidence
```

Listing 2. Packet block composition.

```
def block_composition(left, right):

    return z*I - App - Apq @ inv(z*I - Aqq) @ Aqp
```

The source corpus contains the implementation, tests, tables, figure-generation code and numerical records.

19 Conclusion

The transfer-semigroup realization gives one common operator language to several subjects that are often presented separately. Markov propagation is linear transfer of a probability seed. Conditional expectation is stochastic projection. Bayesian conditioning is normalized nonlinear transfer, and its exact finite coarsening law is characterized by packetwise likelihood sufficiency. Fractional calculus is spectral packet reweighting, and bounded positive refinement defects transfer to fractional powers and fractional semigroups by explicit resolvent and Duhamel estimates. A Green operator reconstructs a field from source packets. Feynman–Kac propagation adds path weights to stochastic transfer. Schur–Feshbach elimination shows that hidden packets are not destroyed. They return through self-energy and memory. Survival and hazard are scalar reconstructions of a transient semigroup.

The central structural identity is

$$\boxed{\text{generator defect} \longrightarrow \text{Duhamel semigroup defect} \longrightarrow \text{controlled refinement error.}}$$

Together with exact packet reconstruction, this makes the semigroup chapter the natural bridge from the foundational calculus to the quantum, computational, and arithmetic realizations that follow.

A Lean verification and scope

The formal development contains 341 explicit Lean theorem declarations across 47 proof modules. The saved compiler record reports a successful build and namespace audit under the pinned toolchain. The audit inspects 782 declarations, including definitions and generated auxiliaries. Only propext, Classical.choice and Quot.sound are allowed. These are different counting units from Part I's 33 theorem-like results.

The ledger has **33 complete, zero partial and zero pending results**. The last two results, 13.2 and 15.1, are complete. The three separately stated conjectures remain open and are excluded from this count.

"Complete" means the stated scope follows from the named checked targets and the ordinary specializations recorded in the ledger. Prose-to-Lean correspondence is manually reviewed. The fractional targets use complex Hilbert spaces. Complexification for real operators is an ordinary mathematical specialization, not a separately checked Lean construction. Completion of the theorem ledger does not certify every prose sentence, numerical figure or open conjecture.

Result	Manuscript statement	Lean scope
1.2	Finite semigroup law	Complete
2.1	Packet semigroup convolution	Complete
2.2	Reducing packets	Complete
3.1	Exact Duhamel refinement identity	Complete
3.2	Norm bound	Complete
3.3	Resolvent refinement identity	Complete
4.1	Finite Markov semigroup	Complete
5.1	Exact lumpability	Complete
5.2	Finite-horizon defect formula	Complete
6.1	Finite conditional-expectation projector	Complete
6.2	Tower law and martingale packets	Complete
7.1	Independent-likelihood composition	Complete
7.2	Bayesian packet reconstruction	Complete
7.3	Likelihood perturbation bound	Complete
8.1	Exact effective-likelihood factorization	Complete
8.2	Bayesian refinement criterion	Complete
8.4	Bayesian information-loss packet	Complete
8.5	Nested Bayesian packet tower	Complete
8.6	Canonical coarsest likelihood-resolving partition	Complete

9.3	Prediction-update reconstruction	Complete
10.1	Fractional packet calculus	Complete
10.2	Poisson subordination	Complete
10.3	Fractional intertwining theorem	Complete
10.4	Fractional semigroup refinement	Complete
10.5	Fractional refinement towers	Complete
11.1	Exact discrete Green reconstruction at grid nodes	Complete
11.2	Second-order low-mode convergence	Complete
12.1	Discrete Feynman–Kac path formula	Complete
13.1	Schur–Feshbach projected resolvent	Complete
13.2	Memory/self-energy correspondence	Complete

Result	Manuscript statement	Lean scope
14.1	Semigroup survival identities	Complete
15.1	Naturality under exact intertwining	Complete

General nonnormal memory (13.2). The actual damped exponential is decomposed into finitely many terms of the form $t^k e^{(\mu-z)t}$. Integrability and convergence to zero follow from $\operatorname{Re}\mu < \operatorname{Re} z$. The formal proof uses generalized eigenspaces of left multiplication on the matrix algebra, so nilpotent Jordan parts are included. Both inverse identities follow by integrating the two exponential derivative formulas. A continuous linear sandwich map gives the literal rectangular matrix memory integral and the actual inverse. No normality or externally supplied growth bound is required.

Canonical holomorphic naturality (15.1). The standard finite Taylor-jet calculus defined before the theorem is constructed using the direct sum of generalized eigenspaces. Uniqueness, cutoff stability and exact rectangular naturality are proved. Cauchy's formula identifies the local coefficients with actual circle integrals. Admissible radii exist in every stated open holomorphic neighborhood, and changing them leaves the canonical operator unchanged. The argument permits disconnected neighborhoods and different matrix dimensions. It makes no assertion about general Banach-algebra contour deformation.

Fractional results (10.3–10.5). The formalization proves the scalar beta normalization, the Lebesgue integral representation of actual positive fractional powers, the literal resolvent-defect formula, both printed norm constants and exact intertwining. The rectangular complex-Hilbert-space semigroup proof substitutes those constants into Duhamel's identity. The varying-space tower proof gives summability of fractional-defect norms and uniform convergence of time-defect norm series on bounded time intervals. Here "summable" means summable in norm. Operators with unrelated codomains are not added together. A separate fixed-space theorem proves operator-series convergence when such a sum is defined.

Verification and numerical evidence. The saved records report the full pinned build, project-wide axiom audit, all 54 companion tests and six verifier controls passed.
The 54 tests comprise the original 37 tests and 17 boundary and validation cases.
The numerical records identify the 19 figure pairs and the separate 79-field comparison.
The numerical comparison and the visual replay have separate execution records.
Source contracts, exact theorem targets, full logs and checked ledgers accompany the source files.
Numerical tests are finite regressions. They are not substitutes for the Lean proofs.

Part II Extended mathematical development

Overview

A bounded generator and a finite packet system turn a semigroup into a matrix of transfer blocks. We prove convolution, differential, path, Laplace, resolvent, and defect formulas. Exact intertwining yields an inverse limit semigroup. Weighted summable adjacent defects give convergent reconstructed evolutions, while range leakage determines whether the limit remains a semigroup. For finite Markov chains we identify a canonical lumping obstruction and quantify its failure. Conditional expectations give orthogonal martingale packets, and the Ornstein–Uhlenbeck semigroup gives a countable Hermite model. Bayesian updating is treated as normalized transfer. We characterize exact coarse sufficiency, determine the coarsest nontrivial fixed sufficient partition for a likelihood family when the common level sets are nontrivial, and split relative information into coarse and local terms. Positive fractional powers are handled through spectral, Balakrishnan, and subordination formulas. Green operators, finite differences, and finite state Feynman–Kac formulas provide analytic realizations. Schur–Feshbach elimination produces a rational self-energy and an exact memory kernel. Every stable finite hidden system yields a polynomial exponential expansion, including Jordan blocks. A certified optimal primary block selection and a Volterra estimate control reduced trajectories. State dependent killing, survival laws, moments, and competing risks complete the finite theory.

E1 Introduction

One parameter semigroups provide a common language for evolution equations, Markov processes, diffusion, and resolvent methods. Standard analytic foundations appear in [Paz83, EN00]. Finite Markov chains and their coarse descriptions are treated in [KS60, Nor97, RP81]. Conditional expectation and martingale difference decompositions are basic parts of probability theory [Wil91]. Gaussian transfer and Hermite expansions provide a spectral model for the Ornstein–Uhlenbeck semigroup [Jan97]. Fractional powers of generators and subordinate semigroups belong to the functional calculus of positive and sectorial operators [Bal60, SSV12]. The Feynman–Kac formula, projection methods, and phase type laws add three further views of transfer [Kac49, Fes58, Zwa61, Neu81].

These subjects share a simple operation. A state is propagated, resolved into declared components, compared across levels, and reconstructed. The same operation can be linear, as in a Markov semigroup, or normalized and nonlinear, as in Bayesian conditioning. Hidden components can be discarded from the state vector without disappearing from the dynamics. Their exact influence returns through a frequency dependent self-energy or a time dependent memory kernel.

The first sections of this part treat bounded semigroups on Banach spaces. A finite packet system resolves every operator into input and output blocks. The semigroup law becomes block convolution. Splitting the generator into its packet diagonal and transfer part gives a convergent Dyson expansion over directed packet paths. For a coarse map C, the generator defect

$$\Delta = CA_f - A_c C$$

produces the entire semigroup defect through a Duhamel integral. The same defect controls resolvents and holomorphic functions of the generators.

The next question concerns refinement towers. Exact intertwining gives a coordinatewise semigroup on the bounded inverse limit. Approximate refinement is more delicate. Even if every adjacent defect is small, reconstruction from a fine level can introduce a second error because a coarse state need not remain inside the reconstructed fine subspace. We separate these two effects. Summability of adjacent defects gives a uniform limit of reconstructed coarse evolutions. An asymptotic closure condition is then sufficient for the limiting family to satisfy the semigroup law.

The probabilistic part begins with finite Markov chains. Exact lumpability is the vanishing of a canonical obstruction on the kernel of aggregation. In coordinates, this is equality of the transition mass sent from any two states in the same source block into every target block. The usual finite horizon defect formula follows from telescoping. Conditional expectation is then treated as an orthogonal projector. A nested family of partitions produces mutually orthogonal martingale packets and an exact energy decomposition.

Bayesian updating requires more care because normalization depends on the current prior. Given a partition, every fine update has an exact two stage description. The block masses are updated by prior dependent average likelihoods, while the conditional distribution inside each block is updated by its centered likelihood variation. A fixed coarse Bayesian rule works for every prior precisely when the likelihood is constant inside each block. This gives a finite and exact form of Bayesian sufficiency. For a family of likelihoods with at least two common level sets, those level sets form the unique coarsest nontrivial fixed sufficient partition. Relative entropy then separates exactly into information retained by the coarse packet masses and information carried by the local conditional changes. The same part derives perturbation bounds, the replicator flow, a variance identity for accumulated evidence, and stability estimates for hidden Markov filtering.

For a positive operator L, spectral packets define L^{α} and $\mathrm{e}^{-tL^{\alpha}}$. Exact intertwining passes to every fractional power. When both fine and coarse operators have a common positive lower bound m, the Balakrishnan formula gives the quantitative estimate

$$\left\| CL_f^{\alpha} - L_c^{\alpha} C \right\| \leq \alpha m^{\alpha-1} \left\| CL_f - L_c C \right\|, \qquad 0 < \alpha < 1.$$

A Duhamel argument then controls the fractional semigroup defect. This closes a finite version of fractional naturality under explicit spectral hypotheses.

The final sections move from generators to source reconstruction and hidden variables. The one-dimensional Dirichlet Green kernel is reproduced exactly by the scaled inverse of the second difference matrix at grid nodes. A discrete maximum principle gives a complete second order error estimate for smooth Poisson solutions. Finite state Feynman–Kac transfer is proved in discrete and continuous time. Schur–Feshbach elimination yields the exact projected resolvent, the retained memory equation, and the Laplace correspondence between memory and self-energy. Every stable finite hidden system gives a polynomial exponential memory expansion. Primary blocks can be ranked optimally for the certified L^1 bound, and a Volterra estimate carries kernel error to the retained solution. Survival, event density, moments, and competing risks are then read directly from a transient semigroup.

Several claims are intentionally absent. No arbitrary unbounded operator is asserted to generate a semigroup. The inverse limit theorem uses bounded generators or an explicit uniform continuity condition. Bayesian sufficiency is proved for a finite partition and a fixed likelihood. The fractional defect estimate uses a common spectral gap. The Poisson estimate concerns the stated one-dimensional scheme. Memory compression is controlled for the declared finite or integrable kernels. General stochastic differential equations, posterior consistency, nonlinear partial differential equations, and optimal model reduction remain outside this part.

Realization	Transfer	Exact coarse condition
Operator evolution	e^{tA}	generator intertwining
Markov chain	K^n or e^{tQ}	equality of aggregated transition masses
Conditional expectation	P_Q	nesting of the underlying partitions
Bayesian update	$\mathcal{B}_\lambda$	likelihood constant inside each coarse packet
Fractional diffusion	e^{-tL^α}	spectral or resolvent intertwining
Hidden dynamics	projected resolvent	vanishing self-energy, or an explicit memory state
Survival law	transient semigroup	summation over all transient states

Table E1. The transfer operations studied in this part and the condition that makes each coarse description exact.

The same words have different meanings in the realizations below. The table records the object that is transferred and the condition that makes its coarse description exact.

E2 Packet resolved semigroups

Let X be a complex Banach space. A finite packet system is a family of bounded idempotents

$$\mathcal{P} = (P_\alpha)_{\alpha \in I}$$

such that

$$P_\alpha P_\beta = \delta_{\alpha\beta} P_\alpha, \qquad \sum_{\alpha \in I} P_\alpha = I_X.$$

No orthogonality is needed in this section.

Definition E2.1 (Packet resolved transfer system)**.** A packet resolved transfer system is a triple

$$(X, A, \mathcal{P})$$

consisting of a Banach state space, a bounded generator, and a finite packet system. A marked transfer system also includes an initial state or source $s \in X$. The topology and all limiting operations are supplied by the ambient Banach space structure.

Definition E2.2 (Packet blocks)**.** For $B \in \mathcal{B}(X)$, define

$$B_{\beta\alpha} = P_\beta B P_\alpha.$$

If $A \in \mathcal{B}(X)$ and $T(t) = e^{tA}$, write

$$T_{\beta\alpha}(t) = P_\beta T(t) P_\alpha.$$

Theorem E2.3 (Semigroup and packet convolution). *For every bounded operator A, the family $T(t) = \mathrm{e}^{tA}$ is a uniformly continuous group and*

$$T(s+t) = T(s)T(t).$$

For every $\alpha, \beta \in I$,

$$T_{\beta\alpha}(s+t) = \sum_{\gamma \in I} T_{\beta\gamma}(s) T_{\gamma\alpha}(t).$$

Proof. The exponential series converges in operator norm. Since every power of A commutes with every other power, the Cauchy product gives the group law. Inserting $I_X = \sum_\gamma P_\gamma$ between the two factors gives the block formula. □

Proposition E2.4 (Block differential system). *The packet blocks are differentiable in operator norm and satisfy*

$$\frac{\mathrm{d}}{\mathrm{d}t} T_{\beta\alpha}(t) = \sum_{\gamma \in I} A_{\beta\gamma} T_{\gamma\alpha}(t) = \sum_{\gamma \in I} T_{\beta\gamma}(t) A_{\gamma\alpha}.$$

Their initial values are

$$T_{\beta\alpha}(0) = \delta_{\beta\alpha} P_\alpha.$$

Proof. Differentiate $T(t)$ in operator norm and insert the packet resolution between A and $T(t)$, then between $T(t)$ and A. □

Theorem E2.5 (Laplace resolvent and packet transform). *Let $A \in \mathcal{B}(X)$, let $T(t) = \mathrm{e}^{tA}$, and let*

$$\operatorname{Re} z > \|A\|.$$

Then the Bochner integral converges in operator norm and

$$(zI - A)^{-1} = \int_0^\infty \mathrm{e}^{-zt} T(t)\, \mathrm{d}t.$$

For every pair of packets,

$$P_\beta (zI - A)^{-1} P_\alpha = \int_0^\infty \mathrm{e}^{-zt} T_{\beta\alpha}(t)\, \mathrm{d}t.$$

Proof. The estimate $\|T(t)\| \le \mathrm{e}^{t\|A\|}$ gives absolute convergence of the operator valued integral. Let

$$R(z) = \int_0^\infty \mathrm{e}^{-zt} T(t)\, \mathrm{d}t.$$

Since $T'(t) = AT(t) = T(t)A$, integration by parts gives

$$(zI - A) R(z) = -\int_0^\infty \frac{\mathrm{d}}{\mathrm{d}t} (\mathrm{e}^{-zt} T(t))\, \mathrm{d}t = I.$$

The same calculation on the other side gives $R(z)(zI - A) = I$. Multiplication by P_β and P_α may be passed under the norm convergent integral, which gives the packet formula. □

Corollary E2.6 (Resolvent expansion over packet paths). *With $A = D + N$ as in the directed path decomposition, let*

$$R_D(z) = (zI - D)^{-1}.$$

If

$$\|R_D(z)N\| < 1,$$

then

$$(zI - A)^{-1} = \sum_{m=0}^{\infty} \bigl(R_D(z)N\bigr)^m R_D(z).$$

After multiplication by P_β and P_α, the term of order m is a sum over directed packet paths of length m from α to β.

Proof. Factor

$$zI - A = (zI - D)(I - R_D(z)N)$$

and expand the second inverse by its norm convergent Neumann series. The diagonal resolvent preserves each packet and every factor N changes the packet along an active transfer edge. □

Theorem E2.7 (Reducing packet criterion). *The following conditions are equivalent.*

1. *$AP_\alpha = P_\alpha A$ for every α.*
2. *$A_{\beta\alpha} = 0$ whenever $\beta \neq \alpha$.*
3. *$T_{\beta\alpha}(t) = 0$ whenever $\beta \neq \alpha$ and $t \in \mathbb{R}$.*
4. *Every packet space $P_\alpha X$ is invariant under $T(t)$ for every t.*

When these conditions hold,

$$T(t)|_{P_\alpha X} = \mathrm{e}^{tA_{\alpha\alpha}}.$$

Proof. The first two conditions are equivalent because the packet resolution gives

$$AP_\alpha = \sum_{\beta} A_{\beta\alpha}, \qquad P_\alpha A = \sum_{\gamma} A_{\alpha\gamma}.$$

A block diagonal generator has block diagonal powers, so the second condition implies the third. Differentiating the off-diagonal blocks at zero proves the converse. The equivalence with invariance follows from the definition of the blocks. The final identity follows by restricting the exponential series. □

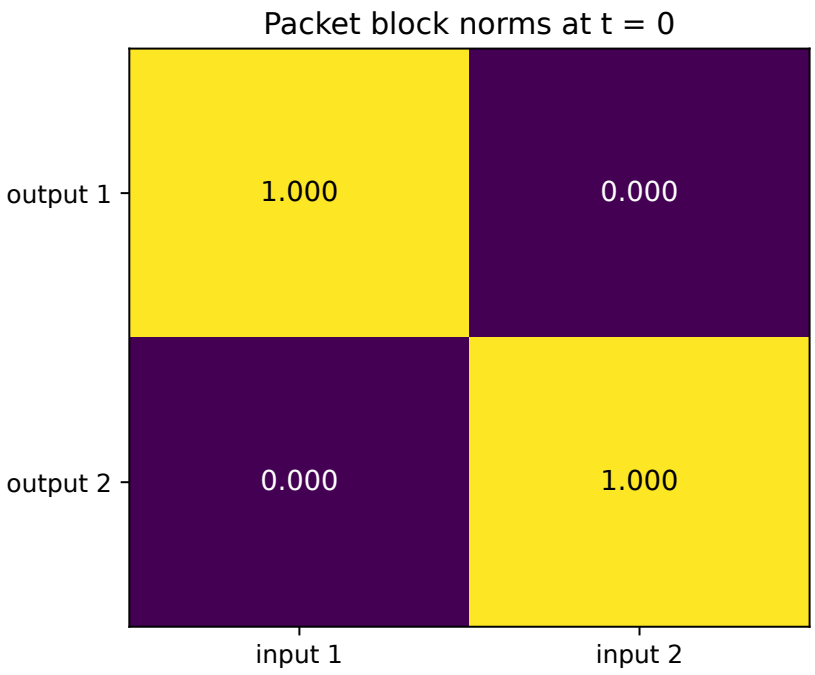

Figure E1. Packet block norms at three times. Transfer appears in the off-diagonal blocks as soon as the generator couples the two packet spaces. The three panels are shown in consecutive figures.

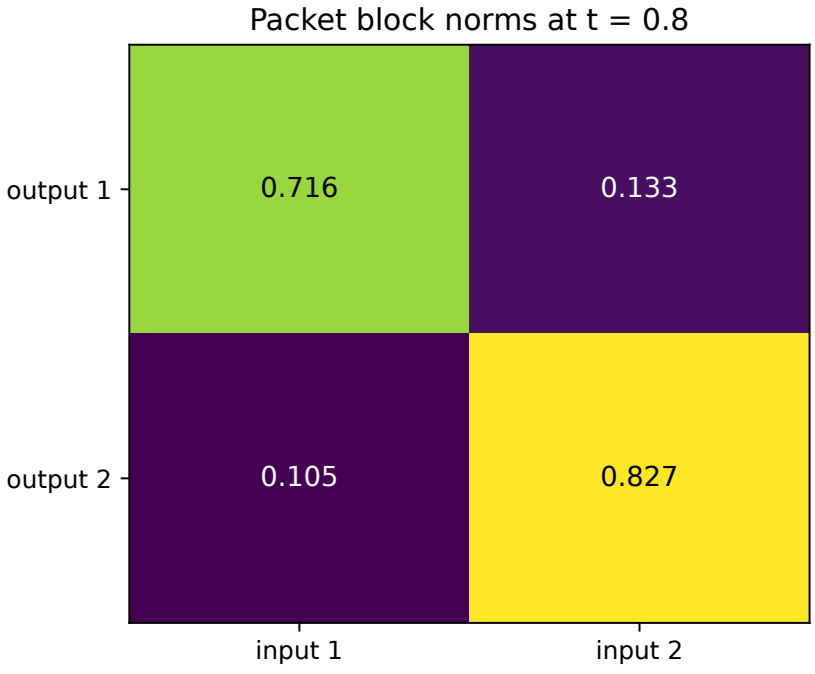

Figure E2. Packet block norms at time 0.8. The same fixed packet spaces and norm scale are used in the preceding panels.

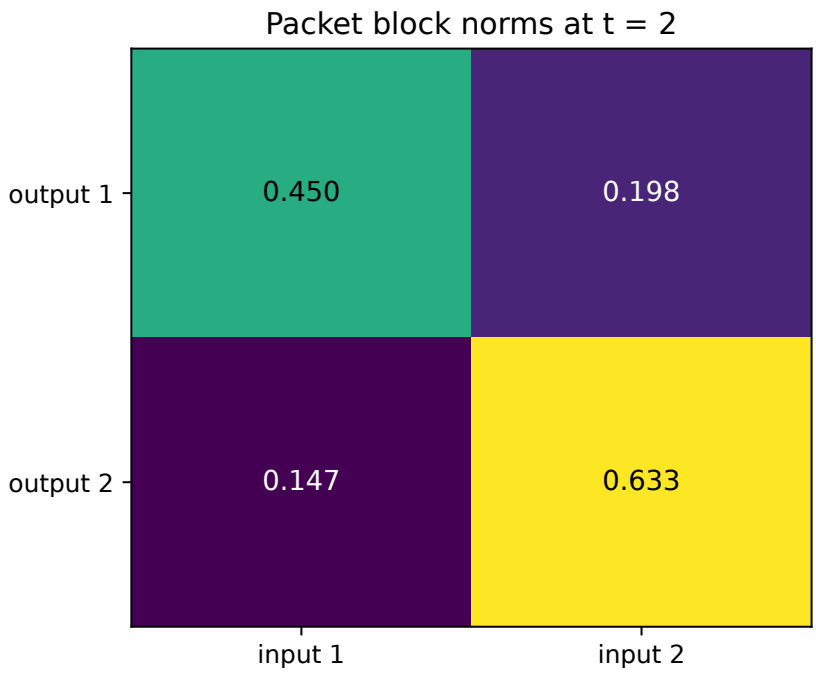

Figure E3. Packet block norms at time 2.0. The same fixed packet spaces and norm scale are used in the preceding panels.

E2.1 Directed path expansion

Set

$$D = \sum_{\alpha \in I} P_\alpha A P_\alpha, \qquad N = A - D.$$

The operator D preserves every packet and N contains only transfers between distinct packets.

Theorem E2.8 (Dyson expansion over packet paths)**.** *For $t \geq 0$,*

$$\mathrm{e}^{tA} = \mathrm{e}^{tD} + \sum_{m=1}^{\infty} \int_{0<s_1<\cdots<s_m<t} \mathrm{e}^{(t-s_m)D} N \mathrm{e}^{(s_m - s_{m-1})D} \cdots N \mathrm{e}^{s_1 D} \, \mathrm{d}s_1 \cdots \mathrm{d}s_m.$$

The series converges absolutely in operator norm. After multiplication by P_β and P_α, the term of order m is a sum over directed packet paths of length m from α to β.

Proof. Write the variation of constants identity

$$\mathrm{e}^{tA} = \mathrm{e}^{tD} + \int_0^t \mathrm{e}^{(t-s)D} N \mathrm{e}^{sA} \, \mathrm{d}s.$$

Iterating the identity gives the displayed series. The norm of the term of order m is at most

$$\mathrm{e}^{t\|D\|} \frac{(t\,\|N\|)^m}{m!}.$$

The majorant is summable. Inserting the packet resolution around every factor N leaves only products whose consecutive packet labels are joined by nonzero transfer blocks. □

Corollary E2.9 (Termination on an acyclic transfer graph)**.** *Suppose the directed graph with an edge $\alpha \to \beta$ whenever $P_\beta N P_\alpha \neq 0$ is acyclic. If its longest directed path has length q, then every Dyson term of order greater than q vanishes.*

Proof. Every nonzero term of order m contains a directed transfer path of length m. An acyclic graph has no path longer than q. □

E3 Generator defects and functional calculus

Let X_f and X_c be complex Banach spaces. Let $A_f \in \mathcal{B}(X_f)$, $A_c \in \mathcal{B}(X_c)$, and $C \in \mathcal{B}(X_f, X_c)$. Define

$$\Delta = CA_f - A_c C$$

and

$$\mathfrak{D}(t) = C\mathrm{e}^{tA_f} - \mathrm{e}^{tA_c} C.$$

Theorem E3.1 (Duhamel defect identity)**.** *For every $t \geq 0$,*

$$\mathfrak{D}(t) = \int_0^t \mathrm{e}^{(t-s)A_c} \Delta \mathrm{e}^{sA_f}\, \mathrm{d}s.$$

If

$$\left\|\mathrm{e}^{tA_f}\right\| \leq M_f \mathrm{e}^{\omega_f t}, \qquad \left\|\mathrm{e}^{tA_c}\right\| \leq M_c \mathrm{e}^{\omega_c t},$$

then

$$\|\mathfrak{D}(t)\| \leq M_f M_c \|\Delta\| \int_0^t \mathrm{e}^{\omega_c (t-s) + \omega_f s}\, \mathrm{d}s.$$

For contraction semigroups,

$$\|\mathfrak{D}(t)\| \leq t \|\Delta\|.$$

Proof. For fixed t, set

$$F(s) = \mathrm{e}^{(t-s)A_c} C \mathrm{e}^{sA_f}.$$

Then

$$F'(s) = \mathrm{e}^{(t-s)A_c} \Delta \mathrm{e}^{sA_f}.$$

Integrating from zero to t gives the identity. The estimates follow by taking norms under the integral. □

Proposition E3.2 (Infinitesimal recovery of the defect)**.** *The generator defect is the first order semigroup defect:*

$$\lim_{t \to 0} \frac{\mathfrak{D}(t)}{t} = \Delta$$

in operator norm. Consequently,

$$C\mathrm{e}^{tA_f} = \mathrm{e}^{tA_c} C \quad \text{for every } t$$

if and only if $CA_f = A_c C$.

Proof. The operator norm expansions

$$\mathrm{e}^{tA_f} = I + tA_f + o(t), \qquad \mathrm{e}^{tA_c} = I + tA_c + o(t)$$

give the limit. The equivalence follows from this limit and theorem E3.1. □

Theorem E3.3 (Resolvent defect identity). *Let z belong to the resolvent sets of A_f and A_c. With*

$$R_f(z) = (zI - A_f)^{-1}, \qquad R_c(z) = (zI - A_c)^{-1},$$

one has

$$CR_f(z) - R_c(z)C = R_c(z)\Delta R_f(z).$$

Proof. Multiply the proposed identity on the left by $zI - A_c$ and on the right by $zI - A_f$. Both sides reduce to

$$(zI - A_c)C - C(zI - A_f) = \Delta.$$

□

Theorem E3.4 (Holomorphic defect formula). *Let Γ be the positively oriented rectifiable boundary of a finite union of pairwise disjoint bounded Jordan domains. Assume that both spectra lie inside this union and that Γ lies in the common resolvent set. Thus its winding number is one about every spectral point. If g is holomorphic on a neighborhood of the closure of the union, then*

$$Cg(A_f) - g(A_c)C = \frac{1}{2\pi \mathrm{i}} \int_\Gamma g(z) R_c(z) \Delta R_f(z)\, \mathrm{d}z.$$

In particular,

$$\left\| Cg(A_f) - g(A_c)C \right\| \le \frac{\operatorname{length}(\Gamma)}{2\pi} \sup_{z \in \Gamma} |g(z)| \sup_{z \in \Gamma} \|R_c(z)\| \sup_{z \in \Gamma} \left\|R_f(z)\right\| \|\Delta\|.$$

Proof. Apply the Dunford integral formula to both operators and use theorem E3.3 under the contour integral. The norm estimate is immediate. □

Corollary E3.5 (Exact naturality). *If $CA_f = A_c C$, then*

$$Cg(A_f) = g(A_c)C$$

for every holomorphic function covered by theorem E3.4. The conclusion includes exponentials, resolvents, and polynomials.

Proof. Set $\Delta = 0$ in theorem E3.4. □

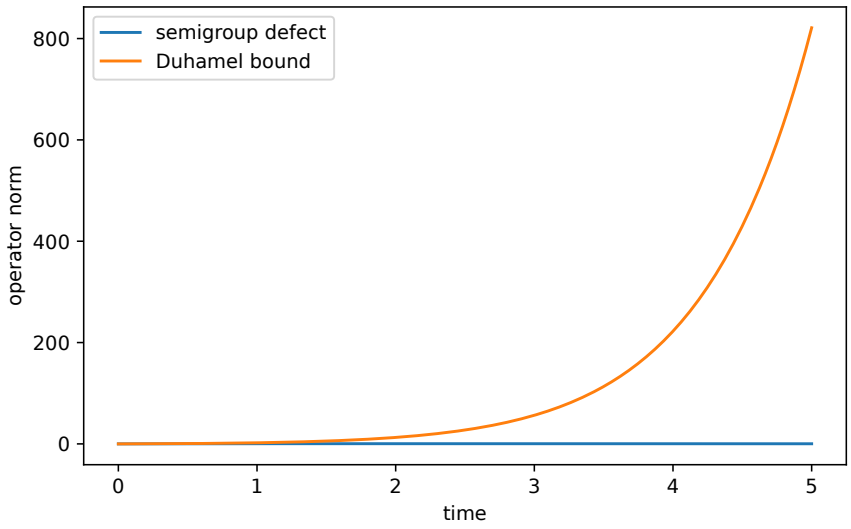

Figure E4. A finite semigroup defect and a direct Duhamel bound. The bound is designed to be uniform rather than sharp in this example.

E4 Refinement towers and limiting evolution

> **How to read the result**
>
> The limiting argument names its topology, reconstruction maps, and summability weights. Convergence of reconstructed trajectories is distinct from closure under the semigroup law. The range-leakage condition identifies the additional obstruction to that closure.

The exact inverse limit and the approximate completion problem require different hypotheses. Exact intertwining preserves the inverse limit coordinate by coordinate. Approximate intertwining gives a Cauchy family only after reconstruction maps are chosen.

E4.1 Exact inverse limits

Let

$$X_0 \xleftarrow{C_0} X_1 \xleftarrow{C_1} X_2 \leftarrow \cdots$$

be Banach spaces with bounded connecting maps. Define the bounded inverse limit

$$X_\infty = \left\{ (x_\ell)_{\ell \geq 0} : C_\ell x_{\ell+1} = x_\ell, \quad \sup_\ell \|x_\ell\| < \infty \right\}$$

with the supremum norm.

Lemma E4.1 (Completeness of the bounded inverse limit). *The space X_∞ is Banach.*

Proof. The product of the spaces X_ℓ, equipped with the bounded supremum norm, is Banach. The equations $C_\ell x_{\ell+1} = x_\ell$ define a closed linear subspace. □

Theorem E4.2 (Exact projective limit semigroup). *For each ℓ, let $T_\ell(t)$ be a strongly continuous semigroup on X_ℓ. Assume*

$$C_\ell T_{\ell+1}(t) = T_\ell(t) C_\ell$$

for every ℓ and $t \geq 0$, and assume the uniform bound

$$\sup_\ell \|T_\ell(t)\| \leq M \mathrm{e}^{\omega t}.$$

Define

$$T_\infty(t)(x_\ell)_\ell = (T_\ell(t) x_\ell)_\ell.$$

Then $T_\infty(t)$ is a bounded semigroup on X_∞. It is strongly continuous if

$$\lim_{t \downarrow 0} \sup_\ell \|T_\ell(t) x_\ell - x_\ell\| = 0$$

for every $(x_\ell)_\ell \in X_\infty$.
If $T_\ell(t) = \mathrm{e}^{tA_\ell}$, the generators are bounded, and

$$\sup_\ell \|A_\ell\| < \infty, \qquad C_\ell A_{\ell+1} = A_\ell C_\ell,$$

then the continuity condition holds and

$$A_\infty(x_\ell)_\ell = (A_\ell x_\ell)_\ell$$

is the bounded generator of T_∞.

Proof. Exact intertwining shows that $(T_\ell(t)x_\ell)_\ell$ remains compatible. The uniform growth bound makes the coordinatewise operator bounded on the supremum norm. The semigroup law holds in every coordinate. The stated continuity condition is exactly strong continuity in the supremum norm.

For bounded generators with common bound M_A,

$$\sup_\ell \left\|(\mathrm{e}^{tA_\ell} - I)x_\ell\right\| \leq (\mathrm{e}^{tM_A} - 1) \sup_\ell \|x_\ell\|.$$

This tends to zero with t. Exact generator intertwining makes $(A_\ell x_\ell)_\ell$ compatible, and coordinatewise differentiation identifies the generator. □

Remark E4.3. Strong continuity on each level does not by itself imply strong continuity in the supremum norm of the inverse limit. The additional uniform condition in theorem E4.2 cannot be omitted without replacing the topology.

E4.2 Summable adjacent defects

Assume now that each $C_\ell : X_{\ell+1} \to X_\ell$ has a bounded right inverse

$$R_\ell : X_\ell \to X_{\ell+1}, \qquad C_\ell R_\ell = I_{X_\ell}.$$

For $m < n$, set

$$C_{m,n} = C_m C_{m+1} \cdots C_{n-1}, \qquad R_{n,m} = R_{n-1} \cdots R_m.$$

The empty products are

$$C_{m,m} = I_{X_m}, \qquad R_{m,m} = I_{X_m}.$$

Definition E4.4 (Reconstructed fine evolution)**.** For a semigroup $T_n(t)$ on X_n, define the evolution seen from level m by

$$U_{m,n}(t) = C_{m,n} T_n(t) R_{n,m}.$$

Theorem E4.5 (Weighted summable defect completion)**.** *Define the adjacent semigroup defect*

$$E_n(t) = C_n T_{n+1}(t) - T_n(t) C_n.$$

Fix a coarse level m and a time horizon $T > 0$. For $n \geq m$, set

$$w_{m,n} = \|C_{m,n}\| \, \|R_n R_{n,m}\|.$$

If

$$\sum_{n=m}^{\infty} w_{m,n} \sup_{0 \leq t \leq T} \|E_n(t)\| < \infty,$$

then $U_{m,n}(t)$ converges in operator norm uniformly for $0 \leq t \leq T$. Its limit is denoted by $U_m(t)$, and

$$\sup_{0 \leq t \leq T} \|U_m(t) - U_{m,n}(t)\| \leq \sum_{j=n}^{\infty} w_{m,j} \sup_{0 \leq t \leq T} \|E_j(t)\|.$$

Proof. Since $C_n R_n = I$,

$$U_{m,n+1}(t) - U_{m,n}(t) = C_{m,n}(C_n T_{n+1}(t) - T_n(t) C_n) R_n R_{n,m}.$$

Therefore

$$\|U_{m,n+1}(t) - U_{m,n}(t)\| \leq w_{m,n} \, \|E_n(t)\|.$$

The weighted summability hypothesis makes the sequence uniformly Cauchy. Summing the tail estimates gives the stated bound. □

Corollary E4.6 (Contractive summable defect completion)**.** *Assume*

$$\|C_\ell\| \leq 1, \qquad \|R_\ell\| \leq 1, \qquad \|T_\ell(t)\| \leq 1$$

for every ℓ and $t \geq 0$. If

$$\sum_{\ell=0}^{\infty} \sup_{0 \leq t \leq T} \|E_\ell(t)\| < \infty,$$

then the conclusion of theorem E4.5 holds, and

$$\sup_{0 \leq t \leq T} \|U_m(t) - U_{m,n}(t)\| \leq \sum_{\ell=n}^{\infty} \sup_{0 \leq t \leq T} \|E_\ell(t)\|.$$

Proof. Every weight $w_{m,n}$ is at most one. □

Corollary E4.7 (Generator defect criterion). *Assume*

$$\|C_\ell\| \le 1, \qquad \|R_\ell\| \le 1,$$

and suppose $T_\ell(t) = \mathrm{e}^{tA_\ell}$ are contraction semigroups with bounded generators. Set

$$\Delta_\ell = C_\ell A_{\ell+1} - A_\ell C_\ell.$$

If

$$\sum_{\ell=0}^{\infty} \|\Delta_\ell\| < \infty,$$

then the conclusion of corollary E4.6 holds on every bounded time interval, and

$$\sup_{0\le t\le T} \left\|U_m(t) - U_{m,n}(t)\right\| \le T \sum_{\ell=n}^{\infty} \|\Delta_\ell\|.$$

Proof. Apply the contraction estimate in theorem E3.1 to every adjacent pair. □

The limit in theorem E4.5 need not satisfy the semigroup law. The obstruction comes from leaving the reconstructed fine subspace between two time steps.

Theorem E4.8 (Asymptotic closure criterion). *Assume the weighted convergence in theorem E4.5 holds for every bounded time interval, and define*

$$P_{m,n} = R_{n,m} C_{m,n}$$

on X_n. Suppose that for every $T > 0$,

$$\rho_{m,n}(T) = \sup_{0\le s,t\le T} \left\|C_{m,n} T_n(s)(I - P_{m,n}) T_n(t) R_{n,m}\right\| \longrightarrow 0.$$

Then

$$U_m(s+t) = U_m(s) U_m(t)$$

for all $s, t \ge 0$. If the convergence in theorem E4.5 is locally uniform and every T_n is norm continuous, then U_m is a norm continuous semigroup.

Proof. At a finite level,

$$U_{m,n}(s)U_{m,n}(t) - U_{m,n}(s+t) = C_{m,n} T_n(s)(P_{m,n} - I) T_n(t) R_{n,m}.$$

Its norm is at most $\rho_{m,n}(T)$ for $s, t \le T$. Pass to the limit using uniform convergence. Norm continuity follows from a uniform limit of norm continuous functions on compact intervals. □

Remark E4.9. Summable generator defects control consistency between adjacent levels. The quantity $\rho_{m,n}(T)$ controls closure of the reconstructed fine range under the fine evolution. These are different requirements.

Example E4.10 (Summable defects do not force a semigroup limit)**.** Let $X_0 = \mathbb{R}$ and let $X_n = \mathbb{R}^2$ for every $n \geq 1$. Set

$$C_0(x, y) = x, \qquad R_0 x = (x, 0),$$

and use identity connecting maps and reconstructions above level one. Let $T_0(t) = I$ and let every higher level carry the rotation group

$$T_n(t) = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}.$$

Only the first adjacent defect is nonzero, so every defect sum is finite. Yet for $n \geq 1$,

$$U_{0,n}(t) = C_0 T_n(t) R_0 = \cos t.$$

The limiting family is not a semigroup because in general

$$\cos(s + t) \neq \cos s \cos t.$$

The failure is exactly the excursion from the reconstructed line into its orthogonal complement between two time steps.

Proposition E4.11 (Range leakage criterion)**.** *Under the contractive assumptions of corollary E4.6, define*

$$\eta_{m,n}(T) = \sup_{0 \leq t \leq T} \left\| (I - P_{m,n}) T_n(t) R_{n,m} \right\|.$$

Then

$$\rho_{m,n}(T) \leq \eta_{m,n}(T).$$

Consequently, $\eta_{m,n}(T) \to 0$ for every $T > 0$ is sufficient for the limiting family U_m to satisfy the semigroup law.

Proof. For $s, t \leq T$, the contraction assumptions give

$$\begin{aligned} &\left\| C_{m,n} T_n(s) (I - P_{m,n}) T_n(t) R_{n,m} \right\| \\ &\quad \leq \left\| (I - P_{m,n}) T_n(t) R_{n,m} \right\|. \end{aligned}$$

Take the supremum and apply theorem E4.8. □

Theorem E4.12 (Generator control of range leakage)**.** *Let $T(t) = \mathrm{e}^{tA}$ on a Banach space X, let P be a bounded projection, and set $Q = I - P$. Assume*

$$\|T(t)\| \leq M \mathrm{e}^{\omega t}$$

and

$$\left\| \mathrm{e}^{t(QAQ)|_{QX}} \right\| \leq M_Q \mathrm{e}^{\omega_Q t}.$$

Then

$$\|QT(t)P\| \leq M M_Q \|P\|^2 \|QAP\| \int_0^t \mathrm{e}^{\omega_Q (t-s) + \omega s} \, \mathrm{d}s.$$

In particular, for orthogonal projections and contraction bounds,

$$\sup_{0\le t\le T}\|QT(t)P\| \le T\,\|QAP\|.$$

Proof. For $x \in PX$, write

$$p(t) = PT(t)x, \qquad q(t) = QT(t)x.$$

The hidden component satisfies

$$q'(t) = QAQq(t) + QAPp(t), \qquad q(0) = 0.$$

Variation of constants gives

$$q(t) = \int_0^t \mathrm{e}^{(t-s)(QAQ)|_{QX}} QAPp(s)\,\mathrm{d}s.$$

Since $\|p(s)\| \le \|P\|\,\|T(s)\|\,\|x\|$ and $x = Px$, the first estimate follows. The contraction case is immediate. □

Corollary E4.13 (A usable closure condition for refinement towers)**.** *Assume the contractive summability hypothesis of corollary E4.6 holds on every bounded time interval. Suppose every $P_{m,n}$ is an orthogonal projection on a Hilbert space and $T_n(t) = \mathrm{e}^{tA_n}$ is contractive. If, for every fixed m,*

$$\big\|(I - P_{m,n})A_nP_{m,n}\big\| \longrightarrow 0,$$

then the limiting family U_m is a semigroup.

Proof. A bounded generator of a contraction semigroup on a Hilbert space is dissipative. If $Q_{m,n} = I - P_{m,n}$ and $y \in Q_{m,n}X_n$, then

$$\operatorname{Re}\langle Q_{m,n}A_nQ_{m,n}y, y\rangle = \operatorname{Re}\langle A_ny, y\rangle \le 0.$$

Hence the compressed hidden semigroup is contractive. Apply theorem E4.12 to $P_{m,n}$. Since $P_{m,n}R_{n,m} = R_{n,m}$,

$$\eta_{m,n}(T) \le T\,\big\|(I - P_{m,n})A_nP_{m,n}\big\|\,\big\|R_{n,m}\big\|.$$

The right side tends to zero. Use proposition E4.11. □

E5 Finite Markov transfer and lumping

Probability vectors are columns. A column stochastic matrix K has nonnegative entries and column sums one. A continuous time generator Q has nonnegative off-diagonal entries and column sums zero.

Theorem E5.1 (Finite Markov semigroup)**.** *If Q is a finite Markov generator, then e^{tQ} is column stochastic for every $t \ge 0$.*

Proof. Choose $a \ge \max_i(-Q_{ii})$. The matrix $Q + aI$ is nonnegative, so its exponential is nonnegative. Hence

$$\mathrm{e}^{tQ} = \mathrm{e}^{-at}\mathrm{e}^{t(Q+aI)}$$

is nonnegative. Since $1^T Q = 0$, differentiation gives

$$1^T \mathrm{e}^{tQ} = 1^T.$$

□

Let $\{B_1, \dots, B_m\}$ be a partition of the fine state set. Its aggregation matrix is

$$C_{\alpha i} = 1_{\{i \in B_\alpha\}}.$$

Definition E5.2 (Canonical lumping obstruction)**.** For a linear fine transition operator K, define

$$\mathrm{Ob}_C(K) = (CK)|_{\mathrm{Ker}\, C} \in \mathcal{B}(\mathrm{Ker}\, C, \mathbb{R}^m).$$

Theorem E5.3 (Descent through an aggregation map)**.** *Let $C : X_f \to X_c$ be a surjective linear map between finite dimensional spaces. A unique operator $\overline{K} : X_c \to X_c$ satisfying*

$$CK = \overline{K}C$$

exists if and only if

$$\mathrm{Ob}_C(K) = 0.$$

For any right inverse R of C, the only possible coarse operator is

$$\overline{K} = CKR,$$

and

$$CK - \overline{K}C = CK(I - RC).$$

Proof. If $CK = \overline{K}C$, then CK vanishes on $\mathrm{Ker}\, C$. Conversely, suppose the obstruction vanishes and define

$$\overline{K}(Cx) = CKx.$$

If $Cx = Cy$, then $x - y \in \mathrm{Ker}\, C$, so the value does not depend on the representative. Surjectivity defines $\overline{K}$ on all of X_c, and the intertwining relation follows from the definition. It also gives uniqueness. If R is a right inverse, then

$$\overline{K} = \overline{K}CR = CKR.$$

Substitution gives the defect identity. □

Corollary E5.4 (Coordinate form of the lumping obstruction)**.** *For the partition aggregation above,* $\mathrm{Ker}\, C$ *is spanned by differences $e_i - e_j$ with i and j in one source block. Also,*

$$\mathrm{Ob}_C(K)(e_i - e_j) = \left(\sum_{r \in B_\alpha} (K_{ri} - K_{rj}) \right)_{\alpha=1}^{m}.$$

Proof. Inside each block, the vectors with coordinate sum zero are spanned by differences of coordinate vectors. Applying CK gives the displayed aggregated column differences. □

Theorem E5.5 (Characterization of exact discrete lumping). *Let K be column stochastic. A coarse column stochastic matrix $\overline{K}$ satisfying*

$$CK = \overline{K}C$$

exists if and only if, for every source block B_β, every pair $i, j \in B_\beta$, and every target block B_α,

$$\sum_{r \in B_\alpha} K_{ri} = \sum_{r \in B_\alpha} K_{rj}.$$

When it exists, $\overline{K}$ is unique and

$$\overline{K}_{\alpha\beta} = \sum_{r \in B_\alpha} K_{ri}$$

for any $i \in B_\beta$.

Proof. The jth column of CK records the transition mass from state j into every target block. The jth column of $\overline{K}C$ is the column of $\overline{K}$ indexed by the source block containing j. Equality therefore holds exactly under the stated condition. The formula gives uniqueness. Summing over α gives one, so the coarse matrix is column stochastic. □

Corollary E5.6 (Continuous time lumping). *A coarse Markov generator $\overline{Q}$ satisfying*

$$CQ = \overline{Q}C$$

exists if and only if the aggregated rates

$$\sum_{r \in B_\alpha} Q_{ri}$$

depend only on the source block of i. In that case

$$C\mathrm{e}^{tQ} = \mathrm{e}^{t\overline{Q}}C$$

for every $t \geq 0$.

Proof. The characterization is the same column argument as in theorem E5.5. The off-diagonal entries of $\overline{Q}$ are nonnegative and its column sums are zero. Exact semigroup intertwining follows from proposition E3.2. □

Theorem E5.7 (Finite horizon lumping defect). *For arbitrary fine and coarse operators K and $\overline{K}$, with the fixed aggregation map C, set*

$$\Delta_K = CK - \overline{K}C.$$

Then

$$CK^n - \overline{K}^n C = \sum_{j=0}^{n-1} \overline{K}^{n-1-j} \Delta_K K^j.$$

If K and $\overline{K}$ are column stochastic, then

$$\left\| CK^n - \overline{K}^n C \right\|_{1\to 1} \leq n \left\| \Delta_K \right\|_{1\to 1}.$$

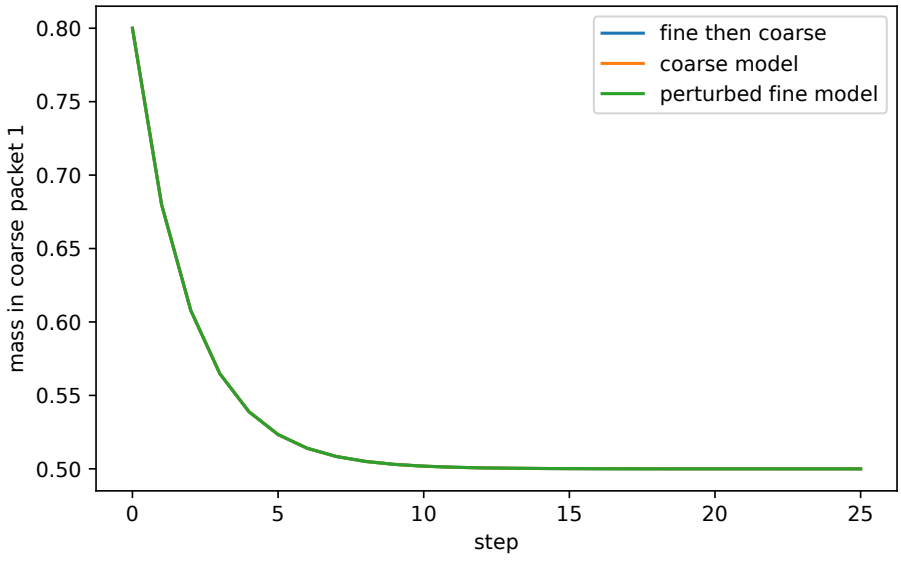

Figure E5. Exact lumping agrees at every horizon. A small violation of the block transition condition produces a visible but controlled discrepancy.

For every probability vector p, the total variation discrepancy is at most

$$\frac{n}{2}\,\|\Delta_K\|_{1\to 1}\,.$$

Proof. Sum the telescoping identities

$$\overline{K}^{n-1-j}CK^{j+1} - \overline{K}^{n-j}CK^{j} = \overline{K}^{n-1-j}\Delta_K K^{j}.$$

Stochastic matrices are contractions in the ℓ^1 norm. The last statement uses total variation equal to one half of the ℓ^1 distance. □

Corollary E5.8 (Stationary mass descends). *If $CK = \overline{K}C$ and $Kp = p$, then*

$$\overline{K}(Cp) = Cp.$$

Proof. Apply the intertwining identity to p. □

E6 Conditional expectation and martingale packets

Let $\Omega = \{1, \dots, n\}$ have strictly positive probabilities π_i. For a partition $\mathcal{Q}$, let $B(i)$ denote the block containing i. Define

$$(P_{\mathcal{Q}} f)_i = \frac{\sum_{j \in B(i)} \pi_j f_j}{\sum_{j \in B(i)} \pi_j}.$$

Equip $\mathbb{C}^n$ with

$$\langle f, g \rangle_\pi = \sum_i \pi_i f_i \overline{g_i}.$$

Theorem E6.1 (Finite conditional expectation)**.** *The operator $P_{\mathcal{Q}}$ is the orthogonal projector onto the functions that are constant on every block of $\mathcal{Q}$. In particular,*

$$P_{\mathcal{Q}}^2 = P_{\mathcal{Q}}, \qquad P_{\mathcal{Q}}^* = P_{\mathcal{Q}}.$$

Proof. One application produces a block constant function, so a second application changes nothing. Expanding both weighted inner products block by block gives

$$\langle P_{\mathcal{Q}} f, g\rangle_\pi = \sum_{B\in\mathcal{Q}} \frac{\left(\sum_{i\in B}\pi_i f_i\right)\overline{\left(\sum_{j\in B}\pi_j g_j\right)}}{\pi(B)} = \langle f, P_{\mathcal{Q}} g\rangle_\pi .$$

The range is exactly the block constant subspace. □

Theorem E6.2 (Tower law and martingale packets)**.** *Let $P_0, P_1, \dots, P_r$ come from increasingly fine partitions, so that*

$$\operatorname{Ran} P_0 \subseteq \operatorname{Ran} P_1 \subseteq \cdots \subseteq \operatorname{Ran} P_r.$$

Define

$$D_0 = P_0, \qquad D_j = P_j - P_{j-1} \quad (1 \le j \le r).$$

Then

$$P_i P_j = P_{\min(i,j)}, \qquad D_i D_j = \delta_{ij} D_j, \qquad P_r = \sum_{j=0}^{r} D_j.$$

Every D_j is an orthogonal projector, and

$$\|P_r f\|_\pi^2 = \sum_{j=0}^{r} \|D_j f\|_\pi^2$$

and

$$\|f\|_\pi^2 = \sum_{j=0}^{r} \|D_j f\|_\pi^2 + \|f - P_r f\|_\pi^2 .$$

Proof. A coarse average of a fine average is the coarse average. A fine average leaves a coarse constant function unchanged. Hence $P_i P_j = P_{\min(i,j)}$. Expanding products of the differences gives the orthogonality relations. The sum telescopes to P_r. Orthogonal Pythagorean identities give the norm formulas. □

Corollary E6.3 (Law of total variance)**.** *For a real valued f, let $P_0 f = \mathbb{E}_\pi[f]1$. Then*

$$\operatorname{Var}_\pi(f) = \operatorname{Var}_\pi(P_{\mathcal{Q}} f) + \|f - P_{\mathcal{Q}} f\|_\pi^2 .$$

Proof. Subtract the mean and apply the orthogonal decomposition into the range of $P_{\mathcal{Q}}$ and its orthogonal complement. □

Standard Fact E6.4 (General conditional expectations). On a probability space, conditional expectation onto a sub sigma algebra is the orthogonal projector in L^2. Nested sigma algebras satisfy the same

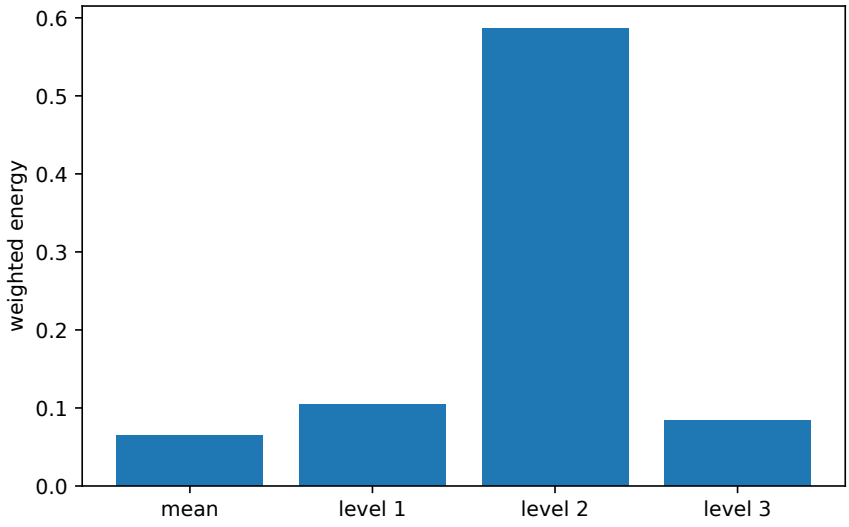

Figure E6. Energy carried by the mean packet and three successive martingale difference packets in a finite weighted example.

tower law. Under the usual hypotheses, martingale convergence gives a limit in L^2 and almost surely. Standard treatments include [Wil91].

E7 Gaussian transfer and Hermite packets

Let γ be the standard Gaussian probability measure on $\mathbb{R}$. For $t \geq 0$, define the Ornstein–Uhlenbeck transfer

$$(\mathcal{O}_t f)(x) = \int_{\mathbb{R}} f\left(\mathrm{e}^{-t}x + \sqrt{1-\mathrm{e}^{-2t}}\, y\right) \gamma(\mathrm{d}y).$$

Let H_n be the probabilists' Hermite polynomial defined by

$$\exp\left(ux - \frac{u^2}{2}\right) = \sum_{n=0}^{\infty} H_n(x)\frac{u^n}{n!},$$

and set $h_n = H_n/\sqrt{n!}$.

Theorem E7.1 (Ornstein–Uhlenbeck semigroup). *The operators $(\mathcal{O}_t)_{t\geq 0}$ form a positive Markov contraction semigroup on $L^p(\gamma)$ for every $1 \leq p \leq \infty$. On $L^2(\gamma)$, the semigroup is self-adjoint and*

$$\mathcal{O}_t h_n = \mathrm{e}^{-nt} h_n.$$

The family $(h_n)_{n\geq 0}$ is an orthonormal basis of $L^2(\gamma)$.

Proof. Positivity and preservation of constants follow from the integral formula. If X and Y are independent standard Gaussian variables, then

$$\mathrm{e}^{-s}\left(\mathrm{e}^{-t}x + \sqrt{1-\mathrm{e}^{-2t}}X\right) + \sqrt{1-\mathrm{e}^{-2s}}Y$$

has the same distribution as

$$\mathrm{e}^{-(s+t)}x + \sqrt{1-\mathrm{e}^{-2(s+t)}}Z$$

with Z standard Gaussian. This proves the semigroup law. Jensen's inequality and invariance of γ give the L^p contraction. The joint Gaussian pair

$$\left(X, \mathrm{e}^{-t}X + \sqrt{1-\mathrm{e}^{-2t}}Y\right)$$

is symmetric under interchange, which proves self-adjointness.

Apply $\mathcal{O}_t$ to the Hermite generating function. Gaussian integration gives

$$\begin{aligned}\mathcal{O}_t \exp\left(ux - \frac{u^2}{2}\right) &= \exp\left(\mathrm{e}^{-t}ux - \frac{\mathrm{e}^{-2t}u^2}{2}\right)\\ &= \sum_{n=0}^{\infty} \mathrm{e}^{-nt} H_n(x)\frac{u^n}{n!}.\end{aligned}$$

Comparison of coefficients proves the eigenvalue formula. The same generating function shows

$$\int H_m H_n \,\mathrm{d}\gamma = n!\delta_{mn}.$$

The Hermite polynomials span all polynomials, and polynomials are dense in $L^2(\gamma)$. Hence the normalized family is an orthonormal basis. See [Jan97] for the general Gaussian Hilbert space setting. □

Corollary E7.2 (Hermite packet reconstruction)**.** *Let P_n be the orthogonal projection onto $\mathbb{C}h_n$. Then*

$$I = \sum_{n=0}^{\infty} P_n$$

in the strong operator topology and

$$\mathcal{O}_t = \sum_{n=0}^{\infty} \mathrm{e}^{-nt} P_n.$$

For $f \in L^2(\gamma)$,

$$\|\mathcal{O}_t f\|_2^2 = \sum_{n=0}^{\infty} \mathrm{e}^{-2nt}\,\|P_n f\|_2^2 .$$

Proof. Apply Parseval's identity and the eigenvalue formula in theorem E7.1. □

Proposition E7.3 (Generator and Dirichlet form)**.** *On the polynomial subspace, the infinitesimal generator of $(\mathcal{O}_t)$ is the differential operator*

$$\mathcal{L}f = f'' - xf'.$$

It satisfies

$$\mathcal{L}h_n = -nh_n.$$

For every polynomial f,

$$\langle -\mathcal{L}f, f\rangle_{L^2(\gamma)} = \int_{\mathbb{R}} |f'(x)|^2 \,\gamma(\mathrm{d}x).$$

Proof. Write

$$\rho_t = \mathrm{e}^{-t} = 1 - t + O(t^2), \qquad \sigma_t^2 = 1 - \mathrm{e}^{-2t} = 2t + O(t^2).$$

For a polynomial f, Taylor expansion at x and Gaussian integration give

$$\begin{aligned}\mathcal{O}_t f(x) &= f(x) + f'(x)(\rho_t - 1)x + \frac{1}{2} f''(x)\sigma_t^2 + o(t) \\ &= f(x) + t(f''(x) - xf'(x)) + o(t).\end{aligned}$$

Every omitted term is a polynomial in the Gaussian variable multiplied by a quantity that is $o(t)$, so the expansion may be integrated term by term. Therefore

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathcal{O}_t f\Big|_{t=0} = f'' - xf'.$$

The Hermite eigenvalue identity also follows by differentiating $\mathcal{O}_t h_n = \mathrm{e}^{-nt} h_n$ at zero. Gaussian integration by parts gives

$$\int_{\mathbb{R}} f'(x)\overline{g(x)}\gamma(\,\mathrm{d}x) = \int_{\mathbb{R}} f(x)\overline{xg(x) - g'(x)}\gamma(\,\mathrm{d}x).$$

Set $g = f'$ and rearrange. □

Corollary E7.4 (Gaussian spectral gap)**.** *If $f \in L^2(\gamma)$ has mean zero, then*

$$\|\mathcal{O}_t f\|_2 \le \mathrm{e}^{-t}\,\|f\|_2 .$$

For every polynomial f,

$$\mathrm{Var}_\gamma(f) \le \int_{\mathbb{R}} |f'(x)|^2\,\gamma(\,\mathrm{d}x).$$

Proof. A mean zero function has no h_0 component, so every surviving Hermite multiplier is at most e^{-t}. For a polynomial

$$f - \mathbb{E}_\gamma f = \sum_{n\ge 1} c_n h_n.$$

Then

$$\mathrm{Var}_\gamma(f) = \sum_{n\ge 1} |c_n|^2 \le \sum_{n\ge 1} n\,|c_n|^2 = \langle -\mathcal{L}f, f\rangle .$$

Apply proposition E7.3. □

Corollary E7.5 (Fractional Hermite transfer)**.** *Let $-\mathcal{L}$ be the nonnegative Ornstein–Uhlenbeck number operator with*

$$-\mathcal{L}h_n = nh_n.$$

For every $\alpha > 0$,

$$\mathrm{e}^{-t(-\mathcal{L})^\alpha} f = \sum_{n=0}^{\infty} \mathrm{e}^{-tn^\alpha} P_n f.$$

This is a contraction semigroup on $L^2(\gamma)$.

Proof. The spectral theorem applies to the orthonormal Hermite basis. Every multiplier has modulus at most one and obeys the scalar semigroup law. □

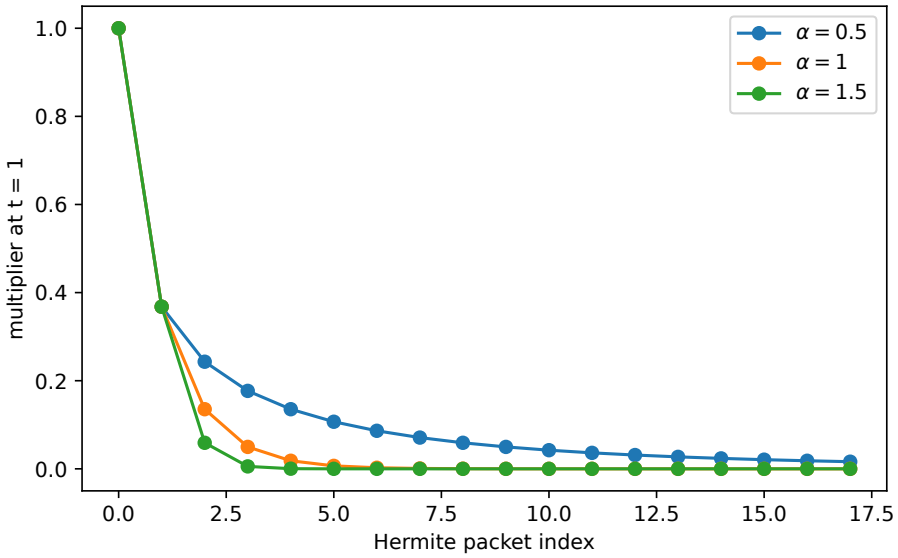

Figure E7. Hermite packet multipliers for the Ornstein–Uhlenbeck semigroup and two fractional powers of its number operator.

E8 Bayesian transfer and evidence packets

Let

$$\Delta_{n-1} = \left\{ p \in \mathbb{R}^n : p_i \geq 0, \quad \sum_i p_i = 1 \right\}$$

be the probability simplex. Let $\lambda \in [0, \infty)^n$ have positive evidence

$$Z_\lambda(p) = \sum_i \lambda_i p_i.$$

The Bayesian transfer is

$$\mathcal{B}_\lambda(p) = \frac{\lambda \odot p}{Z_\lambda(p)}.$$

Proposition E8.1 (Scale invariance and composition)**.** *For every $c > 0$,*

$$\mathcal{B}_{c\lambda} = \mathcal{B}_\lambda.$$

If all relevant evidences are positive, then

$$\mathcal{B}_\mu(\mathcal{B}_\lambda(p)) = \mathcal{B}_{\lambda \odot \mu}(p).$$

Proof. A common likelihood scale cancels between the numerator and denominator. In the second identity, the first evidence appears in both the numerator and the denominator of the second update and cancels. □

Let $I = I_1 \sqcup \cdots \sqcup I_m$ be a partition. Define packet evidences

$$Z_\alpha = \sum_{i \in I_\alpha} \lambda_i p_i.$$

For $Z_\alpha > 0$, define

$$m_\alpha = \frac{Z_\alpha}{\sum_\beta Z_\beta}, \qquad q_{\alpha,i} = \frac{\lambda_i p_i}{Z_\alpha} \quad (i \in I_\alpha).$$

Packets with zero evidence receive posterior mass zero.

Theorem E8.2 (Bayesian packet reconstruction). *The posterior is the disjoint packet synthesis*

$$\mathcal{B}_\lambda(p) = \sum_{\alpha : Z_\alpha > 0} m_\alpha q_\alpha.$$

The local shape q_α depends only on the prior and likelihood inside packet I_α. Coupling between different packets occurs through the normalization of the packet evidences.

Proof. For $i \in I_\alpha$,

$$m_\alpha q_{\alpha,i} = \frac{Z_\alpha}{\sum_\beta Z_\beta} \frac{\lambda_i p_i}{Z_\alpha} = \frac{\lambda_i p_i}{Z_\lambda(p)}.$$

The packet supports are disjoint. □

Theorem E8.3 (Likelihood perturbation). *Let $\lambda, \mu \geq 0$ have positive evidences under a fixed prior p. Set*

$$d_p(\lambda, \mu) = \sum_i |\lambda_i - \mu_i| \, p_i.$$

Then

$$\left\| \mathcal{B}_\lambda(p) - \mathcal{B}_\mu(p) \right\|_1 \leq \frac{2 d_p(\lambda, \mu)}{\max\{Z_\lambda(p), Z_\mu(p)\}}.$$

Proof. Add and subtract $\mu \odot p / Z_\lambda(p)$. This gives

$$\left\| \mathcal{B}_\lambda(p) - \mathcal{B}_\mu(p) \right\|_1 \leq \frac{2 d_p(\lambda, \mu)}{Z_\lambda(p)}.$$

Interchanging λ and μ gives the same estimate with $Z_\mu(p)$. Take the smaller of the two upper bounds. □

Theorem E8.4 (Stability with respect to the prior). *Assume*

$$0 < a \leq \lambda_i \leq b$$

for every i. Then

$$\left\| \mathcal{B}_\lambda(p) - \mathcal{B}_\lambda(q) \right\|_1 \leq \frac{2b}{a} \left\| p - q \right\|_1$$

for all priors $p, q \in \Delta_{n-1}$.

Proof. The evidences are at least a. Add and subtract $\lambda \odot q / Z_\lambda(p)$. The numerator difference is at most $b \left\| p - q \right\|_1$, and the evidence difference has the same bound. The two terms give the stated constant. □

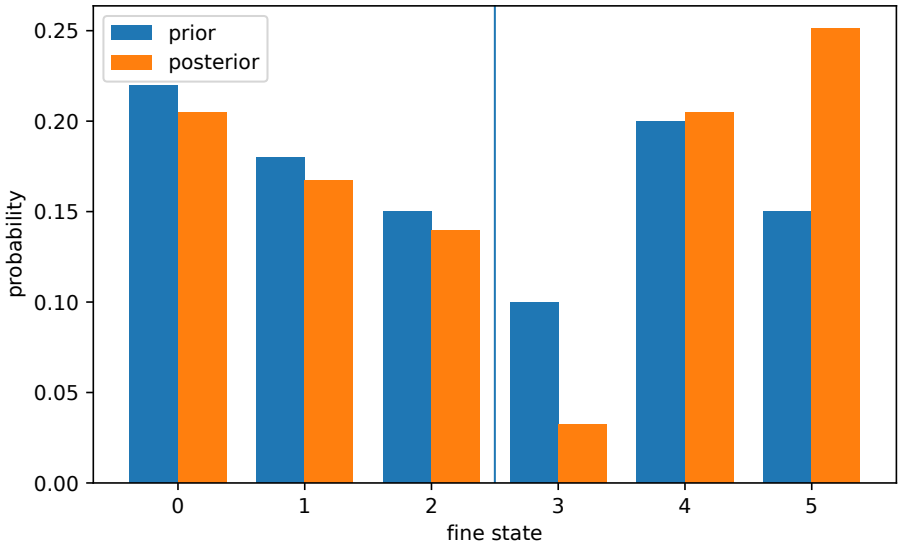

Figure E8. A prior and posterior on two coarse packets. The likelihood is constant in the first packet and varies inside the second, so only the second local conditional distribution changes.

E9 Bayesian coarsening and finite sufficiency

A fixed coarse description will be called sufficient when it reproduces the coarse posterior masses for every positive prior and leaves the conditional distribution inside every packet unchanged. This excludes a coarse rule that hides an unrecorded local update.

Let C send a fine probability vector to its block masses

$$(Cp)_\alpha = \sum_{i \in I_\alpha} p_i.$$

Assume first that every block mass is positive. Write

$$r_{\alpha,i} = \frac{p_i}{(Cp)_\alpha}$$

for the prior conditional distribution inside packet I_α. Define the prior dependent packet average likelihood

$$\overline{\lambda}_\alpha(p) = \sum_{i \in I_\alpha} \lambda_i r_{\alpha,i}.$$

Theorem E9.1 (Exact two stage Bayesian update). *For every strictly positive prior,*

$$C\mathcal{B}_\lambda(p) = \mathcal{B}_{\overline{\lambda}(p)}(Cp).$$

For every packet with $\overline{\lambda}_\alpha(p) > 0$, the posterior conditional distribution is

$$q_{\alpha,i} = \frac{\lambda_i r_{\alpha,i}}{\overline{\lambda}_\alpha(p)}.$$

A packet with zero average likelihood has zero posterior mass. Thus a fine Bayesian update consists of a coarse update by packet average likelihoods followed by independent local updates inside the packets that survive.

Proof. The posterior mass of packet I_α is

$$\frac{\sum_{i\in I_\alpha}\lambda_i p_i}{\sum_j \lambda_j p_j} = \frac{(Cp)_\alpha \overline{\lambda}_\alpha(p)}{\sum_\beta (Cp)_\beta \overline{\lambda}_\beta(p)}.$$

This is the coarse Bayesian formula. Dividing the fine posterior coordinates by the packet mass gives the local formula. □

Theorem E9.2 (Characterization of fixed coarse sufficiency)**.** *Assume $\lambda_i > 0$ for every state. The following conditions are equivalent.*

1. *There is a positive coarse likelihood $\ell \in (0,\infty)^m$ such that*

$$C\mathcal{B}_\lambda(p) = \mathcal{B}_\ell(Cp)$$

   for every strictly positive prior p, and the posterior conditional distribution inside every packet equals its prior conditional distribution.

2. *The likelihood is constant on every packet.*

When these conditions hold, ℓ_α can be chosen as the common value of λ on I_α, and it is unique up to a common positive scale.

Proof. If λ is constant on each packet, theorem E9.1 has packet averages independent of the prior and its local posterior formula gives $q_\alpha = r_\alpha$. This proves the first condition.

Conversely, fix any strictly positive prior. Equality of the local posterior and prior conditionals gives

$$\frac{\lambda_i r_{\alpha,i}}{\overline{\lambda}_\alpha(p)} = r_{\alpha,i}$$

for every $i \in I_\alpha$. Positivity of the conditional prior implies

$$\lambda_i = \overline{\lambda}_\alpha(p)$$

for every state in the packet. Thus the likelihood is constant on every packet. If two positive coarse likelihoods define the same update for every positive coarse prior, comparison of any two posterior odds shows that their coordinate ratios agree. Hence they differ only by a common positive factor. □

Theorem E9.3 (Coarsest fixed sufficient partition)**.** *Let $\mathcal{L}$ be a nonempty family of strictly positive likelihood vectors. Define*

$$i \sim_{\mathcal{L}} j \quad\Longleftrightarrow\quad \lambda_i = \lambda_j \quad \text{for every } \lambda \in \mathcal{L}.$$

Let $\mathcal{Q}_{\mathcal{L}}$ be the partition into equivalence classes. A partition $\mathcal{Q}$ gives a fixed coarse sufficient description in the sense of theorem E9.2 for every $\lambda \in \mathcal{L}$ if and only if every block of $\mathcal{Q}$ is contained in a block of $\mathcal{Q}_{\mathcal{L}}$. Hence $\mathcal{Q}_{\mathcal{L}}$ is the unique coarsest partition with this property.

Proof. Apply theorem E9.2 to every likelihood in the family. A fixed sufficient description exists exactly when each likelihood is constant on every block of $\mathcal{Q}$. This is equivalent to every block of $\mathcal{Q}$ being contained in one common level set of the family. The equivalence class partition is itself admissible, and every other admissible partition refines it. □

Definition E9.4 (Within packet information loss)**.** For a prior p, define

$$\eta_i(p) = \lambda_i - \overline{\lambda}_\alpha(p) \quad \text{when } i \in I_\alpha.$$

Then

$$\sum_{i \in I_\alpha} r_{\alpha,i}\eta_i(p) = 0.$$

Proposition E9.5 (Exact local distortion)**.** *For every packet with positive mass and evidence,*

$$q_{\alpha,i} - r_{\alpha,i} = \frac{r_{\alpha,i}\eta_i(p)}{\overline{\lambda}_\alpha(p)}.$$

Consequently,

$$\|q_\alpha - r_\alpha\|_1 = \frac{\sum_{i \in I_\alpha} r_{\alpha,i}\,|\eta_i(p)|}{\overline{\lambda}_\alpha(p)}.$$

If λ is positive on the packet, then

$$\|q_\alpha - r_\alpha\|_1 \le \frac{\operatorname{osc}_{I_\alpha}(\lambda)}{\min_{i \in I_\alpha} \lambda_i}.$$

Proof. Subtract $r_{\alpha,i}$ from the local posterior formula in theorem E9.1. The norm identity follows because the factor multiplying η_i is nonnegative. The last estimate uses

$$\sum_i r_{\alpha,i}\,|\eta_i| \le \operatorname{osc}_{I_\alpha}(\lambda)$$

and $\overline{\lambda}_\alpha(p) \ge \min_{I_\alpha} \lambda$. □

Theorem E9.6 (Approximate coarse Bayesian rule)**.** *Choose one positive number ℓ_α for every packet and define the block constant fine likelihood*

$$\tilde{\lambda}_i = \ell_\alpha \quad (i \in I_\alpha).$$

Then

$$\|C\mathcal{B}_\lambda(p) - \mathcal{B}_\ell(Cp)\|_1 \le \frac{2\sum_i p_i \left|\lambda_i - \tilde{\lambda}_i\right|}{\max\{Z_\lambda(p), Z_{\tilde{\lambda}}(p)\}}.$$

Proof. Block constancy gives

$$C\mathcal{B}_{\tilde{\lambda}}(p) = \mathcal{B}_\ell(Cp).$$

Aggregation is an ℓ^1 contraction. Apply theorem E8.3 to the two fine posteriors and then aggregate. □

Definition E9.7 (Relative information)**.** For probability vectors q and p, define

$$D(q\|p) = \sum_i q_i \log \frac{q_i}{p_i}.$$

The convention is $0 \log 0 = 0$. A term with $q_i > 0$ and $p_i = 0$ has value $+\infty$.

Theorem E9.8 (Exact information decomposition)**.** *Let p and q be probability vectors on a finite partition $(I_\alpha)_\alpha$, and assume $q_i = 0$ whenever $p_i = 0$. Let*

$$m = Cp, \qquad n = Cq,$$

and let p_α and q_α be the conditional distributions inside packet I_α whenever the corresponding mass is positive. Then

$$D(q\|p) = D(n\|m) + \sum_{\alpha : n_\alpha > 0} n_\alpha D(q_\alpha \| p_\alpha).$$

The first term is the information retained by the coarse masses. The second term is the exact information carried by changes inside the packets.

Proof. For $i \in I_\alpha$, write

$$p_i = m_\alpha p_{\alpha,i}, \qquad q_i = n_\alpha q_{\alpha,i}.$$

Then

$$\log \frac{q_i}{p_i} = \log \frac{n_\alpha}{m_\alpha} + \log \frac{q_{\alpha,i}}{p_{\alpha,i}}.$$

Multiply by q_i, sum first inside each packet, and then sum over the packets. This is the finite relative entropy chain rule. Standard information theoretic treatments include [CT06]. □

Corollary E9.9 (Coarse data processing and equality)**.** *Under the assumptions of theorem E9.8,*

$$D(Cq\|Cp) \le D(q\|p).$$

Equality holds if and only if

$$q_\alpha = p_\alpha$$

for every packet with positive posterior mass.

Proof. Every conditional relative information term in theorem E9.8 is nonnegative. It vanishes exactly when the two conditional distributions agree. □

Corollary E9.10 (Information created by a Bayesian update)**.** *Let $q = \mathcal{B}_\lambda(p)$ with positive likelihood and positive prior. Then*

$$D(q\|p) = \sum_i q_i \log \lambda_i - \log Z_\lambda(p).$$

Inside a packet,

$$D(q_\alpha \| r_\alpha) = \sum_{i \in I_\alpha} q_{\alpha,i} \log \frac{\lambda_i}{\overline{\lambda}_\alpha(p)}.$$

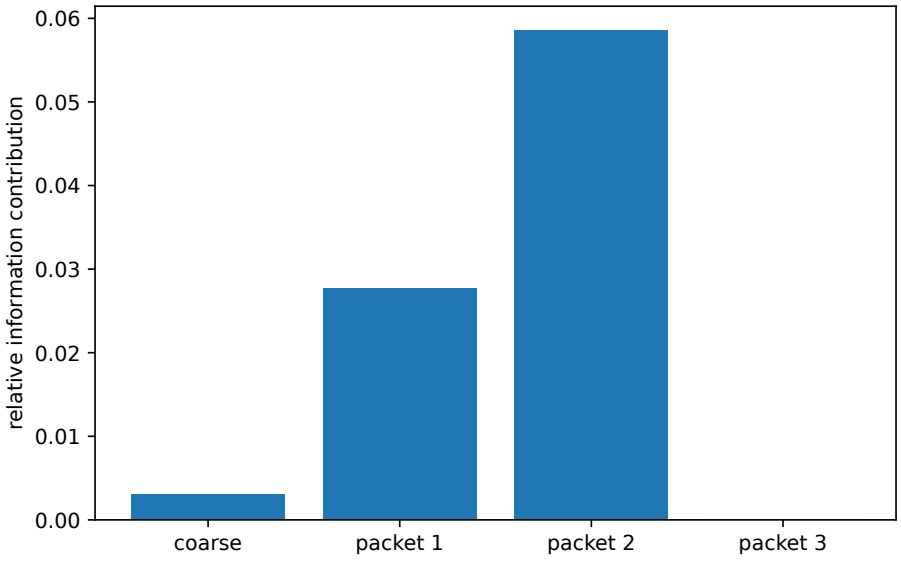

Figure E9. Relative information separated into a coarse packet contribution and conditional contributions inside the packets.

Hence

$$D(q_\alpha \| r_\alpha) \le \log \frac{\max_{i \in I_\alpha} \lambda_i}{\min_{i \in I_\alpha} \lambda_i}.$$

Proof. The posterior ratio is

$$\frac{q_i}{p_i} = \frac{\lambda_i}{Z_\lambda(p)}.$$

The local ratio is

$$\frac{q_{\alpha,i}}{r_{\alpha,i}} = \frac{\lambda_i}{\overline{\lambda}_\alpha(p)}.$$

Insert these identities into the definition of relative entropy. The final estimate follows because both λ_i and the packet average lie between the packet minimum and maximum. □

Corollary E9.11 (Information criterion for local sufficiency)**.** *For a fixed positive likelihood, the within packet term in theorem E9.8 vanishes for every positive prior if and only if the likelihood is constant on every packet.*

Proof. If the likelihood is block constant, every local posterior equals its local prior. Conversely, choose any positive prior. Vanishing relative entropy gives $q_\alpha = r_\alpha$. The local posterior formula then forces all likelihood values in that packet to equal their packet average. Repeat for every packet. □

Remark E9.12. The exact coarse likelihood in theorem E9.1 depends on the conditional prior inside each packet. Theorem E9.2 identifies when that dependence disappears. Theorem E9.8 measures what is lost when only the coarse posterior masses are retained.

E10 Bayesian flows and hidden Markov recursion

Fix a score vector $g \in \mathbb{R}^n$. For $t \geq 0$, define

$$\Phi_t(p)_i = \frac{\mathrm{e}^{tg_i} p_i}{\sum_j \mathrm{e}^{tg_j} p_j}.$$

Theorem E10.1 (Bayesian flow and replicator equation). *The maps Φ_t form a nonlinear semigroup:*

$$\Phi_{s+t} = \Phi_s \circ \Phi_t.$$

Every coordinate satisfies

$$\frac{\mathrm{d}}{\mathrm{d}t} p_i(t) = (g_i - \langle g, p(t) \rangle) p_i(t).$$

The support of $p(t)$ is independent of t, and for any two coordinates in the support,

$$\frac{p_i(t)}{p_j(t)} = \mathrm{e}^{t(g_i - g_j)} \frac{p_i(0)}{p_j(0)}.$$

Proof. The semigroup law follows from multiplication of the likelihoods e^{sg} and e^{tg}. Differentiating the normalized formula gives the replicator equation. A coordinate that starts at zero remains zero, while a positive coordinate remains positive. Dividing two explicit coordinate formulas gives the odds identity. □

Theorem E10.2 (Evidence cumulants and score monotonicity). *Set*

$$\psi(t) = \log \left(\sum_i \mathrm{e}^{tg_i} p_i(0) \right).$$

Then

$$\psi'(t) = \langle g, p(t) \rangle, \qquad \psi''(t) = \mathrm{Var}_{p(t)}(g) \geq 0.$$

Consequently,

$$\frac{\mathrm{d}}{\mathrm{d}t} \langle g, p(t) \rangle = \mathrm{Var}_{p(t)}(g).$$

Proof. Differentiate the log normalizing constant once and twice. The second derivative is the centered second moment under the tilted distribution. □

Corollary E10.3 (Concentration on the maximal score packet). *Let*

$$G = \max\{g_i : p_i(0) > 0\}$$

and let M be the set of supported indices with score G. If M is the full support, then the conclusion below is immediate. Otherwise, suppose

$$\delta = \min\{G - g_i : p_i(0) > 0, \quad i \notin M\} > 0.$$

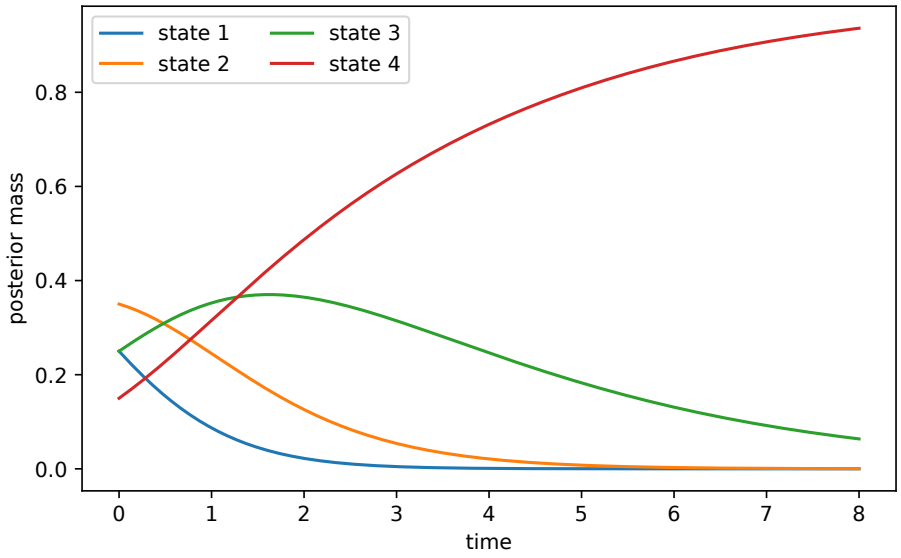

Figure E10. A finite Bayesian flow. Mass concentrates on the states with the largest score, while every relative odds ratio follows an exact exponential law.

Then

$$1 - \sum_{i \in M} p_i(t) \le \frac{1 - p_M(0)}{p_M(0)} \mathrm{e}^{-\delta t},$$

where $p_M(0) = \sum_{i \in M} p_i(0)$.

Proof. Factor e^{tG} from the normalizing constant. The total weight outside M is at most $(1 - p_M(0))\mathrm{e}^{-\delta t}$, while the weight on M is $p_M(0)$. □

E10.1 Prediction and update

Let K be column stochastic and let $\lambda^{(r)}$ be the likelihood of the rth observation. The hidden Markov filter is

$$\hat{p}_r = K p_{r-1}, \qquad p_r = \mathcal{B}_{\lambda^{(r)}}(\hat{p}_r).$$

A standard account of finite hidden Markov models appears in [Rab89].

Proposition E10.4 (Simplex preservation)**.** *Suppose p_{r-1} is a probability vector and the new evidence is positive. Prediction produces the probability vector $\hat{p}_r$, and normalization produces the probability vector p_r.*

Proof. Column stochasticity preserves nonnegativity and total mass. Bayesian normalization then preserves the same properties. □

Theorem E10.5 (One step filter stability)**.** *Let K and $\widetilde{K}$ be column stochastic. Assume*

$$0 < a \le \lambda_i \le b.$$

Then

$$\left\|\mathcal{B}_\lambda(Kp) - \mathcal{B}_\lambda(\widetilde{K}q)\right\|_1 \le \frac{2b}{a}\left(\|p-q\|_1 + \left\|K-\widetilde{K}\right\|_{1\to 1}\right).$$

Proof. Apply theorem E8.4 to Kp and $\widetilde{K}q$. Then use

$$\left\|Kp - \widetilde{K}q\right\|_1 \le \|K(p-q)\|_1 + \left\|(K-\widetilde{K})q\right\|_1$$

and the stochastic contraction property. □

Example E10.6 (Beta binomial transfer)**.** A beta prior with parameters (a, b) and binomial data containing s successes in n trials gives the posterior parameters

$$(a+s, b+n-s).$$

The update is additive in the two exponent coordinates. This is a finite dimensional conjugate realization of likelihood composition. Standard Bayesian references include [BS94].

E11 Fractional functional calculus

Let H be a finite dimensional Hilbert space and let $L = L^* \ge 0$. Write its spectral resolution as

$$L = \sum_j \lambda_j P_j.$$

For $\alpha > 0$, define

$$L^\alpha = \sum_j \lambda_j^\alpha P_j$$

and

$$T_\alpha(t) = \mathrm{e}^{-tL^\alpha} = \sum_j \mathrm{e}^{-t\lambda_j^\alpha} P_j.$$

Theorem E11.1 (Fractional packet calculus)**.** *For $\alpha, \beta > 0$,*

$$L^\alpha L^\beta = L^{\alpha+\beta}.$$

For $s, t \ge 0$,

$$T_\alpha(s)T_\alpha(t) = T_\alpha(s+t).$$

Every spectral packet P_jH reduces L^α and $T_\alpha(t)$.

Proof. The claims hold on each spectral packet and the projectors are mutually orthogonal. □

Theorem E11.2 (Balakrishnan formula in finite dimension)**.** *For $0 < \alpha < 1$,*

$$L^\alpha = \frac{\sin(\pi\alpha)}{\pi}\int_0^\infty s^{\alpha-1} L(sI+L)^{-1}\,\mathrm{d}s.$$

The integral converges in operator norm.

Proof. It is enough to prove the formula on an eigenvector with eigenvalue $x \geq 0$. For $x > 0$, the substitution $s = xu$ gives

$$\frac{\sin(\pi\alpha)}{\pi} \int_0^\infty s^{\alpha-1} \frac{x}{s+x}\, \mathrm{d}s = x^\alpha \frac{\sin(\pi\alpha)}{\pi} \int_0^\infty \frac{u^{\alpha-1}}{1+u}\, \mathrm{d}u = x^\alpha.$$

The value at $x = 0$ is zero. There are finitely many eigenvalues, so the operator integral converges. This is the finite spectral form of the fractional power construction in [Bal60]. □

Theorem E11.3 (Exact fractional naturality)**.** *Let L_f and L_c be finite dimensional positive self-adjoint operators and let C satisfy*

$$CL_f = L_c C.$$

Then, for every $\alpha > 0$ and $t \geq 0$,

$$CL_f^\alpha = L_c^\alpha C$$

and

$$C\mathrm{e}^{-tL_f^\alpha} = \mathrm{e}^{-tL_c^\alpha} C.$$

Proof. The union of the two finite spectra is a finite set. There is a polynomial that agrees with x^α on that set, and another polynomial that agrees with e^{-tx^α}. Exact intertwining passes to every polynomial by induction. □

Theorem E11.4 (Fractional defect bound)**.** *Let $0 < \alpha < 1$. Suppose*

$$L_f \geq mI, \qquad L_c \geq mI$$

for some $m > 0$. Define

$$\Delta_L = CL_f - L_c C.$$

Then

$$\left\| CL_f^\alpha - L_c^\alpha C \right\| \leq \alpha m^{\alpha-1} \left\| \Delta_L \right\|.$$

Consequently,

$$\left\| C\mathrm{e}^{-tL_f^\alpha} - \mathrm{e}^{-tL_c^\alpha} C \right\| \leq \alpha t m^{\alpha-1} \left\| \Delta_L \right\|.$$

Proof. Set

$$R_f(s) = (sI + L_f)^{-1}, \qquad R_c(s) = (sI + L_c)^{-1}.$$

The resolvent identity gives

$$CR_f(s) - R_c(s)C = -R_c(s)\Delta_L R_f(s).$$

Since $LR = I - sR$,

$$CL_f R_f(s) - L_c R_c(s) C = sR_c(s)\Delta_L R_f(s).$$

Insert this into theorem E11.2. The spectral lower bound gives

$$\left\|R_f(s)\right\|, \|R_c(s)\| \le \frac{1}{s+m}.$$

Therefore

$$\begin{aligned}\left\|CL_f^\alpha - L_c^\alpha C\right\| &\le \frac{\sin(\pi\alpha)}{\pi}\|\Delta_L\| \int_0^\infty \frac{s^\alpha}{(s+m)^2}\,\mathrm{d}s \\ &= \alpha m^{\alpha-1}\|\Delta_L\|.\end{aligned}$$

The semigroup estimate follows from theorem E3.1, applied to the contraction generators $-L_f^\alpha$ and $-L_c^\alpha$. □

Remark E11.5. The factor $m^{\alpha-1}$ records the singular behavior of x^α near zero. Without a common positive lower bound, a uniform Lipschitz estimate of this form cannot be expected.

Standard Fact E11.6 (Stable subordination). Let $0 < \alpha < 1$ and $t > 0$. There is a probability measure $\eta_{\alpha,t}$ on $[0,\infty)$ such that

$$\int_0^\infty \mathrm{e}^{-s\lambda}\eta_{\alpha,t}(\,\mathrm{d}s) = \mathrm{e}^{-t\lambda^\alpha}$$

for every $\lambda \ge 0$. Consequently, for a finite dimensional positive self-adjoint operator,

$$\mathrm{e}^{-tL^\alpha} = \int_0^\infty \mathrm{e}^{-sL}\eta_{\alpha,t}(\,\mathrm{d}s)$$

in operator norm. The measures satisfy the convolution law

$$\eta_{\alpha,s} * \eta_{\alpha,t} = \eta_{\alpha,s+t}.$$

The existence of $\eta_{\alpha,t}$ follows from complete monotonicity of $\mathrm{e}^{-t\lambda^\alpha}$. The operator identity is obtained by applying the scalar Laplace transform on every spectral packet. This is the finite spectral form of Bochner subordination. See [SSV12].

Theorem E11.7 (Poisson subordination)**.** *For $t > 0$,*

$$\mathrm{e}^{-t\sqrt{L}} = \frac{t}{2\sqrt{\pi}}\int_0^\infty s^{-3/2}\mathrm{e}^{-t^2/(4s)}\mathrm{e}^{-sL}\,\mathrm{d}s.$$

The integral converges in operator norm.

Proof. On a spectral packet with eigenvalue λ, the formula reduces to

$$\mathrm{e}^{-t\sqrt{\lambda}} = \frac{t}{2\sqrt{\pi}}\int_0^\infty s^{-3/2}\mathrm{e}^{-t^2/(4s)-\lambda s}\,\mathrm{d}s.$$

This scalar identity follows from the Gaussian integral. Recombine the finitely many spectral packets. □

Remark E11.8. For sectorial and nonnormal operators, fractional powers require a resolvent or contour calculus together with domain control. The finite self-adjoint theory proved here does not remove those analytic requirements. A broader account appears in [SSV12].

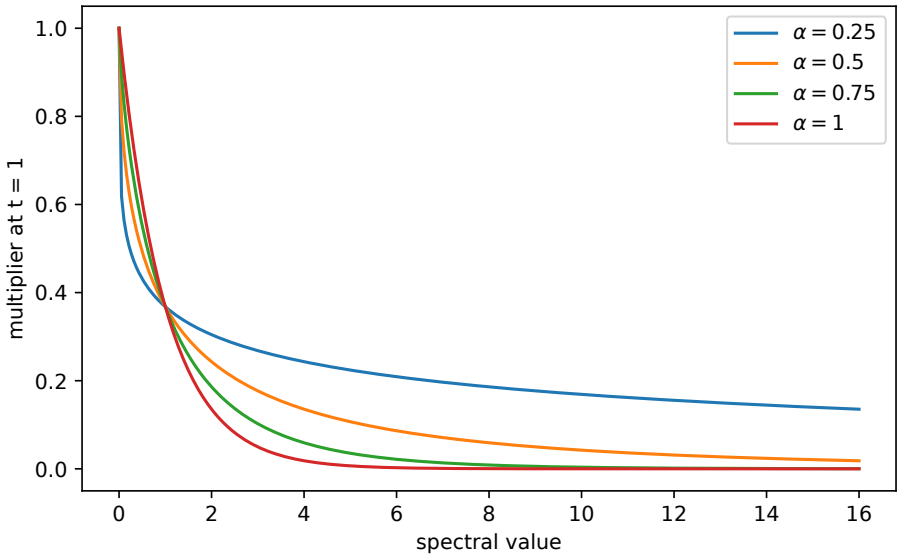

Figure E11. Fractional semigroup multipliers at time one. Smaller exponents preserve more of the high spectral range.

E12 Green operators and finite difference transfer

Consider

$$-u'' = f \quad \text{on } (0,1), \qquad u(0) = u(1) = 0.$$

The continuum Green kernel is

$$G(x,y) = \min(x,y) - xy.$$

Thus

$$u(x) = \int_0^1 G(x,y) f(y)\,\mathrm{d}y.$$

For n interior nodes, let

$$h = \frac{1}{n+1}, \qquad x_i = ih,$$

and define

$$L_h = \frac{1}{h^2}\begin{pmatrix} 2 & -1 & & \\ -1 & 2 & \ddots & \\ & \ddots & \ddots & -1 \\ & & -1 & 2 \end{pmatrix}.$$

Theorem E12.1 (Exact nodal Green reconstruction). *For $1 \le i, j \le n$,*

$$\frac{1}{h}(L_h^{-1})_{ij} = G(x_i, x_j).$$

Proof. The inverse of the unscaled tridiagonal matrix has entry

$$\frac{\min(i,j)(n+1-\max(i,j))}{n+1}.$$

Multiplying by h^2 and dividing by h gives

$$h\min(i,j)\left(1-\frac{\max(i,j)}{n+1}\right)=\min(x_i,x_j)-x_ix_j.$$

□

Corollary E12.2 (Discrete Green quadrature). *If u^h solves*

$$L_hu^h=f^h,$$

then every nodal value has the exact representation

$$u_i^h=h\sum_{j=1}^{n}G(x_i,x_j)f_j^h.$$

Thus the discrete Green operator is the nodal rectangle quadrature of the continuum Green kernel.

Proof. By theorem E12.1,

$$(L_h^{-1})_{ij}=hG(x_i,x_j).$$

Multiply the inverse matrix by the source vector. □

Proposition E12.3 (Discrete maximum bound). *The inverse L_h^{-1} has nonnegative entries and*

$$\left\|L_h^{-1}\right\|_{\infty\to\infty}=\max_{1\le i\le n}\frac{x_i(1-x_i)}{2}\le\frac{1}{8}.$$

Proof. Nonnegativity follows from the entry formula in theorem E12.1. Let $v_i=x_i(1-x_i)/2$. Since the second difference is exact on quadratics,

$$L_hv=1.$$

Hence the ith row sum of L_h^{-1} is v_i. For a nonnegative matrix, the infinity operator norm is the largest row sum. □

Theorem E12.4 (Second order Poisson solution error). *Suppose $u\in C^4[0,1]$ solves the Dirichlet problem above. Let*

$$f_i^h=f(x_i)$$

and let u^h solve

$$L_hu^h=f^h.$$

Then

$$\max_i\left|u_i^h-u(x_i)\right|\le\frac{h^2}{96}\left\|u^{(4)}\right\|_\infty.$$

Proof. Taylor expansion with remainder gives

$$\left\|L_h(u(x_i))_i-f^h\right\|_\infty\le\frac{h^2}{12}\left\|u^{(4)}\right\|_\infty.$$

Apply L_h^{-1} and use proposition E12.3. □

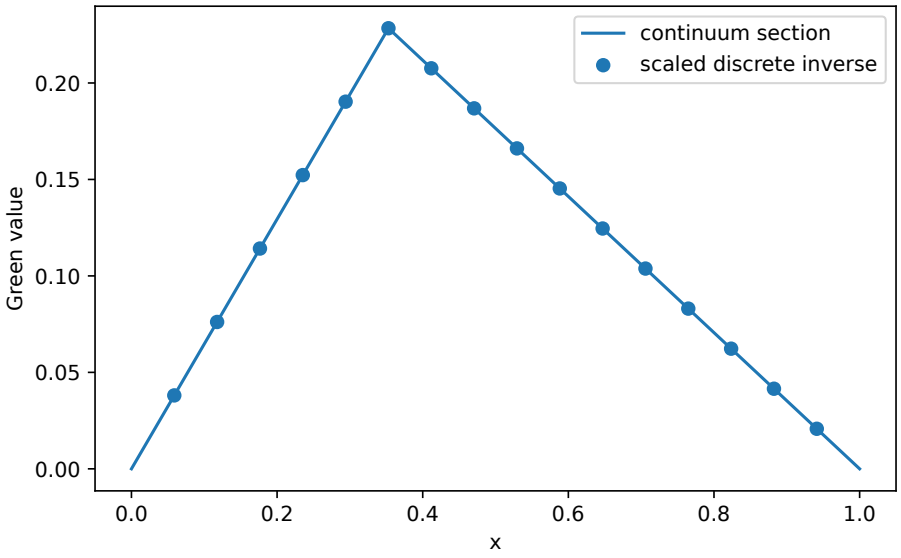

Figure E12. The continuum Dirichlet Green section and the scaled discrete inverse. The nodal values agree exactly.

The discrete eigenpairs are

$$\lambda_{k,h} = \frac{4}{h^2}\sin^2\left(\frac{k\pi h}{2}\right), \qquad v_{k,h}(i) = \sin(k\pi x_i).$$

Theorem E12.5 (Low mode eigenvalue control). *For $kh \le 1$,*

$$0 \le (k\pi)^2 - \lambda_{k,h} \le \frac{(k\pi)^4}{12}h^2.$$

Consequently, for every fixed k,

$$\lambda_{k,h} = (k\pi)^2 + O(h^2).$$

Proof. Set $x = k\pi h/2$. The condition $kh \le 1$ gives $0 \le x \le \pi/2$. On this interval,

$$\sin x \ge x - \frac{x^3}{6},$$

so

$$0 \le x^2 - \sin^2 x \le \frac{x^4}{3}.$$

Multiply by $4/h^2$. □

Corollary E12.6 (Heat and fractional mode transfer). *Let $\lambda_k = (k\pi)^2$. For $t \ge 0$,*

$$0 \le \mathrm{e}^{-t\lambda_{k,h}} - \mathrm{e}^{-t\lambda_k} \le \frac{t(k\pi)^4}{12}h^2\mathrm{e}^{-t\lambda_{k,h}}.$$

For $0 < \alpha \le 1$ and fixed k,

$$\lambda_{k,h}^{\alpha} = \lambda_k^{\alpha} + O(h^2)$$

and

$$\mathrm{e}^{-t\lambda_{k,h}^{\alpha}} = \mathrm{e}^{-t\lambda_k^{\alpha}} + O(th^2)$$

uniformly for t in bounded intervals.

Proof. The ordinary heat estimate follows from the mean value theorem and theorem E12.5. For fixed k, the eigenvalues stay uniformly away from zero once h is small. The function x^{α} is then Lipschitz on a common compact interval containing both eigenvalues. Apply the mean value theorem twice. □

Finite difference schemes and their stability theory are treated more broadly in [Str04]. The present result uses the special one-dimensional Green structure to obtain an explicit constant.

E13 Finite state Feynman–Kac transfer

How to read the result

The potential below is real. Its exponential is a potential weight in general, and a survival weight when the potential is nonnegative. This distinction does not change the finite transfer formula.

Let K be column stochastic. Let V be a real potential on the states and let

$$D_V = \operatorname{diag}(V).$$

For functions written as columns, the backward Markov operator is K^T.

Theorem E13.1 (Discrete Feynman–Kac formula). *Define*

$$M_V = \operatorname{diag}(\mathrm{e}^{-V})K^T.$$

For terminal data f,

$$(M_V^n f)_i = \mathbb{E}_i\left[\exp\left(-\sum_{r=0}^{n-1} V(X_r)\right) f(X_n)\right].$$

Proof. For one step,

$$(M_V f)_i = \mathrm{e}^{-V(i)} \sum_j K_{ji} f_j.$$

Iterating expands the matrix product over all paths. The product of transition entries is the path probability, and the diagonal factors give the exponential potential weight. □

Theorem E13.2 (Continuous time finite state formula). *Let Q be a finite Markov generator and let $(X_t)_{t\geq 0}$ be the corresponding chain. Then*

$$\left(\mathrm{e}^{t(Q^T - D_V)} f\right)_i = \mathbb{E}_i\left[\exp\left(-\int_0^t V(X_s)\,\mathrm{d}s\right) f(X_t)\right].$$

If $V \geq v_0$, then

$$\left\|\mathrm{e}^{t(Q^T - D_V)}\right\|_{\infty\to\infty} \leq \mathrm{e}^{-v_0 t}.$$

Proof. Conditioning over the first small time interval gives the backward equation

$$\dot{u} = (Q^T - D_V)u, \qquad u(0) = f.$$

The finite system has a unique solution, namely the displayed matrix exponential. The expectation bound follows from

$$\exp\left(-\int_0^t V(X_s)\,\mathrm{d}s\right) \le \mathrm{e}^{-v_0 t}.$$

This finite argument is the matrix form of the Feynman–Kac principle originating in [Kac49]. □

Theorem E13.3 (Alternating propagation and killing)**.** *For every $t \ge 0$,*

$$\mathrm{e}^{t(Q^T - D_V)} = \lim_{n\to\infty} \left(\mathrm{e}^{-tD_V/n}\mathrm{e}^{tQ^T/n}\right)^n$$

in operator norm. Each finite product alternates one Markov propagation step with one diagonal survival weight.

Proof. Set $B = -D_V$ and $C = Q^T$. For bounded matrices,

$$\mathrm{e}^{tB/n}\mathrm{e}^{tC/n} = I + \frac{t}{n}(B + C) + O(n^{-2})$$

uniformly in operator norm. The standard telescoping comparison with $(I + t(B + C)/n)^n$ shows that the product converges to $\mathrm{e}^{t(B+C)}$. This is the displayed factor order, so the limit follows. □

Corollary E13.4 (Positivity and composition)**.** *The operators*

$$F_V(t) = \mathrm{e}^{t(Q^T - D_V)}$$

form a positive semigroup. If $f \ge 0$, then $F_V(t)f \ge 0$.

Proof. Both claims follow from the expectation formula. □

E14 Schur–Feshbach elimination

Let $X = X_P \oplus X_Q$ and write

$$A = \begin{pmatrix} A_{PP} & A_{PQ} \\ A_{QP} & A_{QQ} \end{pmatrix}.$$

For $zI - A_{QQ}$ invertible, define

$$\Sigma_P(z) = A_{PQ}(zI - A_{QQ})^{-1}A_{QP}$$

and

$$F_P(z) = zI - A_{PP} - \Sigma_P(z).$$

Theorem E14.1 (Schur–Feshbach resolvent). *Assume $zI - A_{QQ}$ is invertible. Then $zI - A$ is invertible if and only if $F_P(z)$ is invertible. In that case,*

$$P(zI - A)^{-1}P = F_P(z)^{-1}.$$

In finite dimension,

$$\det(zI - A) = \det(zI - A_{QQ}) \det F_P(z).$$

Proof. Set

$$L_z = \begin{pmatrix} I & -A_{PQ}(zI - A_{QQ})^{-1} \\ 0 & I \end{pmatrix}$$

and

$$S_z = \begin{pmatrix} F_P(z) & 0 \\ -A_{QP} & zI - A_{QQ} \end{pmatrix}.$$

Direct multiplication gives $zI - A = L_z S_z$. The first factor is invertible. The claims follow from triangular inversion and the determinant of the second factor. This is the finite block form of the Feshbach reduction [Fes58]. □

E14.1 Time domain memory

For the homogeneous equation $\dot{x} = Ax$, variation of constants gives

$$x_Q(t) = \mathrm{e}^{tA_{QQ}} x_Q(0) + \int_0^t \mathrm{e}^{(t-s)A_{QQ}} A_{QP} x_P(s)\, \mathrm{d}s.$$

Substitution into the retained equation gives

$$\dot{x}_P(t) = A_{PP}x_P(t) + A_{PQ}\mathrm{e}^{tA_{QQ}}x_Q(0) + \int_0^t \mathcal{K}(t-s)x_P(s)\, \mathrm{d}s,$$

where

$$\mathcal{K}(t) = A_{PQ}\mathrm{e}^{tA_{QQ}}A_{QP}.$$

Theorem E14.2 (Memory and self-energy). *If z lies to the right of the spectrum of A_{QQ}, then*

$$\int_0^\infty \mathrm{e}^{-zt}\mathcal{K}(t)\, \mathrm{d}t = \Sigma_P(z).$$

If, for constants $M \geq 0$ and $\gamma > 0$,

$$\left\|\mathrm{e}^{tA_{QQ}}\right\| \leq M\mathrm{e}^{-\gamma t},$$

then

$$\|\mathcal{K}(t)\| \leq M\left\|A_{PQ}\right\|\left\|A_{QP}\right\|\mathrm{e}^{-\gamma t}$$

and

$$\|\mathcal{K}\|_{L^1(0,\infty)} \le \frac{M}{\gamma}\,\|A_{PQ}\|\|A_{QP}\|.$$

Proof. If $X_Q = \{0\}$, the memory kernel and self-energy are both zero, so the identity is immediate. Otherwise write $B = A_{QQ}$, which is a bounded operator on the hidden Banach space, and put $s(B) = \max \operatorname{Re}\operatorname{Spec}(B)$. Choose a real β with $s(B) < \beta < \operatorname{Re} z$. Spectral mapping and the spectral-radius formula give $r(\mathrm{e}^B) = \mathrm{e}^{s(B)} < \mathrm{e}^{\beta}$, hence $\|\mathrm{e}^{nB}\| \le M_\beta \mathrm{e}^{\beta n}$ for every integer $n \ge 0$, after increasing M_β to cover the finitely many initial values. Write $t = n + r$, where $0 \le r < 1$. Then

$$\|\mathrm{e}^{tB}\| \le M_\beta \exp(\|B\| + \max(0, -\beta))\mathrm{e}^{\beta t}.$$

Thus $\mathrm{e}^{-zt}\mathrm{e}^{tB}$ is Bochner integrable and tends to zero. Integrating its derivative gives both inverse identities for $R = \int_0^\infty \mathrm{e}^{-zt}\mathrm{e}^{tB}\,\mathrm{d}t$, so $R = (zI - B)^{-1}$. This is the bounded-generator growth principle in [EN00, Chapter IV, Corollary 3.12]. Multiplication by the coupling blocks gives the first identity. The remaining estimates follow directly from the assumed positive decay rate. □

Theorem E14.3 (Criterion for exact local closure)**.** *Assume $x_Q(0) = 0$ and $d = \dim X_Q < \infty$. The following conditions are equivalent.*

1. *For every retained initial state,*
$$P\mathrm{e}^{tA}P = \mathrm{e}^{tA_{PP}}P$$
for all $t \ge 0$.
2. *$\Sigma_P(z) = 0$ for every sufficiently large z.*
3. *$\mathcal{K}(t) = 0$ for every $t \ge 0$.*
4. *If $d = \dim X_Q$, then*
$$A_{PQ}A_{QQ}^k A_{QP} = 0$$
for $0 \le k < d$.

Proof. By theorem E2.5, the Laplace transform of the projected propagator is the projected resolvent. By theorem E14.1, the first condition is equivalent to

$$(zI - A_{PP} - \Sigma_P(z))^{-1} = (zI - A_{PP})^{-1}$$

for all sufficiently large z, which is equivalent to the second condition. The second and third conditions are equivalent by theorem E14.2 and uniqueness of the Laplace transform.

For large z,

$$\Sigma_P(z) = \sum_{k=0}^{\infty} \frac{A_{PQ}A_{QQ}^k A_{QP}}{z^{k+1}}.$$

Thus the second condition implies the moment identities. Conversely, the first d identities imply all later ones by the Cayley–Hamilton theorem, so the series vanishes. □

Remark E14.4. A finite hidden block produces a strictly proper rational self-energy. It tends to zero as z tends to infinity. Hence a nonzero constant self-energy cannot arise from hidden dynamics alone. A constant correction must already be included in the retained generator.

E15 Memory modes and controlled compression

How to read the result

Stable hidden modes may carry polynomial factors when a Jordan block is present. A spectral gap controls eventual decay, while nonnormal coupling can produce substantial intermediate memory. The compression certificate below is optimal for its declared primary-block selection problem.

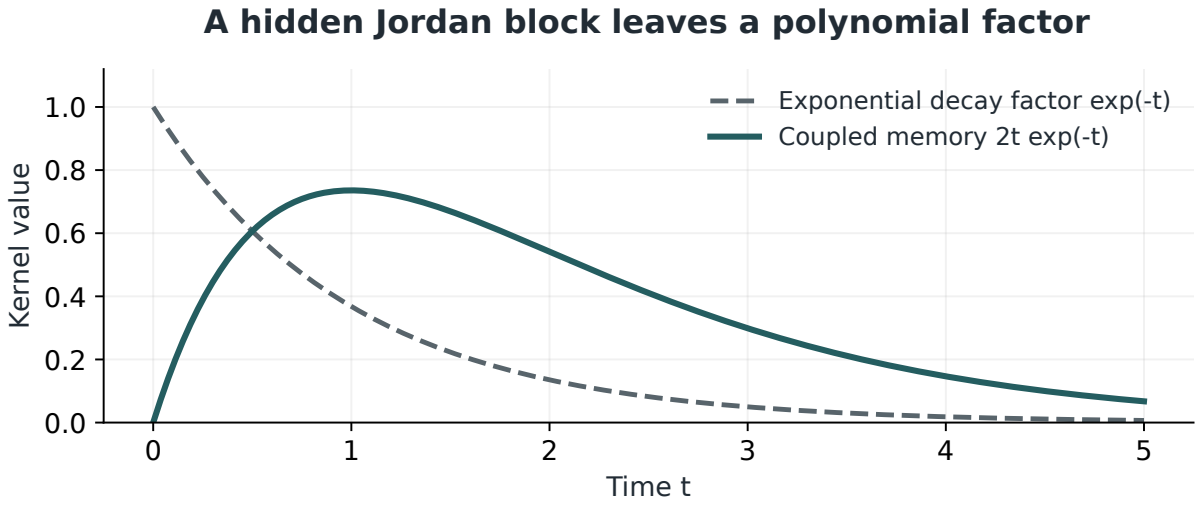

Figure E13. A two-coordinate Jordan hidden block has an exponential decay factor and a polynomial factor. The nilpotent polynomial is checked exactly at the displayed rational times. The exponential curve is a plotted illustration of the formula.

Finite hidden systems produce rational self-energies and finite modal memory. This is the state space viewpoint familiar from linear systems theory [Kai80]. The same formulas also underlie the Mori–Zwanzig representation of reduced dynamics [Zwa61, CHK00].

Theorem E15.1 (Polynomial exponential memory of a finite hidden system)**.** *Let X_Q be a finite dimensional complex space. Let $\mu_1, \dots, \mu_r$ be the distinct eigenvalues of A_{QQ}, let Q_j be the corresponding primary spectral projections, and set*

$$N_j = (A_{QQ} - \mu_j I)Q_j.$$

Let ν_j be the least positive integer for which $N_j^{\nu_j} = 0$, and define

$$B_{j,k} = A_{PQ} N_j^k Q_j A_{QP} \qquad (0 \le k < \nu_j).$$

Then

$$\mathcal{K}(t) = \sum_{j=1}^{r} \mathrm{e}^{\mu_j t} \sum_{k=0}^{\nu_j - 1} \frac{t^k}{k!} B_{j,k}$$

and

$$\Sigma_P(z) = \sum_{j=1}^{r} \sum_{k=0}^{\nu_j - 1} \frac{B_{j,k}}{(z-\mu_j)^{k+1}}.$$

Suppose $\operatorname{Re}\mu_j < 0$ *for every* j*. If* $J \subseteq \{1, \dots, r\}$ *and* $\mathcal{K}_J$ *retains the complete primary blocks indexed by* J*, then*

$$\|\mathcal{K} - \mathcal{K}_J\|_{L^1(0,\infty)} \le \sum_{j \notin J} \sum_{k=0}^{\nu_j - 1} \frac{\|B_{j,k}\|}{(-\operatorname{Re}\mu_j)^{k+1}}.$$

Proof. The primary decomposition gives

$$A_{QQ} Q_j = \mu_j Q_j + N_j$$

with commuting scalar and nilpotent parts on $Q_j X_Q$. Therefore

$$\mathrm{e}^{t A_{QQ}} Q_j = \mathrm{e}^{\mu_j t} \sum_{k=0}^{\nu_j - 1} \frac{t^k}{k!} N_j^k Q_j.$$

Multiplication by A_{PQ} and A_{QP} gives the memory formula. On the jth primary space, the nilpotent resolvent expansion is

$$(zI - A_{QQ})^{-1} Q_j = \sum_{k=0}^{\nu_j - 1} \frac{N_j^k Q_j}{(z-\mu_j)^{k+1}}.$$

Multiplication by the coupling blocks gives the self-energy formula for every z outside the hidden spectrum. Equivalently, on a right half plane it is the Laplace transform identity

$$\int_0^\infty \mathrm{e}^{-zt} \mathrm{e}^{\mu_j t} \frac{t^k}{k!} \, \mathrm{d}t = \frac{1}{(z-\mu_j)^{k+1}}.$$

Under stability,

$$\int_0^\infty \mathrm{e}^{\operatorname{Re}\mu_j t} \frac{t^k}{k!} \, \mathrm{d}t = \frac{1}{(-\operatorname{Re}\mu_j)^{k+1}}.$$

Sum the omitted terms. □

Corollary E15.2 (Optimal selection for the certified primary block bound)**.** *Under the stable assumptions of theorem E15.1, define the primary block weights*

$$w_j = \sum_{k=0}^{\nu_j - 1} \frac{\|B_{j,k}\|}{(-\operatorname{Re}\mu_j)^{k+1}}.$$

Among all sets J containing k primary blocks, the certified upper bound

$$\sum_{j\notin J} w_j$$

is minimized by retaining the k largest weights. If

$$w_{(1)} \geq w_{(2)} \geq \cdots \geq w_{(r)},$$

then the least number of retained primary blocks certified to give L^1 error at most ε is the least k for which

$$\sum_{j>k} w_{(j)} \leq \varepsilon.$$

Proof. If a retained set contains a block with smaller weight than an omitted block, exchanging them reduces the omitted weight sum. Repeating the exchange gives the set of the k largest weights. The tolerance statement is the corresponding sorted tail condition. □

Corollary E15.3 (Normal hidden dynamics)**.** *Suppose X_Q is a finite dimensional Hilbert space. If A_{QQ} is normal with spectral resolution*

$$A_{QQ} = \sum_{j=1}^{r} \mu_j Q_j,$$

then

$$\mathcal{K}(t) = \sum_{j=1}^{r} \mathrm{e}^{\mu_j t} B_j, \qquad \Sigma_P(z) = \sum_{j=1}^{r} \frac{B_j}{z-\mu_j},$$

where

$$B_j = A_{PQ} Q_j A_{QP}.$$

If $\operatorname{Re}\mu_j < 0$, then

$$\|\mathcal{K} - \mathcal{K}_J\|_{L^1(0,\infty)} \leq \sum_{j\notin J} \frac{\|B_j\|}{-\operatorname{Re}\mu_j}.$$

Proof. Normality removes every nilpotent part, so $\nu_j = 1$. Apply theorem E15.1. □

Corollary E15.4 (Pole order and hidden Jordan depth)**.** *Every finite hidden block produces a strictly proper rational self-energy. At an eigenvalue μ_j, its pole order is at most the size of the largest Jordan block of A_{QQ} at μ_j. Equality holds when the corresponding highest coefficient B_{j,ν_j-1} is nonzero.*

Proof. Read the pole order from the partial fraction expansion in theorem E15.1. □

Corollary E15.5 (Finite auxiliary state realization)**.** *Every kernel of the form*

$$\mathcal{K}(t) = B\mathrm{e}^{tD}C$$

can be represented exactly by adjoining the finite auxiliary state

$$\dot{y} = Dy + Cx_P, \qquad \dot{x}_P = A_{PP}x_P + By, \qquad y(0) = 0.$$

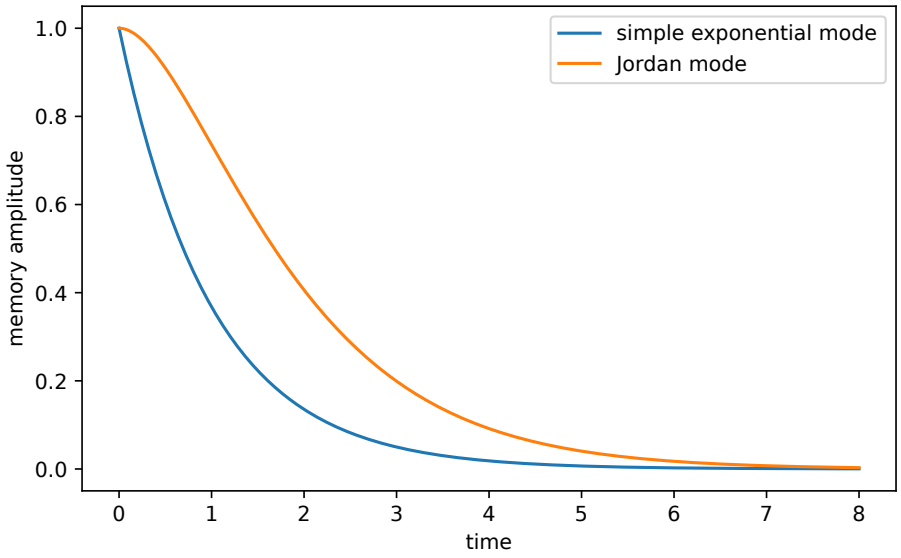

Figure E14. A stable Jordan block produces a polynomial exponential memory mode. A diagonal hidden block produces only pure exponentials.

A nonzero auxiliary initial state adds the explicit forcing $Be^{tD}y(0)$. The self-energy of the augmented system is

$$B(zI - D)^{-1}C.$$

Proof. Eliminate y by variation of constants or apply theorem E14.1 to the augmented block matrix. □

Theorem E15.6 (Volterra stability under kernel compression). *Let $S(t)$ be a strongly continuous semigroup on a Banach space X, fix $T > 0$, and assume*

$$\|S(t)\| \le M_T \quad (0 \le t \le T).$$

Let $K, \widetilde{K} \in L^1((0,T), \mathcal{B}(X))$, let $g \in L^1((0,T), X)$, and let $x, \tilde{x} \in C([0,T], X)$. Suppose these are mild solutions with the same initial state and forcing, except that K is replaced by $\widetilde{K}$:

$$x(t) = S(t)x_0 + \int_0^t S(t-s)g(s)\,\mathrm{d}s + \int_0^t S(t-s)\int_0^s K(s-r)x(r)\,\mathrm{d}r\,\mathrm{d}s.$$

Assume

$$\sup_{0\le t\le T} \|\tilde{x}(t)\| \le B.$$

Set

$$L = \|K\|_{L^1(0,T)}, \qquad \varepsilon = \left\|K - \widetilde{K}\right\|_{L^1(0,T)}.$$

Then

$$\sup_{0\le t\le T} \|x(t) - \tilde{x}(t)\| \le M_T B T \varepsilon \exp(M_T L T).$$

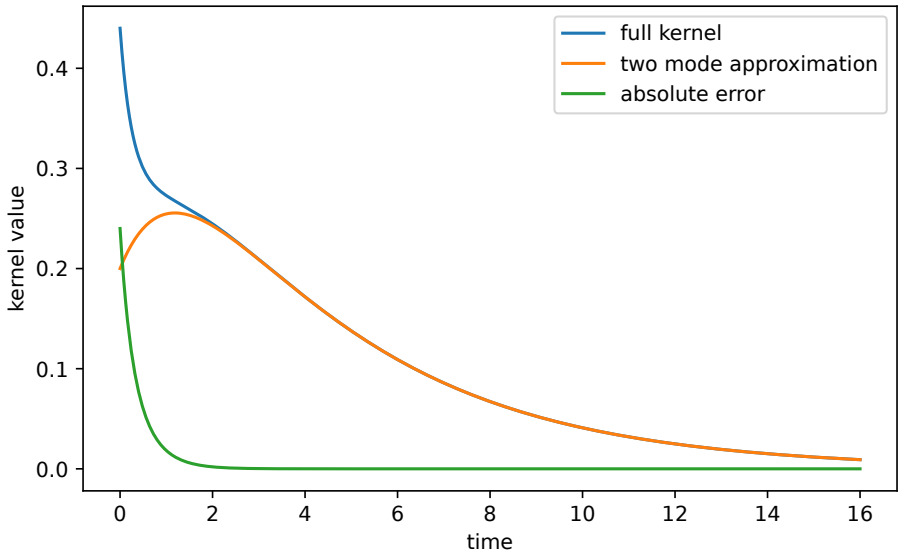

Figure E15. Full and truncated memory kernels with their pointwise difference. The bound uses integrated error.

Proof. Let

$$E(t) = \sup_{0 \le r \le t} \|x(r) - \tilde{x}(r)\|.$$

Subtract the two mild equations. Fubini's theorem and the triangle inequality give

$$E(t) \le M_T L \int_0^t E(r)\,\mathrm{d}r + M_T B t \varepsilon.$$

For $t \le T$, replace the last factor t by T and apply Gronwall's inequality. □

Corollary E15.7 (Trajectory bound for modal truncation)**.** *Under the assumptions of theorems E15.1 and E15.6, replacing $\mathcal{K}$ by $\mathcal{K}_J$ changes the retained trajectory by at most*

$$M_T B T \exp(M_T L T) \sum_{j \notin J} \sum_{k=0}^{\nu_j - 1} \frac{\|B_{j,k}\|}{(-\operatorname{Re} \mu_j)^{k+1}}.$$

Proof. Insert the L^1 error from theorem E15.1 into theorem E15.6. □

Remark E15.8. A finite hidden realization is exact for rational self-energy. A general memory kernel may require infinitely many modes or a continuum of modes. The compression theorem gives a stability estimate once an L^1 approximation has been supplied. The largest weight rule is optimal for the certified blockwise bound. It need not minimize the true kernel error when different modal terms cancel.

E16 Survival, moments, and competing risks

Let A be a transient state subgenerator. Its off-diagonal entries are nonnegative and its column sums are nonpositive. Let p_0 be a transient probability vector. Define

$$p(t) = \mathrm{e}^{tA}p_0, \qquad S(t) = 1^T p(t), \qquad a^T = -1^T A.$$

The row vector a^T contains the exit rates.

Theorem E16.1 (State dependent killing as survival). *Let Q be a finite Markov generator, let $V \geq 0$, and set*

$$A = Q - D_V.$$

For an initial distribution p_0, define

$$S_V(t) = 1^T \mathrm{e}^{tA}p_0.$$

Then

$$S_V(t) = \mathbb{E}_{p_0}\left[\exp\left(-\int_0^t V(X_s)\,\mathrm{d}s\right)\right].$$

Also,

$$-S_V'(t) = 1^T D_V \mathrm{e}^{tA}p_0.$$

The matrix $A = Q - D_V$ has nonnegative off-diagonal entries and nonpositive column sums, so it is the subgenerator of the killed, possibly nontransient chain. Thus the potential in the finite Feynman–Kac formula is a state dependent killing rate in the forward sub-Markov semigroup. Almost-sure absorption follows under the additional spectral stability hypothesis used below.

Proof. Average theorem E13.2 with terminal function $f = 1$ against the initial distribution. Transposition gives

$$p_0^T \mathrm{e}^{t(Q^T - D_V)}1 = 1^T \mathrm{e}^{t(Q - D_V)}p_0.$$

Since $1^T Q = 0$, differentiation gives

$$S_V'(t) = -1^T D_V \mathrm{e}^{tA}p_0.$$

□

Theorem E16.2 (Survival and hazard identities). *The event density and hazard are*

$$f(t) = a^T \mathrm{e}^{tA}p_0 = -S'(t), \qquad h(t) = \frac{f(t)}{S(t)}$$

whenever $S(t) > 0$. The survival function is nonincreasing and

$$S(t) = \exp\left(-\int_0^t h(s)\,\mathrm{d}s\right).$$

Proof. Because A is a Metzler matrix, e^{tA} is nonnegative. The column sum assumption makes a^T nonnegative. Differentiate $S(t)$:

$$S'(t) = 1^T A \mathrm{e}^{tA} p_0 = -a^T \mathrm{e}^{tA} p_0.$$

The remaining identity follows by integrating $(\log S)' = -h$. □

Theorem E16.3 (Laplace transform and moments). *Assume the spectrum of A lies in the open left half plane. Then absorption occurs with probability one. For $s \geq 0$,*

$$\mathbb{E}[\mathrm{e}^{-s\tau}] = a^T (sI - A)^{-1} p_0.$$

For every integer $m \geq 1$,

$$\mathbb{E}[\tau^m] = m! 1^T (-A)^{-m} p_0.$$

Proof. The Laplace transform follows by integrating the density in theorem E16.2. Stability of A gives

$$\int_0^\infty \mathrm{e}^{-st} \mathrm{e}^{tA} \, \mathrm{d}t = (sI - A)^{-1}.$$

At $s = 0$,

$$a^T (-A)^{-1} p_0 = 1^T p_0 = 1.$$

For the moments,

$$\int_0^\infty t^m \mathrm{e}^{tA} \, \mathrm{d}t = m! (-A)^{-m-1}.$$

Multiplying by $a^T = 1^T(-A)$ gives the result. These are the standard matrix formulas for phase type laws [Neu81, ANO96]. □

Proposition E16.4 (Residual life as a restarted semigroup). *For $S(t) > 0$, define the conditional transient distribution*

$$p_t = \frac{\mathrm{e}^{tA} p_0}{S(t)}.$$

Then

$$\frac{S(t+s)}{S(t)} = 1^T \mathrm{e}^{sA} p_t.$$

Proof. Use the semigroup law in the numerator $S(t+s) = 1^T \mathrm{e}^{sA} \mathrm{e}^{tA} p_0$. □

Theorem E16.5 (Competing risk packets). *Suppose the exit row splits into nonnegative cause rows*

$$a^T = \sum_{r=1}^{q} a_r^T.$$

Define

$$f_r(t) = a_r^T \mathrm{e}^{tA} p_0.$$

Then

$$f(t) = \sum_{r=1}^{q} f_r(t).$$

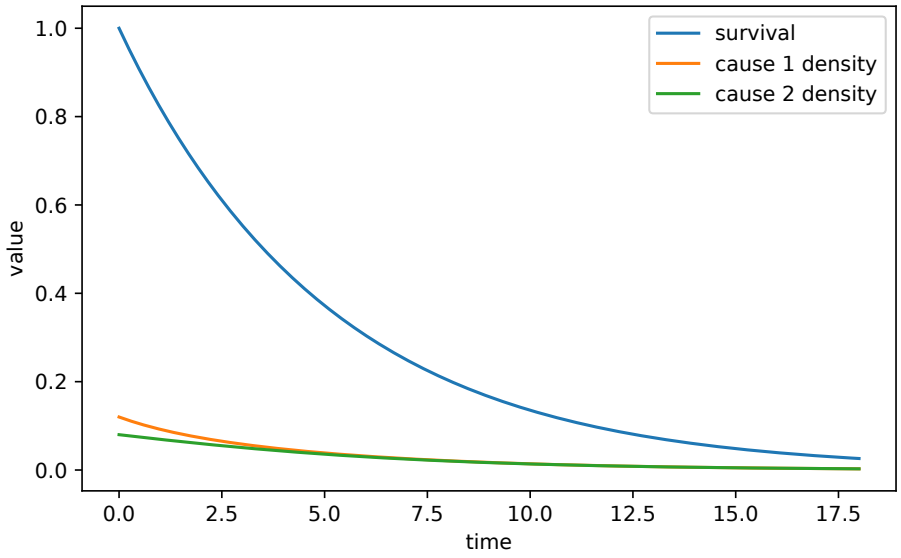

Figure E16. Survival and two cause specific event densities from one transient semigroup.

The cause specific hazard is

$$h_r(t) = \frac{f_r(t)}{S(t)},$$

and

$$h(t) = \sum_{r=1}^{q} h_r(t).$$

If the spectrum of A lies in the open left half-plane, the eventual probability of cause r is

$$\int_0^\infty f_r(t)\,\mathrm{d}t = a_r^T(-A)^{-1}p_0.$$

Proof. Every identity follows by linearity and the stable resolvent integral. □

Remark E16.6. A finite phase type hazard need not be monotone. The semigroup formulas guarantee nonnegative density and decreasing survival, not monotonicity of the hazard.

E17 Finite illustrations and computational checks

The figures in this part use small matrices chosen to make each mechanism visible. They are not evidence for claims outside the proved finite setting. The accompanying verification script recomputes the following identities with independently generated data.

1. Packet block convolution, the block differential system, and the Laplace resolvent formula.
2. The Duhamel and resolvent defect identities.
3. Exact and perturbed Markov lumping.

Identity	Typical residual
Packet block convolution	below 3×10^{-14}
Duhamel defect	below 3×10^{-12}
Markov lumping	below 3×10^{-14}
Bayesian reconstruction	below 3×10^{-15}
Fractional spectral law	below 3×10^{-12}
Nodal Green identity	below 3×10^{-13}
Feynman–Kac enumeration	below 3×10^{-14}
Schur–Feshbach resolvent	below 3×10^{-12}
Memory Laplace identity	below 3×10^{-11}
Survival moment formulas	below 3×10^{-11}

Table E2. Numerical tolerances in the finite verification suite. The proofs do not depend on these computations.

4. Conditional expectation, tower laws, martingale packet energy, and Hermite multipliers.
5. Bayesian reconstruction, sufficiency, local distortion, and information decomposition.
6. The evidence variance identity along a Bayesian flow.
7. The Balakrishnan formula and the fractional defect estimate.
8. Nodal Green reconstruction and the Poisson error bound.
9. Discrete Feynman–Kac path enumeration.
10. The Schur–Feshbach resolvent and memory transform.
11. Jordan memory modes, modal truncation, and the Volterra stability estimate.
12. Feynman–Kac killing, survival transforms, moments, and competing risk masses.

E18 Limits and further questions

The bounded inverse limit theorem isolates one clean route to continuum evolution. Unbounded generators require graph norms, domain compatibility, and a generation theorem. The range leakage theorem converts the closure quantity into an off-diagonal generator estimate for bounded orthogonal refinement models. Concrete discretizations still require a uniform estimate for that off-diagonal block.

The finite Bayesian sufficiency theorem is exact, but it concerns one likelihood and one fixed partition. The relative entropy chain rule measures both retained and discarded information for that update. Statistical sufficiency for a parametric family requires a common packet structure that preserves the full parameter dependence. In continuous models the corresponding object is a sufficient sigma algebra or statistic.

The fractional defect theorem uses a common spectral gap. Removing that gap requires weaker norms or a Hölder estimate near the null space. For sectorial operators, the same calculation should be carried out through resolvent bounds on a sector, with domains tracked explicitly. The finite spectral statement does not settle those issues.

The Green and Poisson results exploit a one-dimensional second difference matrix. Higher dimensions, irregular meshes, and variable coefficients require a separate stability theory. The packet language remains useful only after coercivity, consistency, and boundary approximation have been established.

Memory compression is exact once a finite hidden realization is known and quantitative once an integrable kernel approximation is supplied. The primary decomposition shows that a finite hidden block always produces polynomial exponential modes, including the effects of Jordan chains. Choosing a short approximation remains a different problem. Strongly nonnormal systems can exhibit transient growth and may require balanced or rational approximation methods. General Volterra kernels need not admit a short finite realization.

Finally, Markov lumping, Bayesian sufficiency, and memory closure answer different questions. Lumpability asks whether coarse probabilities evolve autonomously. Bayesian sufficiency asks whether a fixed coarse likelihood reproduces the posterior packet masses without hiding a change in the conditional distribution inside a packet. Memory closure asks whether discarded dynamics can be represented without history. Similar notation should not obscure these distinctions.

E19 Conclusion

A bounded semigroup becomes a matrix of packet transfers once a finite packet system is fixed. The matrix obeys convolution in time, a closed differential system, a Laplace resolvent formula, and a directed path expansion. A generator defect propagates through Duhamel's formula and through the resolvent calculus. Exact compatibility gives a semigroup on the bounded inverse limit. Summable adjacent defects give convergent reconstructed evolutions. Range leakage, and in particular an off-diagonal generator block, determines whether the limit retains the semigroup law.

In probability, the same structure appears in several forms. Markov transfer is linear and exact lumpability is the vanishing of a canonical kernel obstruction. Conditional expectation is an orthogonal stochastic projector whose differences form martingale packets. The Ornstein–Uhlenbeck semigroup resolves exactly into Hermite packets. Bayesian transfer is nonlinear because of evidence normalization. Its exact two stage decomposition separates coarse packet evidence from local conditional change. Relative entropy then records exactly how much information lies at each level. A fixed sufficient coarse description exists for every prior precisely when the likelihood is constant inside each packet. The common level sets of a likelihood family give its unique coarsest fixed sufficient partition.

Positive fractional powers preserve exact intertwining. Under a common spectral gap, the Balakrishnan formula turns an ordinary generator defect into an explicit fractional defect. Green operators and finite differences show how source reconstruction fits the same transfer language. Feynman–Kac weights Markov paths by a potential without leaving the semigroup framework.

Exact elimination returns hidden packets as a rational self-energy in the resolvent and a causal memory kernel in time. The primary decomposition of the hidden generator produces every finite memory kernel as a finite sum of polynomial exponential modes. Stable blocks can be truncated with an integrated error certificate, and the Volterra estimate transfers that certificate to the retained trajectory. State dependent killing identifies the Feynman–Kac potential with a survival mechanism. Survival and competing risks are then scalar reconstructions of a transient semigroup.

This part therefore separates four operations that are often compressed into one informal idea of coarse dynamics:

$$\begin{aligned} \text{intertwining} &\longrightarrow \text{refinement control} \\ &\longrightarrow \text{statistical sufficiency} \\ &\longrightarrow \text{memory closure}. \end{aligned}$$

Each arrow has its own hypotheses and its own obstruction.

Part III Retained results and operator calculus

R1 Transfer paths and product-topology limits

Let $T(t)$ be an arbitrary strongly continuous semigroup on a complex Banach space X, with generator A, and suppose $\|T(t)\| \le Me^{\omega t}$ for $M \ge 1$ and $\omega \in \mathbb{R}$. Let $(P_\alpha)_{\alpha\in I_0}$ be a finite family of bounded pairwise orthogonal idempotents summing to I, and put $T_{\beta\alpha}(t) = P_\beta T(t) P_\alpha$. The generator need not be bounded. In the following resolvent statement the integral is strong: apply the integrand to each $x \in X$ and take its Bochner integral in X. It is not asserted to be a Bochner integral in the operator-norm space $\mathcal{B}(X)$. The general Laplace formula is [EN00, Chapter II, Theorem 1.10].

Theorem R1.1 (Packet convolution). *For all $s, t \ge 0$ and all packets α, β,*

$$\boxed{T_{\beta\alpha}(s+t) = \sum_{\gamma\in I_0} T_{\beta\gamma}(s) T_{\gamma\alpha}(t).}$$

The original semigroup is reconstructed from its blocks by

$$T(t) = \sum_{\alpha,\beta\in I_0} T_{\beta\alpha}(t).$$

Proof. Insert the identity between the two semigroup factors:

$$\begin{aligned} P_\beta T(s+t) P_\alpha &= P_\beta T(s) \left(\sum_\gamma P_\gamma\right) T(t) P_\alpha \\ &= \sum_\gamma P_\beta T(s) P_\gamma T(t) P_\alpha. \end{aligned}$$

The reconstruction formula follows by inserting the packet identity on both sides of $T(t)$. □

Proposition R1.2 (Packet resolvent convolution). *Let z belong to the resolvent set of A. If $\operatorname{Re} z$ is larger than a growth bound for the semigroup, then*

$$P_\beta (zI - A)^{-1} P_\alpha = \int_0^\infty \mathrm{e}^{-zt} T_{\beta\alpha}(t)\,\mathrm{d}t.$$

Proof. The standard Laplace representation of the resolvent is

$$(zI - A)^{-1} = \int_0^\infty \mathrm{e}^{-zt} T(t)\,\mathrm{d}t.$$

Multiplication by the bounded packet projections may be passed through the Bochner integral. □

For the path-order statement, now assume A is bounded as in Part II. A directed edge from α to β means that $P_\beta A P_\alpha$ is nonzero, with $\alpha \ne \beta$. A packet always has the length-zero path to itself.

Corollary R1.3 (Minimum transfer order)**.** *Suppose every directed packet path from α to β uses at least m_0 off-diagonal transfers. Then*

$$P_\beta \mathrm{e}^{tA} P_\alpha = O(t^{m_0}) \quad \text{as } t \downarrow 0.$$

If there is no directed path from α to β, the block vanishes for all t.

Proof. Every nonzero term in theorem E2.8 contains at least m_0 time integrations. The simplex $0 < r_1 < \cdots < r_m < t$ has volume $t^m/m!$, so the first possible order is t^{m_0}. If there is no path, every packet term vanishes. □

Let $C_j : X_{j+1} \to X_j$ be bounded linear maps, and put $C_{\ell,m} = C_\ell \cdots C_{m-1}$ for $\ell < m$, with $C_{j,j} = I$. No common ambient space is assumed.

Theorem R1.4 (Multilevel telescoping identity)**.** *Let T_j be bounded operators on X_j, and set*

$$E_j = C_j T_{j+1} - T_j C_j.$$

Then

$$\boxed{C_{\ell,m} T_m - T_\ell C_{\ell,m} = \sum_{j=\ell}^{m-1} C_{\ell,j} E_j C_{j+1,m}.}$$

Proof. Expand each summand as

$$C_{\ell,j+1} T_{j+1} C_{j+1,m} - C_{\ell,j} T_j C_{j,m}.$$

The intermediate terms cancel. The first surviving term is $C_{\ell,m} T_m$, and the last is $-T_\ell C_{\ell,m}$. □

Corollary R1.5 (Summable generator defects)**.** *Suppose C_j are contractions and $(T_j(t))$ are contraction semigroups with bounded generators A_j. Set*

$$\delta_j = \left\| C_j A_{j+1} - A_j C_j \right\|.$$

Then

$$\left\| C_{\ell,m} T_m(t) - T_\ell(t) C_{\ell,m} \right\| \le t \sum_{j=\ell}^{m-1} \delta_j.$$

If $\sum_{j \ge 0} \delta_j < \infty$, the right side tends to zero as $\ell \to \infty$, uniformly in $m > \ell$ and uniformly for t in a fixed bounded interval.

Proof. By theorem E3.1, the interlevel semigroup defect has norm at most $t\delta_j$. Apply theorem R1.4 and use the contraction bounds on all coarsening maps. □

Definition R1.6 (Projective limit space)**.** Let (X_j, C_j) be a sequence of Banach spaces and bounded linear maps $C_j : X_{j+1} \to X_j$. Its projective limit is

$$X_\infty = \left\{ (x_j)_{j \ge 0} \in \prod_{j \ge 0} X_j : C_j x_{j+1} = x_j \text{ for every } j \right\}.$$

We equip X_∞ with the subspace topology inherited from the product topology.

Theorem R1.7 (Exact projective limit semigroup). *Suppose each X_j carries a strongly continuous semigroup $(T_j(t))_{t\geq 0}$, and*

$$C_j T_{j+1}(t) = T_j(t) C_j$$

for every j and every $t \geq 0$. Then

$$T_\infty(t)(x_j)_{j\geq 0} = (T_j(t)x_j)_{j\geq 0}$$

defines a strongly continuous semigroup on X_∞.

Proof. Exact intertwining gives

$$C_j T_{j+1}(t) x_{j+1} = T_j(t) C_j x_{j+1} = T_j(t) x_j.$$

Thus the coordinatewise evolution remains in the projective limit. The semigroup law holds in every coordinate. Strong continuity in the product topology follows because every coordinate map

$$t \longmapsto T_j(t)x_j$$

is continuous. □

Corollary R1.8 (Coordinate generators). *Assume the setting of theorem R1.7. If $x = (x_j)$ satisfies $x_j \in \mathrm{Dom}(A_j)$ and the sequence $(A_j x_j)$ belongs to X_∞, then x lies in the generator domain of T_∞ and*

$$A_\infty x = (A_j x_j)_{j\geq 0}.$$

Proof. The difference quotients converge in every coordinate to $A_j x_j$. The assumed compatibility places the coordinatewise limit in X_∞, which is exactly convergence in the product topology. □

The product topology used here differs from the bounded inverse-limit norm of Part II. No uniform boundedness of coordinate generators is required by the coordinatewise statement.

R2 Reversible coarse dynamics

Let Q be a finite Markov generator acting on column probability vectors, let (B_a) be a partition into nonempty blocks, and let $C_{ai} = 1_{i\in B_a}$. Strong lumpability means $CQ = \overline{Q}C$ for a coarse Markov generator. For observables, the backward generator is Q^T. Weighted L^2 inner products use the stated stationary probability.

Theorem R2.1 (Reversibility descends). *Assume Q is strongly lumpable and reversible with respect to a positive stationary distribution π, so*

$$Q_{ij}\pi_j = Q_{ji}\pi_i.$$

Define

$$\overline{\pi}_a = \sum_{i\in B_a} \pi_i.$$

Then $\overline{\pi}$ is stationary for $\overline{Q}$, and

$$\overline{Q}_{ab}\overline{\pi}_b = \overline{Q}_{ba}\overline{\pi}_a.$$

Thus the coarse chain is reversible.

Proof. Stationarity follows from

$$\overline{Q}\overline{\pi} = \overline{Q}C\pi = CQ\pi = 0.$$

For reversibility, use the aggregate rate formula:

$$\begin{aligned}\overline{Q}_{ab}\overline{\pi}_b &= \sum_{j\in B_b}\pi_j \sum_{i\in B_a} Q_{ij} \\ &= \sum_{i\in B_a}\sum_{j\in B_b}\pi_i Q_{ji} \\ &= \overline{Q}_{ba}\overline{\pi}_a.\end{aligned}$$

□

Corollary R2.2 (Coarse Dirichlet form)**.** *Under the hypotheses of theorem R2.1, let Jg be the fine function that is constant with value g_a on B_a. Then*

$$-\left\langle Jg, Q^T Jg\right\rangle_{L^2(\pi)} = -\left\langle g, \overline{Q}^T g\right\rangle_{L^2(\overline{\pi})}.$$

Proof. Expand the left side and group the fine indices by their coarse blocks. The aggregate rate criterion converts the resulting sums into the coarse generator entries. □

R3 Prior-restricted sufficiency and filtering

Let L be a strictly positive finite likelihood and let $\mathcal{B}_L(p) = L \odot p / \langle L, p\rangle$ for a probability vector p. Fix probability vectors $r^{(a)}$ supported on B_a, and restrict the priors to $p_i = q_a r_i^{(a)}$ for $i \in B_a$, with q a coarse probability vector.

Proposition R3.1 (Sufficiency relative to a prior disintegration)**.** *Define*

$$\overline{L}_a = \sum_{i\in B_a} L_i r_i^{(a)}.$$

For every prior in the declared family,

$$C\mathcal{B}_L(p) = \mathcal{B}_{\overline{L}}(q).$$

Proof. The evidence in block B_a is

$$Z_a = q_a \sum_{i\in B_a} L_i r_i^{(a)} = q_a \overline{L}_a.$$

Apply theorem E8.2. □

Lemma R3.2 (Normalization bound). *Let $a, b \in [0,\infty)^m$ be nonzero, and set $A = \|a\|_1$ and $B = \|b\|_1$. Then*

$$\boxed{\|a/A - b/B\|_1 \le \frac{2\,\|a-b\|_1}{\max\{A,B\}}.}$$

Proof. Using A in the denominator gives

$$\|a/A - b/B\|_1 \le \frac{\|a-b\|_1}{A} + \|b\|_1 \,|1/A - 1/B|\,.$$

The second term equals $|B-A|/A$, which is at most $\|a-b\|_1/A$. Interchanging a and b gives the analogous bound with B. Taking the smaller of the two bounds gives the result. □

For an arbitrary prior p, put $q = Cp$ and $Z(p,L) = \langle L, p\rangle$. Define $\ell_a(p) = \sum_{i\in B_a} L_i p_i / q_a$ when $q_a > 0$. Choose any positive value when $q_a = 0$. Only the product $q_a \ell_a(p)$ enters the formulas.

Theorem R3.3 (Exact information loss formula). *For every prior,*

$$\boxed{C\mathcal{B}_L(p) = \mathcal{B}_{\ell(p)}(q).}$$

Let $\overline{L}$ be any fixed positive coarse likelihood and set

$$d(p \mid L, \overline{L}) = \sum_{a=1}^{m} q_a \left|\ell_a(p) - \overline{L}_a\right|.$$

Then

$$\|C\mathcal{B}_L(p) - \mathcal{B}_{\overline{L}}(q)\|_1 \le \frac{2d(p \mid L, \overline{L})}{\max\{Z(p,L), \langle \overline{L}, q\rangle\}}.$$

Proof. The packet evidence in block a is $q_a \ell_a(p)$, which proves the exact identity. Apply lemma R3.2 to

$$a = q \odot \ell(p), \qquad b = q \odot \overline{L}.$$

Their ℓ^1 norms are the two evidences, and $\|a-b\|_1 = d(p \mid L, \overline{L})$. □

Corollary R3.4 (Oscillation bound). *Suppose $\overline{L}_a$ is any representative likelihood for block B_a, and set*

$$\omega_a = \max_{i\in B_a} \left|L_i - \overline{L}_a\right|.$$

Then

$$d(p \mid L, \overline{L}) \le \sum_a q_a \omega_a.$$

Thus small within block likelihood oscillation gives a small coarse posterior defect whenever the evidence is bounded away from zero.

Proof. The conditional average $\ell_a(p)$ lies in the convex hull of the likelihood values inside B_a. Hence

$$\left|\ell_a(p) - \overline{L}_a\right| \le \omega_a.$$

Multiply by q_a and sum. □

Along the Bayesian flow $p_i(t) = e^{tg_i}p_i(0)/\sum_j e^{tg_j}p_j(0)$, the following statement holds for every real observable h.

Corollary R3.5 (Covariance identity). *For any observable $h \in \mathbb{R}^n$,*

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}_{p(t)}[h] = \mathrm{Cov}_{p(t)}(h, g).$$

In particular,

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}_{p(t)}[g] = \mathrm{Var}_{p(t)}(g) \geq 0.$$

Proof. Differentiate $\sum_i h_i p_i(t)$ and insert the replicator equation. □

For stochastic matrices $K, \overline{K}$ and positive likelihoods $L_y, \overline{L}_y$, put $\Phi_y = \mathcal{B}_{L_y} \circ K$ and $\overline{\Phi}_y = \mathcal{B}_{\overline{L}_y} \circ \overline{K}$.

Theorem R3.6 (Exact coarse hidden Markov filter). *Assume*

$$CK = \overline{K}C$$

and every likelihood L_y is constant on each coarse block with block values $\overline{L}_y$. Then

$$C\Phi_y(p) = \overline{\Phi}_y(Cp)$$

for every prior. For any observation sequence $y_1, \dots, y_r$, the complete filtering recursion commutes with aggregation:

$$C\Phi_{y_r} \circ \cdots \circ \Phi_{y_1} = \overline{\Phi}_{y_r} \circ \cdots \circ \overline{\Phi}_{y_1} C.$$

Proof. Exact Markov lumping gives $CKp = \overline{K}Cp$. The Bayesian sufficiency criterion gives exact commutation of the update. Their composition proves the one step identity. Iterate it over the observation sequence. □

Theorem R3.7 (One step filter defect). *Let $r = Kp$, $q = Cr$, and let $\ell_y(r)$ be the exact coarse likelihood obtained by averaging L_y inside each block with respect to r. Assume*

$$0 < \overline{m} \leq (\overline{L}_y)_a \leq \overline{M}.$$

Then

$$\left\|C\Phi_y(p) - \overline{\Phi}_y(Cp)\right\|_1 \leq \frac{2d(r \mid L_y, \overline{L}_y)}{\max\{\langle L_y, r\rangle, \langle \overline{L}_y, q\rangle\}} + \frac{2\overline{M}}{\overline{m}}\left\|CKp - \overline{K}Cp\right\|_1.$$

Proof. Insert the intermediate posterior $\mathcal{B}_{\overline{L}_y}(CKp)$. The first difference is bounded by theorem R3.3. The second is bounded by theorem E8.4 applied to the coarse likelihood. □

R4 Fractional modes and killed transfer

For the one-dimensional Dirichlet difference operator, let $h = 1/M$ with an integer $M \geq 2$, let $1 \leq k \leq M-1$, and set $\lambda_{k,h} = 4h^{-2}\sin^2(k\pi h/2)$. The retained explicit coefficient below is valid for every discrete mode.

Corollary R4.1 (Fractional low mode dispersion). *Let $0 < \alpha \leq 1$. Then*

$$0 \leq (k\pi)^{2\alpha} - \lambda_{k,h}^{\alpha} \leq \frac{\alpha(4k^2)^{\alpha-1}(k\pi)^4}{12}h^2.$$

For every $t \geq 0$,

$$\left|\mathrm{e}^{-t\lambda_{k,h}^{\alpha}} - \mathrm{e}^{-t(k\pi)^{2\alpha}}\right| \leq \frac{t\alpha(4k^2)^{\alpha-1}(k\pi)^4}{12}h^2.$$

Proof. The chord bound $\sin x \geq 2x/\pi$ on $[0, \pi/2]$ gives $\lambda_{k,h} \geq 4k^2$. Since $x \mapsto x^{\alpha}$ is increasing and has decreasing derivative,

$$(k\pi)^{2\alpha} - \lambda_{k,h}^{\alpha} \leq \alpha\lambda_{k,h}^{\alpha-1}((k\pi)^2 - \lambda_{k,h}).$$

Use theorem E12.5 and the lower bound for $\lambda_{k,h}$. The exponential estimate follows from

$$\left|\mathrm{e}^{-ta} - \mathrm{e}^{-tb}\right| \leq t\,|a-b|$$

for nonnegative a and b. □

Let Q and $\overline{Q}$ be finite Markov generators in the column convention. All times in this section satisfy $t \geq 0$.

Theorem R4.2 (Potential perturbation bound). *Let V and W be nonnegative diagonal matrices. In the supremum norm,*

$$\boxed{\left\|\mathrm{e}^{t(Q^T-V)} - \mathrm{e}^{t(Q^T-W)}\right\|_{\infty\to\infty} \leq t\,\|V-W\|_{\infty\to\infty}.}$$

Proof. Both killed Markov semigroups are contractions in the supremum norm. Apply the Duhamel identity with generator defect $W - V$. □

Theorem R4.3 (Coarse Feynman–Kac transfer). *Assume $CQ = \overline{Q}C$, and let $J = C^T$ lift a coarse function to the corresponding block constant fine function. Suppose the potential is block constant, so*

$$VJ = J\overline{V}.$$

Then

$$\boxed{\mathrm{e}^{t(Q^T-V)}J = J\mathrm{e}^{t(\overline{Q}^T-\overline{V})}}$$

for every $t \geq 0$.

Proof. Transpose the Markov intertwining relation to obtain

$$Q^TJ = J\overline{Q}^T.$$

Together with $VJ = J\overline{V}$, this gives

$$(Q^T - V)J = J(\overline{Q}^T - \overline{V}).$$

The exponential intertwining follows from the power series. □

R5 Memory compression, rational realization, and phase-type consequences

Fix $T > 0$. For the next estimate let A be a bounded operator on a Banach space X, let $\mathcal{K}, \widetilde{\mathcal{K}} \in L^1((0,T), \mathcal{B}(X))$, and let f be continuous. Take continuously differentiable solutions of the displayed equations. This direct bounded-generator estimate retains a sharper exponential constant than the general mild-semigroup estimate in Part II.

Theorem R5.1 (Stability of memory compression). *Let x and $\tilde{x}$ solve*

$$\dot{x}(t) = Ax(t) + \int_0^t \mathcal{K}(t-s)x(s)\,\mathrm{d}s + f(t)$$

and

$$\dot{\tilde{x}}(t) = A\tilde{x}(t) + \int_0^t \widetilde{\mathcal{K}}(t-s)\tilde{x}(s)\,\mathrm{d}s + f(t)$$

with the same initial value. Fix $T > 0$, and assume

$$\sup_{0\le t\le T} \|\tilde{x}(t)\| \le M.$$

Set

$$a = \|A\|, \qquad k = \|\mathcal{K}\|_{L^1(0,T)}, \qquad \delta = \left\|\mathcal{K} - \widetilde{\mathcal{K}}\right\|_{L^1(0,T)}.$$

Then

$$\boxed{\sup_{0\le t\le T} \|x(t) - \tilde{x}(t)\| \le MT\delta \mathrm{e}^{(a+k)T}.}$$

Proof. Let $e = x - \tilde{x}$. Integrating the difference equation and changing the order of integration gives

$$\|e(t)\| \le (a+k)\int_0^t \|e(r)\|\,\mathrm{d}r + Mt\delta.$$

Since $t \le T$, Gronwall's inequality gives

$$\|e(t)\| \le MT\delta \mathrm{e}^{(a+k)t}.$$

Take the supremum over $[0,T]$. □

For the exact closure criterion of Part II, allowing an arbitrary bounded local generator B does not enlarge the class: differentiating $Pe^{tA}P = e^{tB}P$ at $t = 0$ forces $B = A_{PP}$ on the retained space. Thus its zero-memory criterion excludes every alternative bounded local generator.

A finite auxiliary realization of a matrix kernel means $\mathcal{K}(t) = Be^{tD}C$, with finite matrices of compatible sizes. Laplace transforms are taken in a right half-plane of absolute convergence. The rational characterization concerns continuous kernels of exponential order, so uniqueness of the ordinary Laplace transform applies.

Theorem R5.2 (Rational memory realization)**.** *A matrix valued memory transform has a finite auxiliary realization if and only if it is a strictly proper rational matrix function. More precisely,*

$$\boxed{\widehat{\mathcal{K}}(z) = B(zI - D)^{-1}C}$$

if and only if

$$\boxed{\mathcal{K}(t) = B\mathrm{e}^{tD}C.}$$

Proof. The forward implication follows by taking the Laplace transform. The resulting matrix is rational and tends to zero as z tends to infinity.

Conversely, decompose every entry of a strictly proper rational matrix into partial fractions. A term

$$\frac{c}{(z-\lambda)^r}$$

is an entry of the resolvent of an r by r Jordan block with eigenvalue λ. Taking a direct sum of these blocks and choosing the input and output maps entry by entry gives matrices B, D, C with the required resolvent. Inverse Laplace transformation gives the time domain formula. □

Corollary R5.3 (Exponential sum memory)**.** *If*

$$\mathcal{K}(t) = \sum_{j=1}^{m} B_j \mathrm{e}^{\lambda_j t} C_j,$$

then $\mathcal{K}$ has a finite auxiliary realization with one auxiliary block for each exponential. Repeated poles produce polynomial factors in t and are realized by Jordan blocks.

Proof. If B_j and C_j have an intermediate space of dimension d_j, use a block diagonal matrix D with blocks $\lambda_j I_{d_j}$, or the required Jordan blocks when poles repeat. Assemble the matrices B_j and C_j into the output and input maps. □

For the survival consequences, A is a finite Metzler matrix with nonpositive column sums and spectrum in the open left half-plane, p_0 is a probability vector, $S(t) = 1^T e^{tA} p_0$, and $f(t) = -S'(t)$. The one-phase model has $\lambda > 0$. The survival Laplace identity of Part II also holds for every complex s with $\operatorname{Re} s \geq 0$: stability gives absolute convergence of $\int_0^\infty e^{-st} e^{tA}\, dt = (sI - A)^{-1}$, and multiplying by the exit row and p_0 gives the same transform.

Corollary R5.4 (Phase type rationality)**.** *The Laplace transform of every finite phase type distribution is rational. If A is diagonalizable, then $S(t)$ and $f(t)$ are finite linear combinations of exponential functions. Jordan blocks add polynomial factors in t.*

Proof. The resolvent $(sI - A)^{-1}$ is rational. The time domain statement follows from the Jordan form of A. □

Corollary R5.5 (One phase model). *If $A = (-\lambda)$ and $p_0 = 1$, then*

$$S(t) = \mathrm{e}^{-\lambda t}, \qquad f(t) = \lambda \mathrm{e}^{-\lambda t}, \qquad h(t) = \lambda.$$

Proof. Insert the scalar generator into theorem E16.2. □

R6 Additional exact examples

These five examples use numerical parameters distinct from the visual studies.

Example R6.1 (One transfer between two packets). Let

$$A = \begin{pmatrix} a & 0 \\ c & b \end{pmatrix}$$

and let the two coordinate axes be the packet spaces. If $a \neq b$, then

$$\mathrm{e}^{tA} = \begin{pmatrix} \mathrm{e}^{at} & 0 \\ c\dfrac{\mathrm{e}^{at} - \mathrm{e}^{bt}}{a - b} & \mathrm{e}^{bt} \end{pmatrix}.$$

The lower left block is produced by one transfer from the first packet to the second. Its expansion begins with ct, in agreement with corollary R1.3. When $a = b$, the same block is $ct\mathrm{e}^{at}$.

Example R6.2 (A four state lumpable chain). Partition four states into $B_1 = \{1, 2\}$ and $B_2 = \{3, 4\}$. For positive rates a, b, u, v, set

$$Q = \begin{pmatrix} -u - a & u & b/2 & b/2 \\ u & -u - a & b/2 & b/2 \\ a/2 & a/2 & -v - b & v \\ a/2 & a/2 & v & -v - b \end{pmatrix}.$$

The rates u and v move inside the coarse blocks. Every state in B_1 leaves for B_2 at total rate a, and every state in B_2 leaves for B_1 at total rate b. Hence

$$\overline{Q} = \begin{pmatrix} -a & b \\ a & -b \end{pmatrix}$$

and $CQ = \overline{Q}C$. The internal rates disappear from the coarse generator even though they remain present in the fine evolution.

Example R6.3 (A visible likelihood loss). Let $B_1 = \{1, 2\}$, let $B_2 = \{3\}$, and take

$$p = (3/10, 2/10, 5/10), \qquad L = (1, 3, 2).$$

The coarse prior is $(1/2, 1/2)$. The exact block likelihoods are

$$\ell_1(p) = \frac{(3/10) + 3(2/10)}{1/2} = \frac{9}{5}, \qquad \ell_2(p) = 2.$$

Thus the exact coarse posterior is $(9/19, 10/19)$. If the first block is replaced by the fixed representative value 2, the approximate coarse posterior is $(1/2, 1/2)$. The ℓ^1 defect is $1/19$, while theorem R3.3 gives the valid upper bound $1/10$.

Example R6.4 (One hidden mode)**.** Consider

$$A = \begin{pmatrix} -a & c \\ d & -b \end{pmatrix}, \qquad a, b > 0,$$

and retain the first coordinate. The memory kernel and self-energy are

$$\mathcal{K}(t) = cd\mathrm{e}^{-bt}, \qquad \Sigma(z) = \frac{cd}{z+b}.$$

The retained coordinate has an exact time local closure for every retained initial value precisely when $cd = 0$. When $cd \neq 0$, one auxiliary scalar state realizes the memory exactly.

Example R6.5 (Two sequential phases)**.** Let

$$A = \begin{pmatrix} -\lambda & 0 \\ \lambda & -\mu \end{pmatrix}, \qquad p_0 = \begin{pmatrix} 1 \\ 0 \end{pmatrix},$$

where $\lambda \neq \mu$ are positive. The first phase moves to the second at rate λ, and the second is absorbed at rate μ. Direct calculation gives

$$S(t) = \frac{\mu\mathrm{e}^{-\lambda t} - \lambda\mathrm{e}^{-\mu t}}{\mu - \lambda},$$

$$f(t) = \frac{\lambda\mu}{\mu - \lambda}\left(\mathrm{e}^{-\lambda t} - \mathrm{e}^{-\mu t}\right).$$

The ratio $f(t)/S(t)$ is generally not constant. A time local Markov model on two transient phases can therefore produce a nonconstant hazard after the phase coordinate is hidden.

R7 Holomorphic operator substitution

> **A route through this section**
>
> The scalar function, zero-free domain, and logarithm branch are fixed before substituting an operator. The bounded Banach-space functional calculus here is separate from the finite canonical-jet contract of Part I. Keep those spaces and hypotheses visible when using the reciprocal family.

This section presents the operator-substitution result transferred from Chapter IV. Fix an integer $N \geq 1$ and the entire scalar function

$$\mathsf{D}_N(z) = \sum_{m=0}^{\infty} \frac{(-1)^m z^{Nm}}{(Nm)!}.$$

More generally, the result applies to any specified holomorphic scalar function that is nonzero on the declared domain. On a simply connected zero-free domain U, choose $g = \log \mathsf{D}_N$ once and define $\mathsf{S}_N^{(r)}(z) = \exp(-rg(z))$ for complex r. The bounded Banach-space result below uses classical holomorphic functional calculus. It is separate from the finite canonical-jet calculus formalized in Part I.

Standard Fact R7.1 (Holomorphic functional calculus). Let A be a bounded operator on a complex Banach space. If f is holomorphic on a neighborhood of $\mathrm{Spec}(A)$, then

$$f(A) = \frac{1}{2\pi i} \int_\Gamma f(z)(zI - A)^{-1}\, dz$$

for an admissible positively oriented contour Γ lying in the holomorphy domain and the resolvent set, with winding number one about the spectrum and zero outside the domain. The calculus preserves sums, products, and composition. We use the standard form from [DS58]. An accessible proof is given in [Tay, Appendix A].

Proposition R7.2 (Operator reciprocal family)**.** *Let A be bounded and suppose $\mathrm{Spec}(A)$ lies in a simply connected region on which D_N has no zeros. Fix a holomorphic branch $g = \log \mathsf{D}_N$ there. Then*

$$\mathsf{S}_N^{(r)}(A) = \exp(-rg(A)) = (\mathsf{D}_N^{-r})(A)$$

is well defined and

$$\mathsf{S}_N^{(r)}(A)\mathsf{S}_N^{(s)}(A) = \mathsf{S}_N^{(r+s)}(A).$$

If (P_i) is a finite complete family of bounded idempotents, then

$$P_i f(A) P_j = \frac{1}{2\pi i} \int_\Gamma f(z) P_i (zI - A)^{-1} P_j\, dz$$

for every holomorphic f on a neighborhood of the spectrum.

Proof. The spectral mapping theorem makes $\mathsf{D}_N(A)$ invertible. The product identity follows from multiplicativity of the functional calculus and the fixed logarithm. Applying P_i and P_j to the Cauchy integral formula gives the packet formula. □

How to use this volume

The guide follows small models whose matrices, probability laws, and transfer formulas can be calculated explicitly. The traditional volume supplies the general arguments. The formal companion records a separate formal contract.

Routes through the guide

Plates VI.1 through VI.42 identify worked pages independently of PDF pagination. The references on Plates VI.1–VI.28 use the theorem numbering of Traditional Part I. References from Plate VI.29 onward name the corresponding strengthened result in Traditional Part II. These references distinguish preserved manuscript branches rather than merging their result counts.

Route	Mathematical question	Plates
Complete transfer	Which coordinates and modes reconstruct the same evolution?	1–6, 29
Probability and evidence	What survives averaging, aggregation, or an observation?	7–14, 26, 32, 34–36
Spectral evolution	How do rates, gaps, fractional clocks, and Gaussian modes interact?	15–17, 25, 33, 41
Green and path formulas	How do grid units and weighting conventions enter?	18–20
Eliminating hidden states	What memory returns, and how can it be compressed?	21–24, 37–40
Passing to limits	What additional conditions give convergence and closure?	27, 30–31
Evidence	Which calculations and formal records support which claims?	28, 42

Three distinctions to keep visible

A coordinate decomposition retains the whole vector if all components are kept. An aggregation map usually loses information. Elimination recovers exact retained dynamics only after adding a memory term and any hidden-state initial forcing.

An exact example checks its stated finite model. A theorem provides an argument under quantified assumptions. A Lean record certifies its declared formal statement under the recorded environment. None of these automatically certifies the other two.

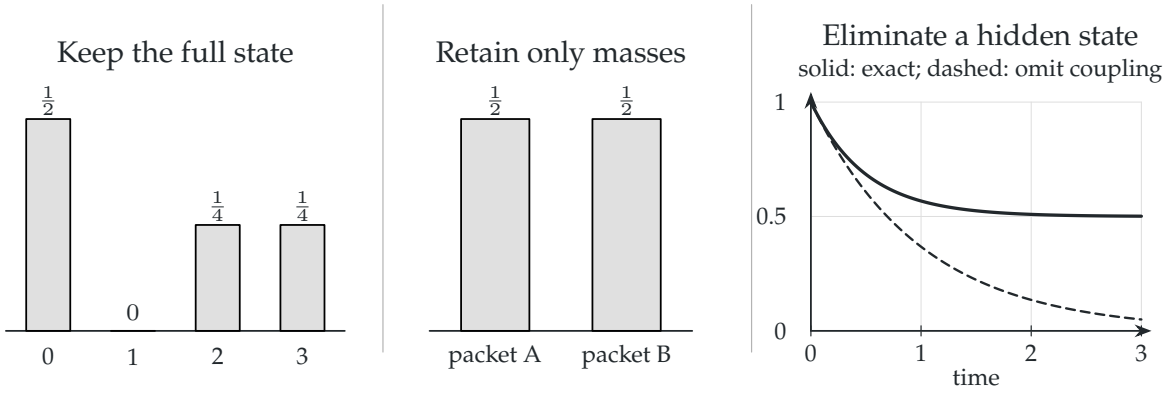
Mathematical coverage

The first twenty-eight worked pages develop the finite models. Fourteen further pages connect them to the extended results. Forty editable vector figures illustrate these constructions. Their source files and retained generation records accompany the mathematical text and its formal correspondence.

The inherited formal baseline records 33 scoped results, 341 supporting theorem declarations, and 47 proof modules. The strengthened traditional branch is a separate collection of written proofs. Its broader content is not added to the formal denominator.

Traditional Part III retains complementary results with an R prefix: reversibility and Dirichlet forms (R2), prior disintegrations and filtering (R3), potential perturbation and coarse Feynman–Kac transfer (R4), and finite realizations (R5). Related models appear on Plates VI.5–VI.8, Plate VI.11, Plate VI.13, Plate VI.20, Plate VI.26, and Plates VI.39–VI.40. The bounded-operator reciprocal result migrated from Chapter IV is R7.2. Plate VI.25 and Plate VI.41 explain related finite matrix calculus. These models do not replace the supplementary hypotheses.

Read this as: Choose a question, work through its small model, then check the hypotheses in the corresponding traditional proof and formal contract.



Part IV Worked visual atlas

Plate VI.1 / PAPER VI / A WORKED VISUAL ATLAS

Three ways to reduce a model

Chapter VI, Part I: Sections 1–3, 8, and 13. Read the three operations separately.

This guide follows small objects that can be computed completely. A four-state chain connects packet transfer, Markov aggregation, and Bayesian conditioning. A two-state coupled evolution exposes memory. A three-node Dirichlet problem makes the Green-operator normalization visible. These models are related by the chapter's language, not by pretending that their state spaces are identical.

Left and center use one probability vector and its two block masses. The right panel is a separate retained/hidden model, developed on Plate VI.22. Every curve is drawn from an explicit formula.

Coordinates retain, aggregation forgets, and elimination remembers

Keeping every component $P_a x$ is an exact change of representation when $\sum_a P_a = I$. Reconstruct by summing the components. In contrast, replacing (p_0, p_1, p_2, p_3) by $(p_0 + p_1, p_2 + p_3)$ forgets how mass was distributed inside either pair. That information can matter for later observations.

Eliminating a hidden state is different again. Its coordinates disappear from the displayed state, but the exact retained equation acquires a history integral. Simply deleting the coupling produces the dashed curve above, not the original evolution.

Question	Worked route	Plates
When is coarse evolution exact?	Aggregate columns, then test intertwining.	VI.4–VI.6
When is a coarse posterior exact?	Compare two hidden shapes with the same masses.	VI.9–VI.13
What changes under a fractional power?	Keep modes, change spectral rates.	VI.15–VI.17
What returns after elimination?	Compute the self-energy and memory kernel.	VI.21–VI.25

Read this as: The chapter supplies exact identities and conditional bounds. Whether a particular coarse model satisfies their hypotheses is a separate calculation.

Plate VI.2 / READ BEFORE MULTIPLYING / CONVENTIONS

A dictionary with orientations

Chapter VI, Part I: Sections 2, 4, 6, 7, and 12. Column probabilities and backward observables.

An apparent disagreement between two transfer formulas often comes from acting on different objects. Throughout this guide, probabilities are columns and observables are functions written as columns. Their pairing is $f^{\mathsf{T}}p$. The transpose distinguishes the forward action on distributions from the backward action on observations.

Object	Exact meaning	What to check
p	A nonnegative column with $\mathbf{1}^{\mathsf{T}}p = 1$.	It is not a vector of function values.
Q	Continuous Markov generator.	Off-diagonal entries are nonnegative and columns sum to zero.
K	One discrete stochastic step.	$\mathbf{1}^{\mathsf{T}}K = \mathbf{1}^{\mathsf{T}}$ and $K_{ij} \geq 0$.
$K^{\mathsf{T}}f$	Expected next observable given the current state.	The same dynamics, with the opposite action on the dual object.
P_a	A coordinate packet projector.	All packets together reconstruct the full state.
C	Sums fine probability masses into coarse blocks.	Usually rectangular and not invertible.
E_π	Conditional expectation of observables.	A weighted average, self-adjoint for the π inner product.
$\mathcal{B}_\lambda$	$\operatorname{diag}(\lambda)p/(\lambda^{\mathsf{T}}p)$.	Nonnegative likelihood and positive total evidence.
L	A nonnegative self-adjoint operator.	Its evolution is e^{-tL}, not e^{tL}.
$R(z)$	$(zI - A)^{-1}$.	z belongs to the resolvent set.
$\mathcal{K}(t)$	The memory kernel after hidden-state elimination.	It is not the transition matrix K.

One convention test

For

$$K_2 = \begin{pmatrix} 3/4 & 1/4 \\ 1/4 & 3/4 \end{pmatrix}, \qquad p = e_0, \qquad f = (2,1)^{\mathsf{T}},$$

we obtain $K_2 p = (3/4, 1/4)^{\mathsf{T}}$ and

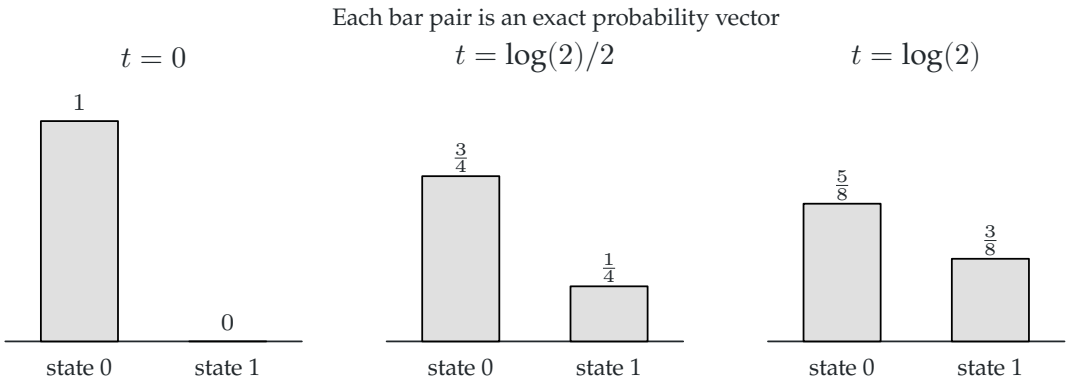
$$f^{\mathsf{T}}K_2 p = 7/4 = (K_2^{\mathsf{T}}f)_0.$$

With departure weights $w_i = e^{-V(i)}$, the backward Feynman–Kac operator is $\operatorname{diag}(w)K_2^{\mathsf{T}}$. Its forward dual is $K_2 \operatorname{diag}(w)$. Interchanging these factors changes when the weight is applied.

> **Read this as:** Always name the object being transported. The transpose and the position of the likelihood or potential are mathematical choices, not typographic details.

Plate VI.3 / CONTINUOUS TRANSFER / THE ENTIRE SOLUTION

A clock generated by one matrix



Chapter VI, Part I: Theorems 1.2 and 4.1. Finite matrix exponentials and Markov positivity.

Take the generator

$$G = \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}.$$

The total-mass direction $(1, 1)$ has eigenvalue zero. The contrast $(1, -1)$ has eigenvalue -2. Resolving those two directions gives the full transfer, not only its first-order approximation:

$$T(t) = e^{tG} = \frac{1}{2}\begin{pmatrix} 1 + e^{-2t} & 1 - e^{-2t} \\ 1 - e^{-2t} & 1 + e^{-2t} \end{pmatrix}.$$

A point seed at state zero approaches the uniform distribution. The displayed times were selected so that every bar label is rational. This is continuous-time evolution, not a simulated trajectory.

Two checks explain the mechanism

The constant mode is unchanged, while each elapsed interval multiplies the contrast by e^{-2t}. Consequently two intervals multiply their contrast factors:

$$e^{-2s}e^{-2t} = e^{-2(s+t)}, \qquad T(s)T(t) = T(s+t).$$

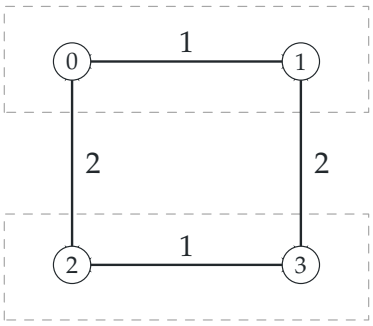
For $t \geq 0$, the entries are nonnegative and every column sums to one. Differentiation gives $T'(t) = GT(t)$. These three facts separately check the initial condition, the evolution equation, and preservation of probability.

At $t = \log 2$, the retained first coordinate is $5/8$. It would instead be $1/2$ under the isolated scalar equation $\dot{x} = -x$. The discrepancy is the mass that can leave state zero and return. On Plate VI.22, we remove the second coordinate correctly and recover exactly the same $5/8$ using a memory integral.

> **Read this as:** The semigroup lives on the complete state. One diagonal entry of a semigroup need not itself satisfy a scalar semigroup law.

Plate VI.4 / FOUR-STATE MODEL / COORDINATES AND MODES

One evolution, two packet choices



Chapter VI, Part I: Theorem 2.1, Corollary 2.2, and the packet path expansion.

Our main finite model has generator

$$Q = \begin{pmatrix} -3 & 1 & 2 & 0 \\ 1 & -3 & 0 & 2 \\ 2 & 0 & -3 & 1 \\ 0 & 2 & 1 & -3 \end{pmatrix}.$$

The graph shows rates between actual states. The four normalized sign vectors on the right form an orthonormal basis u_j. Their projectors $P_j = u_j u_j^{\mathsf{T}}$ sum to the identity and satisfy $P_i P_j = 0$ for $i \neq j$.

Off-diagonal rates of Q

Top pair A; bottom pair B

Mode signs (each divided by 2)

	0	1	2	3	rate
constant	1	1	1	1	0
within	1	−1	1	−1	−2
between	1	1	−1	−1	−4
mixed	1	−1	−1	1	−6

State coordinates have off-diagonal transfers. Spectral packets reduce the generator and evolve independently. The two dashed state groups are the coarse partition used next.

The same evolution has a closed formula

Writing $q = e^{-2t}$ gives

$$e^{tQ} = P_0 + qP_1 + q^2 P_2 + q^3 P_3.$$

At $q = 1/2$, the point seed e_0 becomes $(15, 5, 9, 3)^{\mathsf{T}}/32$. The polynomial identity $T(q)T(r) = T(qr)$ checks composition exactly, without numerical matrix exponentiation.

Any other complete packet family still has exact block convolution. For the coordinate groups A and B,

$$P_b e^{(s+t)Q} P_a = \sum_{c \in \{\mathrm{A},\mathrm{B}\}} (P_b e^{sQ} P_c)(P_c e^{tQ} P_a).$$

The intermediate packet cannot generally be omitted. Only a reducing family eliminates all cross terms.

For later discrete calculations define $K = I + Q/8$. This matrix is stochastic, but *it is not* $e^{Q/8}$. It is the step kernel in the uniformization identity $e^{tQ} = e^{-8t} \sum_{n \geq 0} (8t)^n K^n / n!$.

> **Read this as:** Changing packet coordinates does not change the evolution. Replacing continuous time by one discrete step does.

Plate VI.5 / EXACT LUMPABILITY / AGGREGATE COLUMNS

When two states are truly equivalent

Chapter VI, Part I: Theorem 5.1. The hypothesis is an intertwining identity.

Group states $0, 1$ into A and states $2, 3$ into B. The aggregation map and the candidate coarse kernel are

$$C = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix}, \qquad \bar{K} = \begin{pmatrix} 3/4 & 1/4 \\ 1/4 & 3/4 \end{pmatrix}.$$

A fine state in A has probability $1/4$ of entering B in one step, regardless of which fine state in A was occupied. The analogous statement holds for B.

$8K$

	0	1	2	3
0	5	1	2	0
1	1	5	0	2
2	2	0	5	1
3	0	2	1	5

CK: aggregate transition columns

	0	1	2	3
A	$\frac{3}{4}$	$\frac{3}{4}$	$\frac{1}{4}$	$\frac{1}{4}$
B	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{4}$

$$\bar{K} = \begin{pmatrix} 3/4 & 1/4 \\ 1/4 & 3/4 \end{pmatrix}$$

Fine trajectories differ. Coarse predictions agree.

Columns 0 and 1 agree; columns 2 and 3 agree.

The fine columns are visibly different. Their sums over each target packet agree within each source packet. That equality is the reason a two-state description works.

A one-step calculation controls every discrete horizon

The displayed columns give $CK = \bar{K}C$. Multiplication then yields

$$CK^n = \bar{K}^n C \qquad (n \geq 0).$$

For example, e_0 and e_1 have the same coarse initial vector $(1, 0)^{\mathsf{T}}$. Their fine evolutions differ, but their coarse vectors agree at every step. No choice of the within-A conditional distribution is needed for the prediction.

The continuous generator also closes:

$$CQ = \bar{Q}C, \qquad \bar{Q} = \begin{pmatrix} -2 & 2 \\ 2 & -2 \end{pmatrix}.$$

The Duhamel identity therefore gives $Ce^{tQ} = e^{t\bar{Q}}C$. This is a second consequence of the corresponding generator identity, not an inference that K is a fixed-time sample of Q.

Aggregation is still not invertible. The theorem says the discarded details are irrelevant for *these predictions*. It does not say they are irrelevant to every later likelihood. The observation counterexample on Plate VI.10 uses this exact same partition.

> **Read this as:** A partition is not automatically a valid Markov model. The aggregate transition columns must be constant within each source block.

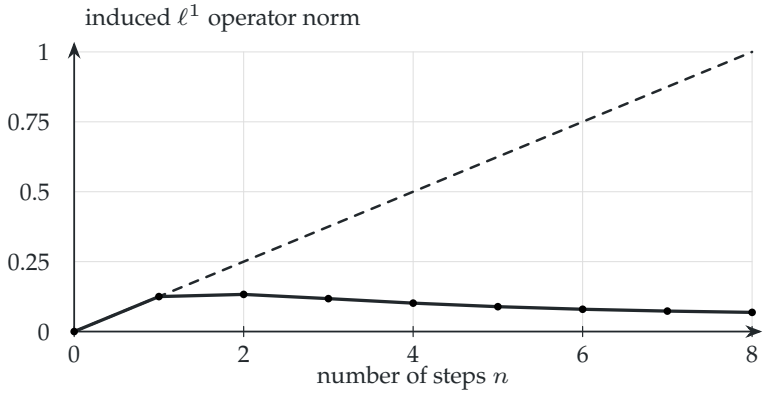


Plate VI.6 / DEFECTS / A GUARANTEE WITHOUT A FIT

A broken lump and its error budget

Chapter VI, Part I: Theorems 3.1, 3.3, and 5.2. Continuous and discrete defect identities.

Modify only column zero of K: move $1/16$ of its mass from target state zero to target state two. The perturbed matrix K_ε remains stochastic, but its aggregate column now differs from column one. Relative to the unchanged coarse kernel,

$$\Delta = CK_\varepsilon - \bar{K}C = \begin{pmatrix} -1/16 & 0 & 0 & 0 \\ 1/16 & 0 & 0 & 0 \end{pmatrix}, \qquad \|\Delta\|_1 = 1/8.$$

$\|\Delta\|_1 = 1/8$

solid: exact defect
dashed: $n/8$

The bound is a guarantee, not a fitted trend.

The solid values are computed with rational matrix powers. The dashed certificate uses only stochasticity and the exact one-step defect. It need not be sharp.

Telescoping tells us where every error originates

For $n \geq 0$,

$$CK_\varepsilon^n - \bar{K}^n C = \sum_{j=0}^{n-1} \bar{K}^{n-1-j} \Delta K_\varepsilon^j.$$

Each summand propagates one defect between an earlier fine evolution and a later coarse evolution. Column-stochastic matrices have induced ℓ^1 norm one, so the norm is at most $n/8$. The empty sum at $n = 0$ is zero.

The continuous counterpart is equally explicit. With fine generator -1, coarse generator -2, and $C = 1$, the generator defect is 1 and

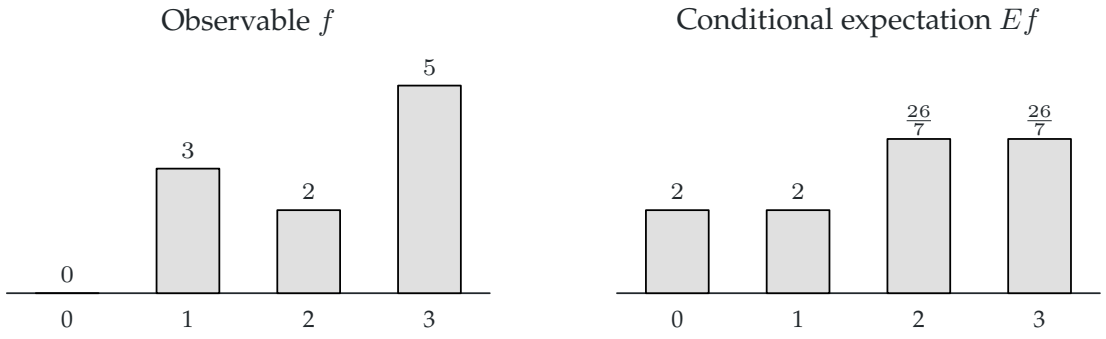
$$e^{-t} - e^{-2t} = \int_0^t e^{-2(t-r)} e^{-r}\, dr.$$

Its resolvent version is $1/(z+1) - 1/(z+2) = 1/((z+1)(z+2))$ for $z > 0$.

Read this as: A small defect does not disappear. The identity specifies how it accumulates, and the norm assumptions turn that identity into a finite-horizon certificate.

Plate VI.7 / OBSERVABLES / WEIGHTED ORTHOGONALITY

Averaging is not summing



Chapter VI, Part I: Theorem 6.1. Strictly positive weights are part of the setting.

For this observable example, choose the fixed probability weights $\pi = (1, 2, 3, 4)/10$. They are not being identified with the stationary law of the earlier symmetric chain. On the same two-block partition, conditional expectation is

$$E = \begin{pmatrix} 1/3 & 2/3 & 0 & 0 \\ 1/3 & 2/3 & 0 & 0 \\ 0 & 0 & 3/7 & 4/7 \\ 0 & 0 & 3/7 & 4/7 \end{pmatrix}.$$

It replaces function values by their *weighted block average*. In particular, $f = (0, 3, 2, 5)^{\mathsf{T}}$ becomes $Ef = (2, 2, 26/7, 26/7)^{\mathsf{T}}$.

Weights $\pi = (1, 2, 3, 4)/10$; the block values are 2 and $26/7$.

The bars are function values, not state probabilities. Their total need not be one. The block masses $3/10$ and $7/10$ determine the denominators in the averaging formula.

Which inner product makes this an orthogonal projection?

Put $W = \mathrm{diag}(\pi)$. Direct multiplication checks

$$E^2 = E, \qquad WE = E^{\mathsf{T}}W, \qquad E\mathbf{1} = \mathbf{1}.$$

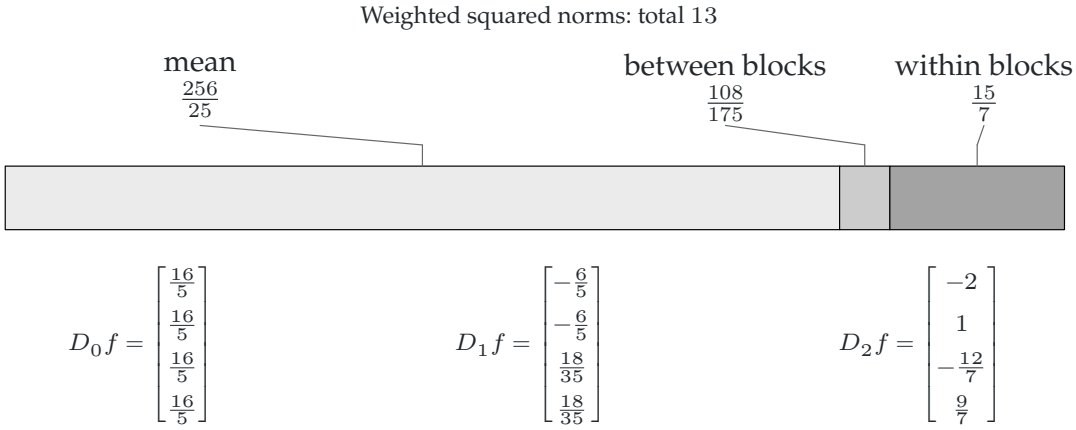
The middle equation is weighted self-adjointness. Ordinary symmetry fails: $E_{01} = 2/3$ whereas $E_{10} = 1/3$. Testing $E = E^{\mathsf{T}}$ would therefore reject a correct conditional-expectation projector.

The range consists exactly of functions constant on each block. The error $f - Ef$ has weighted mean zero inside every block, so it is weighted-orthogonal to every block-constant function. This is the finite projection interpretation of conditional expectation.

In contrast, C acts on probability columns by summing masses. The shapes of C and E differ, and their domains have different interpretations. The notation "coarsening" alone does not specify which operation is intended.

> **Read this as:** An exact weighted projector can be oblique in the unweighted Euclidean picture. Keep the measure and the inner product in the model.

Plate VI.8 / MARTINGALE PACKETS / THREE EXACT PIECES



Where the variance goes

Chapter VI, Part I: Theorem 6.2. Nested weighted projections and their differences.

Keep the weights and observable from Plate VI.7. Let $E_0 f$ be the constant global mean, let $E_1 = E$ average within A and B, and let $E_2 = I$ retain every value. Define

$$D_0 = E_0, \qquad D_1 = E_1 - E_0, \qquad D_2 = I - E_1.$$

Then $D_0 f$ is the mean, $D_1 f$ describes the contrast between block means, and $D_2 f$ is the fluctuation left inside each block.

The strip lengths are proportional to the three exact weighted energies. The between-block component is small but not zero. The vectors below specify the corresponding directions, not only their sizes.

The energy identity follows from actual orthogonality

The tower identities give $E_0 E_1 = E_1 E_0 = E_0$. Together with weighted self-adjointness, these imply

$$D_i D_j = 0 \ (i \neq j), \qquad \sum_{j=0}^{2} D_j = I.$$

For the chosen f, the total weighted energy is $\|f\|_\pi^2 = 13$ and the mean is $16/5$. Consequently

$$\mathrm{Var}_\pi(f) = 13 - \left(\frac{16}{5}\right)^2 = \frac{69}{25} = \frac{108}{175} + \frac{15}{7}.$$

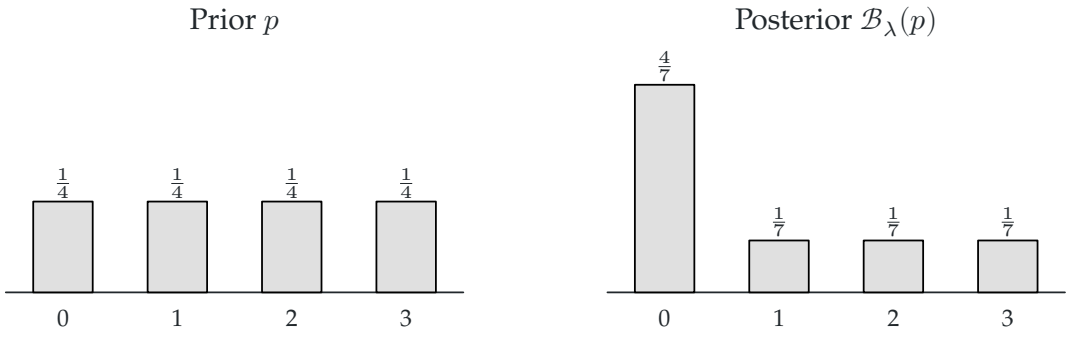
The first term is the energy of the between-block contrast, and the second is the weighted within-block variance. This is a decomposition of one observable in one fixed weighted space.

Changing the probability weights between levels would change the inner products and the averaging operators. The displayed orthogonal decomposition would no longer follow merely from nesting the sets. Likewise, choosing unrelated projections can preserve the telescope $\sum D_j = I$ while losing orthogonality and the energy sum.

> **Read this as:** The differences between nested conditional expectations are not just bookkeeping. They are orthogonal, separately measurable parts of the original signal.

Plate VI.9 / BAYESIAN TRANSFER / AN EXACT POSTERIOR

Evidence changes shape and mass



Chapter VI, Part I: Theorems 7.1–7.3. Normalization, packet reconstruction, and positive evidence.

Start with $p = (1,1,1,1)^{\mathsf{T}}/4$ and likelihood weights $\lambda = (4,1,1,1)^{\mathsf{T}}$. The unnormalized vector is $(1,1/4,1/4,1/4)^{\mathsf{T}}$, its evidence is $Z = 7/4$, and

$$\mathcal{B}_\lambda(p) = \frac{(4,1,1,1)^{\mathsf{T}}}{7}.$$

Likelihood weights may be rescaled, so an evidence larger than one is not a probability claim. Multiplying all likelihoods by one common positive factor leaves this posterior unchanged.

$\lambda = (4,1,1,1)$; evidence $Z = 7/4$

The A packet becomes heavier and its internal shape changes. The B packet retains an equal internal split but loses total mass. These are different effects of the same likelihood.

Reconstruct from packet mass times packet shape

The unnormalized packet evidences are $Z_{\mathrm{A}} = 5/4$ and $Z_{\mathrm{B}} = 1/2$. The resulting masses and conditional shapes are

$$m_{\mathrm{A}} = 5/7, \quad q_{\mathrm{A}} = (4/5, 1/5, 0, 0)^{\mathsf{T}}, \qquad m_{\mathrm{B}} = 2/7, \quad q_{\mathrm{B}} = (0, 0, 1/2, 1/2)^{\mathsf{T}}.$$

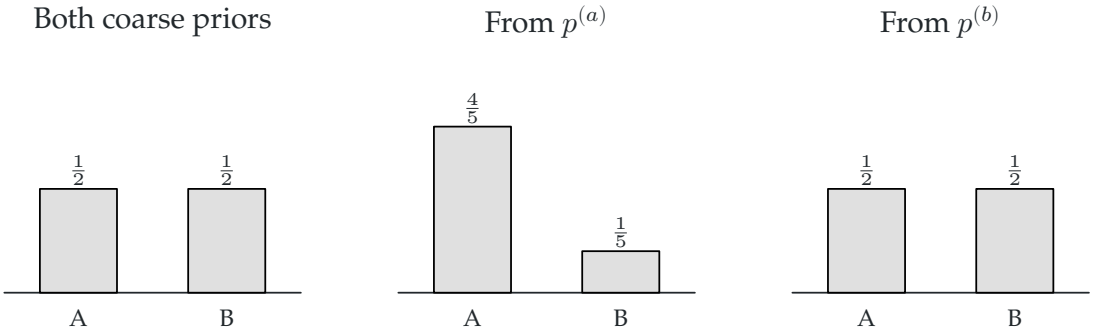
Thus $m_{\mathrm{A}} q_{\mathrm{A}} + m_{\mathrm{B}} q_{\mathrm{B}}$ is exactly the displayed posterior. Keeping only the masses would not reconstruct the fine state.

There is no need to divide by a zero packet evidence. For likelihood $(0,0,1,1)$, packet A has mass zero and contributes the zero vector. Only the occupied B packet has a conditional probability vector. If the *total* evidence is zero, however, the Bayesian update is not defined and the implementation rejects the input.

> **Read this as:** Bayesian reconstruction uses two kinds of data: how much posterior mass a packet carries and how that mass is distributed inside the packet.

Plate VI.10 / SUFFICIENCY / A COMPUTABLE FAILURE WITNESS

Two priors that fool the coarse model



Chapter VI, Part I: Theorem 8.2 and the one-packet exception.

Keep the same likelihood $\lambda = (4, 1, 1, 1)^{\mathsf{T}}$ and partition A$= \{0, 1\}$, B$= \{2, 3\}$. Compare

$$p^{(a)} = (1/2, 0, 1/2, 0)^{\mathsf{T}}, \qquad p^{(b)} = (0, 1/2, 1/2, 0)^{\mathsf{T}}.$$

Both have coarse prior $(1/2, 1/2)^{\mathsf{T}}$. A procedure given only that two-entry vector cannot distinguish them.

Hidden redistribution changes the packet-A posterior from $1/2$ to $4/5$.

After the identical fine likelihood is applied, the coarse posteriors are $(4/5, 1/5)$ and $(1/2, 1/2)$. A single deterministic update of the common coarse prior cannot produce both.

Why this witnesses the necessity of blockwise constancy

The A evidence for $p^{(a)}$ is 2, whereas it is $1/2$ for $p^{(b)}$. Their B evidence is $1/2$ in both cases. The posterior odds therefore distinguish the hidden distribution inside A.

For strictly positive fine and coarse likelihoods, and at least two coarse blocks, the manuscript proves the all-prior criterion

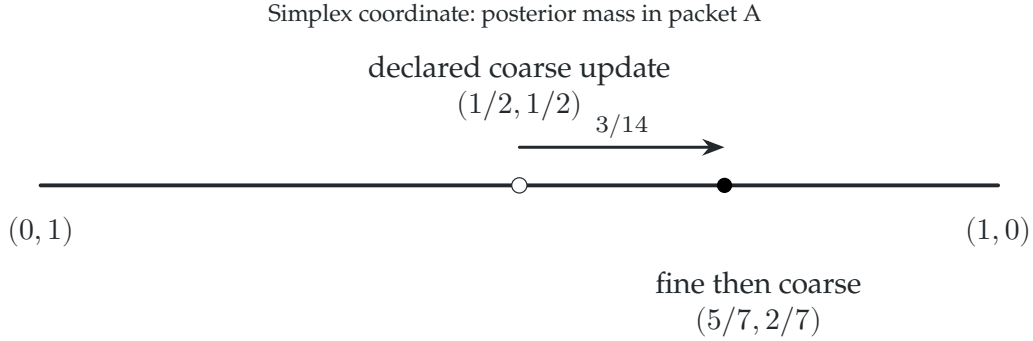
$$C\mathcal{B}_\lambda(p) = \mathcal{B}_{\bar{\lambda}}(Cp) \quad \text{for every } p \quad \Longleftrightarrow \quad \lambda_i = c\bar{\lambda}_a \quad (i \in I_a)$$

for one global $c > 0$. The global scale is invisible after normalization. A different arbitrary scale for each packet is not invisible: it changes posterior odds.

If all states are merged into a single packet, every normalized posterior coarsens to (1). That degenerate commutation holds for every likelihood and cannot identify any within-packet information. It is explicitly excluded from the nontrivial criterion.

> **Read this as:** A prior-dependent effective likelihood can always summarize the update. A fixed likelihood that works for every prior is a much stronger requirement.

Plate VI.11 / BAYESIAN DEFECT / MORE THAN AN ERROR BAR



The exact information-loss vector

Chapter VI, Part I: Theorems 8.1 and 8.4, and Corollary 8.6.

For a prior p, let $P = Cp$ and let $r_a(p)$ be the conditional average of the fine likelihood inside packet a. For the uniform prior and $\lambda = (4, 1, 1, 1)$,

$$P = (1/2, 1/2)^{\mathsf{T}}, \qquad r = (5/2, 1)^{\mathsf{T}}.$$

The exact coarse posterior is $\mathcal{B}_r(P) = (5/7, 2/7)^{\mathsf{T}}$. Suppose instead that the declared coarse likelihood is $\bar{\lambda} = (1, 1)$.

The posterior error lies along the mass-preserving direction of the two-state simplex. Its entries are opposite because both endpoints have total mass one.

Compute the factorization, including the null direction

Here $\bar{b} = \mathcal{B}_{\bar{\lambda}}(P) = P$, $\delta = r - \bar{\lambda} = (3/2, 0)^{\mathsf{T}}$, and $Z_r = 7/4$. Hence

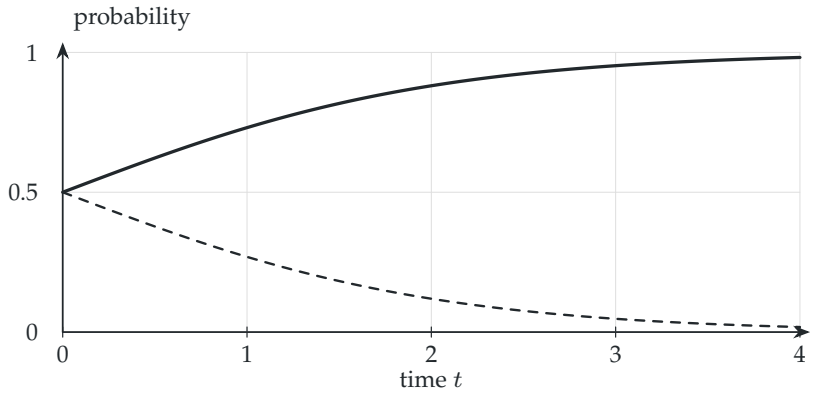
$$\frac{1}{Z_r}\left(\operatorname{diag}(P) - \bar{b}P^{\mathsf{T}}\right)\delta = \frac{4}{7}\begin{pmatrix} 1/4 & -1/4 \\ -1/4 & 1/4 \end{pmatrix}\begin{pmatrix} 3/2 \\ 0 \end{pmatrix} = \begin{pmatrix} 3/14 \\ -3/14 \end{pmatrix}.$$

This is the actual fine-to-coarse discrepancy, not a fitted approximation. The matrix kills $\bar{\lambda}$, recording the common-scale null direction. Its ℓ^1 error is $3/7$.

For a family of likelihoods, states may be grouped by equality of their *whole likelihood profile*. The family $(3, 3, 1, 1)$ and $(1, 2, 1, 2)$ separates all four states even though either likelihood alone permits a coarser grouping. The common refinement is therefore the discrete partition. The theorem's one-packet exception still remains.

> **Read this as:** The defect factors through exactly the conditional evidence information missing from the declared coarse model. A new observation family can require a finer partition.

Plate VI.12 / BAYESIAN FLOW / COMPOSITION WITHOUT LINEARITY



A nonlinear semigroup of odds

Chapter VI, Part I: Theorems 7.1 and 9.1. Likelihood composition and the replicator field.

Let the score vector be $g = (1, 0)$ and start at $(1/2, 1/2)$. The likelihood at time t is $(e^t, 1)$, so the first posterior coordinate is

$$p_0(t) = \frac{e^t}{1 + e^t}, \qquad p_1(t) = \frac{1}{1 + e^t}.$$

The odds p_0/p_1 grow exponentially, while the probabilities remain inside the simplex. At $t = \log 2$ the posterior is exactly $(2/3, 1/3)$.

$$p_0(t) = \frac{e^t}{1 + e^t}$$

$$p_1(t) = \frac{1}{1 + e^t}$$

$$\dot{p}_0 = p_0(1 - p_0)$$

Mass stays one.
Mixtures are not preserved.

The solid and dashed curves sum to one. The curvature is caused by the shared evidence denominator, not by a nonlinear likelihood multiplication law.

Two properties that must not be conflated

If $a > 0$ multiplies the odds, the first-coordinate map is

$$\phi_a(x) = \frac{ax}{1 + (a - 1)x}.$$

Direct algebra gives $\phi_a(\phi_b(x)) = \phi_{ab}(x)$. Thus $a = e^t$ gives a nonlinear semigroup. Nevertheless, $\phi_3(1/2) = 3/4$, while the mean of $\phi_3(0)$ and $\phi_3(1)$ is $1/2$. Superposition fails.

Differentiation of the normalized flow yields the centered score equation

$$\dot{p}_i = (g_i - \langle g, p \rangle) p_i.$$

For the displayed model, $\dot{p}_0 = p_0(1 - p_0)$. The negative average-score term is what keeps the total derivative zero. Omitting the derivative of the normalizer would not preserve mass.

Likelihood composition also preserves the evidence identity: the first evidence times the second conditional evidence equals the combined evidence. Normalization cancels in the posterior, but that factor still matters when comparing data models.

> **Read this as:** A semigroup is a composition law in time. It does not imply that the maps are linear or that they preserve mixtures.

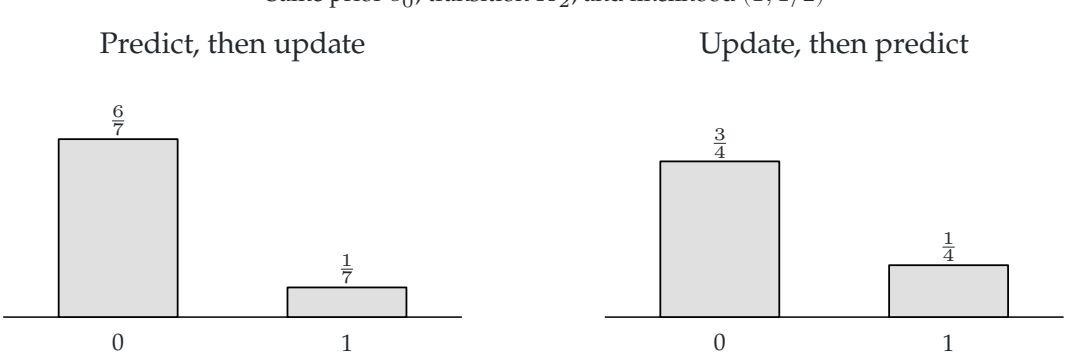


Plate VI.13 / HIDDEN MARKOV FILTERING / TIME ORDER

Prediction and observation do not commute

Chapter VI, Part I: Proposition 9.3. Linear prediction followed by a positive-evidence update.

Use the two-state kernel K_2 from Plate VI.2, the initial distribution e_0, and likelihood $(1, 1/2)$. Predicting first gives $(3/4, 1/4)$. Its likelihood-weighted vector is $(3/4, 1/8)$, with evidence $7/8$, so the posterior is $(6/7, 1/7)$.

Updating first leaves e_0 unchanged. Predicting afterward gives $(3/4, 1/4)$ instead. The order of operations expresses which time the observation concerns.

Both routes produce valid probability vectors. Their difference is therefore not a normalization bug. It is a different conditioning problem.

Keep an unnormalized path alongside the filter

For a sequence of observations, let $D_r = \operatorname{diag}(\lambda^{(r)})$. The forward recursion is

$$\hat{p}_r = K p_{r-1}, \qquad p_r = D_r \hat{p}_r / Z_r.$$

Its unnormalized companion is

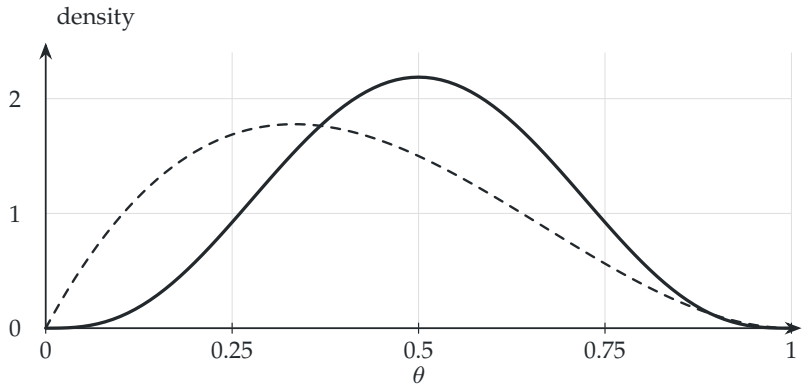
$$v_r = D_r K \cdots D_1 K p_0, \qquad p_r = \frac{v_r}{\mathbf{1}^{\mathsf{T}} v_r}, \qquad \mathbf{1}^{\mathsf{T}} v_r = \prod_{j=1}^{r} Z_j.$$

The product of evidences records the normalization lost at each individual step. The four-state computation on Plate VI.26 checks both paths independently, including their coarse versions.

Here $D_r K$ means an observation after prediction. In the Feynman–Kac example on Plate VI.20, departure-state weighting has forward operator $K D_w$. Both conventions are legitimate once their meanings are fixed, but they cannot be substituted for one another.

> **Read this as:** Write the chronological sequence before multiplying matrices. A product can be normalized correctly and still answer the wrong time-ordered question.

Plate VI.14 / BETA MODEL / POSTERIOR AND EVIDENCE



Conjugacy tracks exponents

Chapter VI, Part I: Example 9.2. A finite-parameter conjugate family, not a universal posterior model.

For a small exact example, take the Beta$(2, 3)$ density

$$\rho(\theta) = 12\theta(1-\theta)^2, \qquad 0 \le \theta \le 1.$$

Observe a specified ordered sequence with two successes and one failure. Its likelihood is $\theta^2(1-\theta)$. Multiplication adds exponents, so the posterior belongs to Beta$(4, 4)$ with density $140\theta^3(1-\theta)^3$.

The dashed prior is asymmetric. The solid posterior is symmetric with mean $1/2$. Polynomial integration verifies the normalizers exactly. The curves are sampled drawings of those polynomials.

The observation convention changes the evidence

The integral of the unnormalized posterior is

$$\int_0^1 12\theta^3(1-\theta)^3\,d\theta = \frac{3}{35}.$$

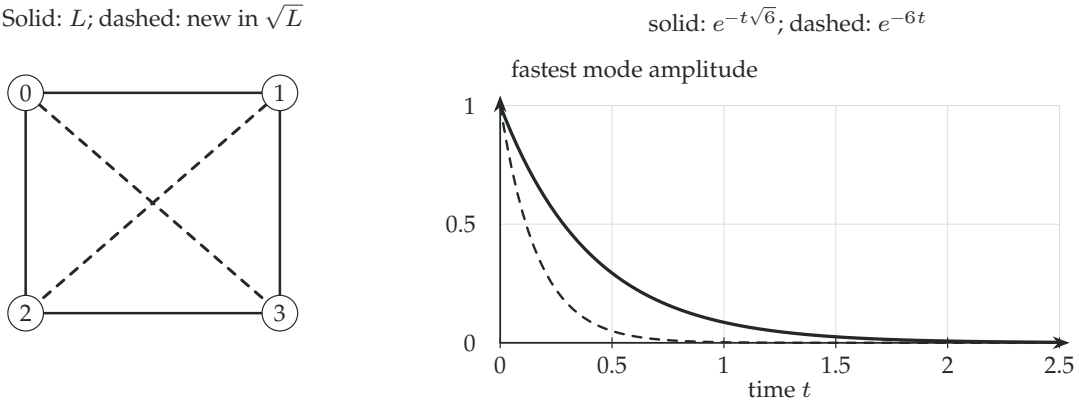
Dividing by $3/35$ gives the displayed normalized density. If the observation is instead the *count* of two successes in three trials, there are $\binom{3}{2} = 3$ compatible ordered sequences. The count likelihood is therefore $3\theta^2(1-\theta)$ and its evidence is $9/35$.

The extra factor does not depend on θ, so it cancels from the posterior. The two experiments thus have the same posterior distribution but different data probabilities. Evidence is not determined by the final normalized density alone.

The exact check also integrates both densities to one and integrates θ against the posterior to obtain $1/2$. This demonstrates one conjugate family in elementary terms. It does not show that arbitrary likelihoods preserve that family or that all posterior information can be compressed into two exponents.

Read this as: Conjugacy gives a closed parameter update when a specified likelihood respects a specified family. Preserve the evidence as well as the normalized posterior.

Plate VI.15 / FRACTIONAL DIFFUSION / NEW COUPLINGS



The modes stay as their clocks change

Chapter VI, Part I: Theorem 10.1. A positive self-adjoint finite model and its spectral powers.

Return to the four-state generator on Plate VI.4 and put $L = -Q$. It is real symmetric and nonnegative, with orthogonal projectors P_0, P_1, P_2, P_3 and eigenvalues $0, 2, 4, 6$. Its square root is

$$L^{1/2} = \sqrt{2}P_1 + 2P_2 + \sqrt{6}P_3, \qquad (L^{1/2})^2 = L.$$

Both heat evolutions retain these modes. Ordinary diffusion multiplies mode j by e^{-2jt}. Square-root diffusion multiplies it by $e^{-\sqrt{2j}\,t}$. The constant mode is unchanged in both.

The highest mode decays at rates 6 and $\sqrt{6}$. The graph beside the curves shows the additional couplings in the fractional operator. Curves display the explicit formulas, not an empirical fit.

Fractional does not mean entrywise

Although $L_{03} = 0$, its spectral square root satisfies

$$(L^{1/2})_{03} = \frac{\sqrt{6} - \sqrt{2} - 2}{4} < 0.$$

Thus $-L^{1/2}$ permits a direct transition between states 0 and 3, which were not neighbors for Q. Taking the square root of each matrix entry would neither produce this value nor square back to L.

The exact block aggregation remains compatible in this example:

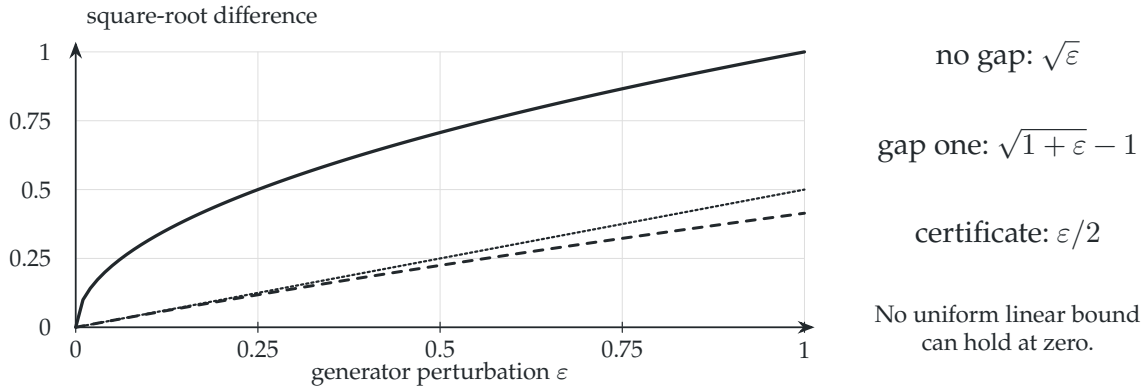
$$CL^{1/2} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} C.$$

The coarse matrix is the positive square root of $-Q_c$. This is a concrete naturality identity, checked on the full matrices. It is not a claim that an arbitrary partition commutes with every fractional construction.

The computation uses a nonnegative self-adjoint operator and a specified spectral branch. General nonnormal matrices, unbounded domains, and positivity of other fractional evolutions need their own hypotheses.

> **Read this as:** Fractional powers alter modal decay rates. Reassembling those modes can introduce long-range spatial interactions even when the original generator was sparse.

Plate VI.16 / FRACTIONAL DEFECTS / NEAR ZERO VERSUS AWAY FROM ZERO



A gap changes the error scale

Chapter VI, Part I: Theorem 10.3 and Corollary 10.4. Separate generator error from fractional error.

The function $a \mapsto \sqrt{a}$ changes most rapidly near zero. A scalar model already shows why a spectral gap appears in fractional-defect estimates:

$$|\sqrt{\varepsilon} - \sqrt{0}| = \sqrt{\varepsilon}, \qquad \sqrt{1+\varepsilon} - 1 = \frac{\varepsilon}{\sqrt{1+\varepsilon}+1} \le \frac{\varepsilon}{2}.$$

The same input difference has a square-root scale at zero and a linear bound above a fixed positive lower bound.

The upper curve compares 0 with ε. The lower curve compares 1 with $1+\varepsilon$. The dotted line $\varepsilon/2$ bounds the latter. All plotted values come from the displayed scalar formulas.

Read an operator bound with its hypotheses

For positive self-adjoint finite matrices $A, B \ge mI$ and $0 < \alpha < 1$, the manuscript's gapped estimate has the form

$$\|CA^{\alpha} - B^{\alpha}C\| \le \alpha m^{\alpha-1} \|CA - BC\|.$$

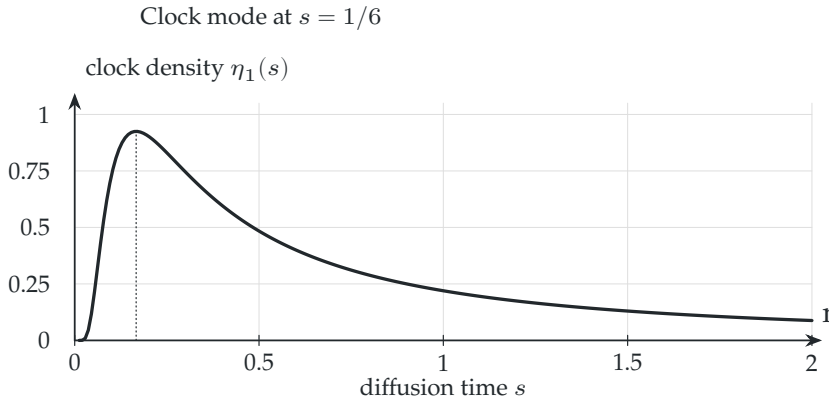
It concerns an intertwining defect, not just two eigenvalue lists. With $C = 1$, $A = 4$, $B = 9$, $m = 4$, and $\alpha = 1/2$, the generator defect has size 5, the fractional defect has size 1, and the bound is $5/4$.

The common zero mode of a Markov generator cannot simply be included in a positive-gap estimate. One must either work on an appropriate gapped subspace, handle the zero mode separately, or use the gapless estimate. In particular, a good estimate on each finite level need not have a constant uniform in the refinement level.

On Plate VI.27, the sequences $1/n^2$ and $1/n$ turn this change in error scale into a concrete distinction between summable and nonsummable defects.

Read this as: A fixed gap is quantitative information. It prevents the derivative of the fractional function from becoming singular along the comparison.

Plate VI.17 / SUBORDINATION / A DISTRIBUTION OF ORDINARY TIMES



A random diffusion clock

Chapter VI, Part I: Theorem 10.2. The Poisson subordination formula for the finite positive model.

Square-root evolution can be written as an average of ordinary diffusion over a positive clock variable s:

$$e^{-t\sqrt{L}} = \int_0^\infty \eta_t(s) e^{-sL}\, ds, \qquad \eta_t(s) = \frac{t}{2\sqrt{\pi}} s^{-3/2} e^{-t^2/(4s)}, \quad t > 0.$$

Here t is the external time, and s is the ordinary diffusion time being mixed. They are not interchangeable variables.

$$\int_0^\infty \eta_t(s)\, ds = 1$$

$$\int_0^\infty s\eta_t(s)\, ds = \infty$$

A probability clock need not have a finite mean.

The density η_1 peaks at $s = 1/6$ but has a long right tail. The drawing ends at $s = 2$. It does not claim that the missing tail has zero mass.

Check the normalizer before interpreting a density

Under $s = t^2/(4u^2)$, reversing the integration limits gives

$$\eta_t(s)\,|ds| = \frac{2}{\sqrt{\pi}} e^{-u^2}\, du.$$

Its integral over $u > 0$ is one, so η_t is a probability density. On each eigenmode of L, the operator formula reduces to the scalar Laplace identity

$$\int_0^\infty \eta_t(s) e^{-\lambda s}\, ds = e^{-t\sqrt{\lambda}}.$$

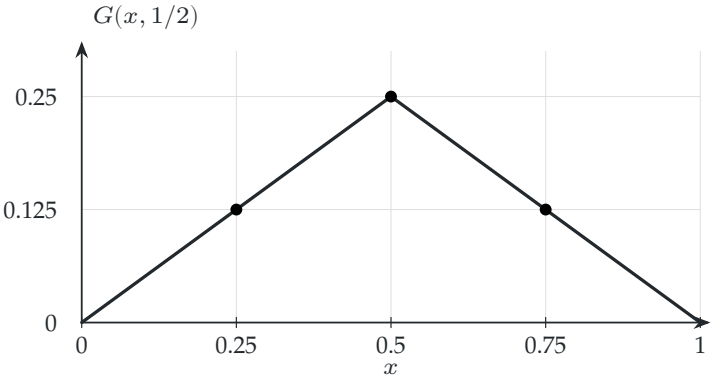
The manuscript supplies that scalar identity and its spectral assembly. The appendix separately checks the change of variables and normalization. Sampled curves are not used to certify an improper integral.

A normalized density need not have a finite mean. For large s, the exponential factor tends to one and $\eta_t(s)$ is proportional to $s^{-3/2}$. Consequently $s\eta_t(s)$ has a nonintegrable $s^{-1/2}$ tail. The clock has infinite mean even though its total mass is one.

> **Read this as:** Subordination is a weighted mixture of diffusion times. Replacing the clock distribution by a single average time is not justified, and here that average is infinite.

Plate VI.18 / DIRICHLET GRID / THE MISSING FACTOR OF h

A Green kernel is an inverse with units



Chapter VI, Part I: Theorem 11.1. Exact nodal Green reconstruction for this one-dimensional stencil.

Take three interior nodes $x_i = i/4$ on $[0, 1]$, with zero boundary values and $h = 1/4$. The discrete negative second derivative is

$$L_h = \frac{1}{h^2}\begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{pmatrix}.$$

For the continuous Dirichlet problem, the Green function is $G(x, y) = \min(x, y) - xy$. At these nodes the exact comparison is

$$L_h^{-1} = h\,[G(x_i, x_j)]_{i,j=1}^{3} = \frac{1}{64}\begin{pmatrix} 3 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 3 \end{pmatrix}.$$

$64L_h^{-1}$, $h = 1/4$

3	2	1
2	4	2
1	2	3

$L_h^{-1} = hG_{\text{nodes}}$

The tent is the central column of the continuous Green kernel. It has nodal values $(1, 2, 1)/8$. Its discrete inverse column is $(1, 2, 1)/32$, smaller by the factor h.

A forcing vector is not a quadrature-weighted measure

For sampled forcing f_j, the finite solution is

$$u_i = \sum_j (L_h^{-1})_{ij} f_j = h \sum_j G(x_i, x_j) f_j.$$

The factor h converts samples into the quadrature weights appropriate to this formula. Dropping it multiplies the computed solution by four on the displayed grid.

A discrete unit coordinate vector and a discretized unit point mass use different normalizations. For $f = e_2$, the result is the second inverse column. For $f = e_2/h$, it is the unscaled tent sampled at the nodes. Either convention can be useful, but it must be specified before comparing answers.

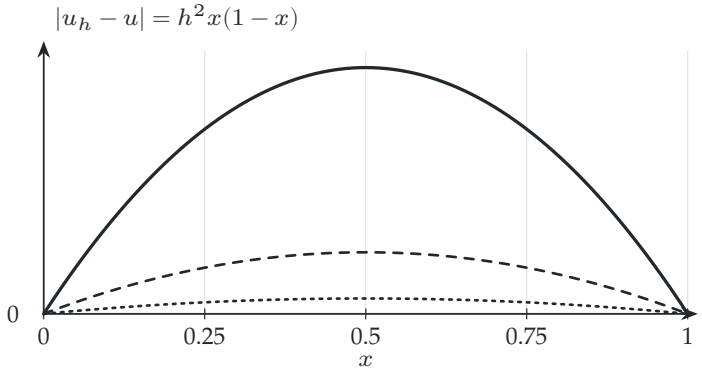
Exact checks multiply L_h by the proposed inverse at $1, 3, 7$, and 15 interior nodes. The general identity is the manuscript theorem. These finite checks do not extend it to arbitrary meshes, dimensions, or boundary conditions.

> **Read this as:** An inverse kernel carries a measure convention. A tent that looks correct can give a wrong solution if the grid weight is omitted.

Plate VI.19 / FINITE DIFFERENCES / A QUARTIC TEST PROBLEM

Convergence with a nonzero exact error

Chapter VI, Part I: Theorems 11.1–11.2. Exact nodal inversion and the scale of low-mode errors.



Use $u(x) = x - x^4$, which vanishes at both endpoints and solves $-u'' = 12x^2$. Its centered second difference is not exact:

$$L_h u|_{\text{nodes}} = 12x_i^2 + 2h^2.$$

Since the stencil differentiates the quadratic $x(1-x)$ exactly, the solution u_h to the sampled forcing $12x_i^2$ satisfies

$$\boxed{u_h(x_i) - u(x_i) = -h^2 x_i(1-x_i).}$$

This gives both the sign and size of the error, rather than merely a log–log slope.

grid spacing h	maximum error
$\frac{1}{4}$	$\frac{1}{64}$
$\frac{1}{8}$	$\frac{1}{256}$
$\frac{1}{16}$	$\frac{1}{1024}$

The three curves show magnitudes of the exact nodal errors for $h = 1/4, 1/8, 1/16$. Lines between grid points are visual guides, not an additional continuous numerical solution. The error is negative on every interior node.

One refinement divides this error by four

All three grids include $x = 1/2$, where the maximum absolute nodal error is $h^2/4$. It equals $1/64$, $1/256$, and $1/1024$, respectively. Exact rational matrix inversion verifies these values independently of the closed error formula.

The manuscript also compares the discrete eigenvalues

$$\lambda_{k,h} = 4h^{-2}\sin^2(k\pi h/2)$$

with $(k\pi)^2$, with error at most $(k\pi)^4 h^2/12$. For a fixed mode k, the bound tends to zero quadratically. It does not claim a uniform small error for modes whose index grows like $1/h$.

The nodal Green identity is exact, while the discretization of the differential equation still has a truncation error. These statements concern different comparisons and do not contradict one another.

> **Read this as:** An exact inverse of the discrete operator does not make that operator equal to the differential operator. Keep algebraic inversion and continuum approximation separate.

Plate VI.20 / FEYNMAN–KAC / DEPARTURE-STATE WEIGHTS

Eight paths, one weighted expectation

Chapter VI, Part I: Theorem 12.1. A finite path sum with its time convention displayed.

Let $K_2 = \frac{1}{4}\begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}$, start at state 0, use weights $w = (1, 1/2)$, and terminal observable $f = (2, 1)$. For three transitions, there are eight possible state sequences after the fixed initial state. We evaluate

$$\mathbb{E}_0\left[\prod_{r=0}^{2} w(X_r)\, f(X_3)\right].$$

Each path contributes its transition probability times its three departure weights times its terminal value.

Path	probability	weight	terminal	contribution
0000	$27/64$	1	2	$27/32$
0001	$9/64$	1	1	$9/64$
0010	$3/64$	$1/2$	2	$3/64$
0011	$9/64$	$1/2$	1	$9/128$
0100	$3/64$	$1/2$	2	$3/64$
0101	$1/64$	$1/2$	1	$1/128$
0110	$3/64$	$1/4$	2	$3/128$
0111	$9/64$	$1/4$	1	$9/256$

Total probability $= 1$; weighted terminal expectation $= 311/256$.

Every possible path is included. The probability column sums to one. The contribution column sums to $311/256$, agreeing exactly with the transfer calculation.

Check which side of the transition gets weighted

The backward operator on observables is $D_w K_2^{\mathsf{T}}$. Therefore the expectation is the zeroth coordinate of

$$(D_w K_2^{\mathsf{T}})^3 f.$$

Its forward dual is $K_2 D_w$: weight the mass at the departing state, then move it. Weighting arrival states instead gives $D_w K_2$, a different expression. The exact tests deliberately check that the two conventions do not agree in this example.

The answer $311/256$ exceeds one, but it is not a probability. The terminal observable can equal two. With $0 \le w_i \le 1$, the weighted expectation is bounded by the maximum terminal value, not necessarily by one.

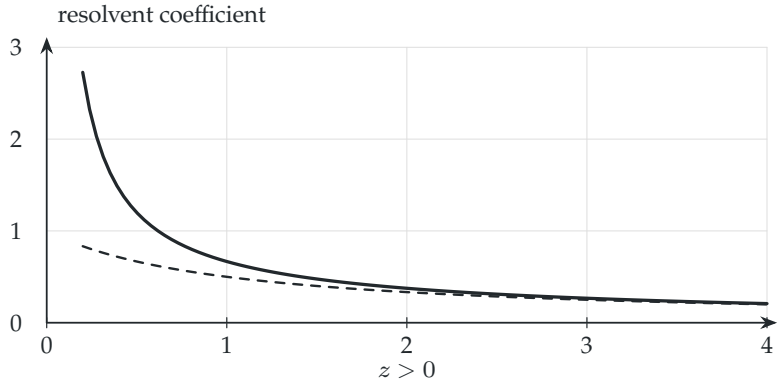
This calculation certifies a finite three-step identity for a stated model. The continuous-time theorem uses the corresponding infinitesimal generator and potential, with the direction of action kept consistent.

> **Read this as:** A Feynman–Kac weight changes the value assigned to each path. Its location relative to a transition is part of the model, not a typographical choice.

Plate VI.21 / SCHUR–FESHBACH / RETAINED RESOLVENT

Elimination makes a frequency-dependent term

Chapter VI, Part I: Theorem 13.1. A two-state Schur complement with the inverse checked directly.



The two-state evolution from Plate VI.3 has generator

$$A = \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}.$$

Retain the first coordinate and eliminate the second. For z away from the relevant poles, the retained entry of $(zI - A)^{-1}$ is

$$R_x(z) = \left[z + 1 - \frac{1}{z+1} \right]^{-1} = \frac{z+1}{z(z+2)}.$$

The term $\Sigma(z) = 1/(z+1)$ is the hidden coordinate's self-energy.

exact: $\dfrac{z+1}{z(z+2)}$

omit hidden state: $\dfrac{1}{z+1}$

The pole at zero survives through hidden feedback.

The full inverse gives a rational response with two poles, at 0 and -2. Its partial fractions are $R_x(z) = \frac{1}{2}z^{-1} + \frac{1}{2}(z+2)^{-1}$. The hidden intermediate inverse has its own excluded point $z = -1$.

An eliminated variable has not disappeared

If the coupling to the second coordinate were simply deleted, the retained resolvent would be $(z+1)^{-1}$. That has a different pole and a different long-time limit. The correction is frequency dependent, so it cannot be represented by one constant scalar generator on the retained coordinate.

The Schur expression first requires $z + 1 \neq 0$, as well as invertibility of the full matrix. Its simplified rational form has a removable intermediate singularity at $z = -1$, where the retained entry of the full inverse is well-defined and equals zero. Simplification does not retroactively make the eliminated block invertible there.

For $z > 0$, the Laplace transform of $(1 + e^{-2t})/2$ is exactly $R_x(z)$. The next page derives the time-domain equation producing that response.

> **Read this as:** The Schur complement is exact elimination, not independent dynamics on a smaller state space. Hidden evolution returns as a z-dependent self-energy.

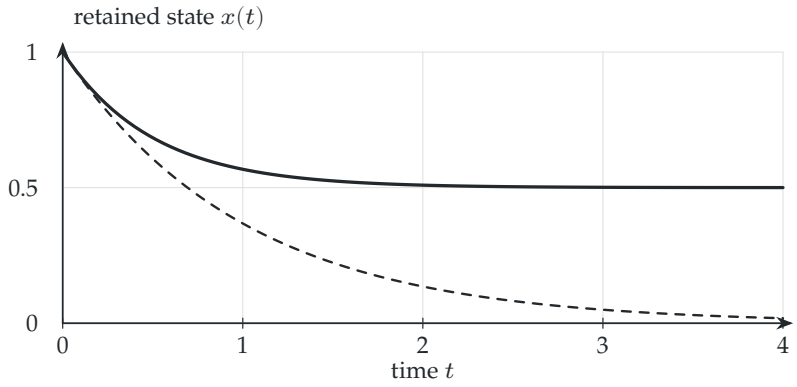
Plate VI.22 / EXACT RETAINED DYNAMICS / NOT A SCALAR SEMIGROUP

Hidden state returns as memory

Chapter VI, Part I: Theorem 13.2. The retained-state memory identity, including hidden initial data.

Write the same system as

$$x' = -x + y, \qquad y' = x - y.$$



Solving the second equation first gives

$$y(t) = e^{-t}y(0) + \int_0^t e^{-(t-r)}x(r)\,dr.$$

Substitution is exact:

$$x'(t) = -x(t) + e^{-t}y(0) + \int_0^t e^{-(t-r)}x(r)\,dr.$$

The hidden initial state produces a separate forcing term. It must be retained even when the memory kernel is known.

exact: $\dfrac{1 + e^{-2t}}{2}$

naive deletion: e^{-t}

$K(t) = e^{-t}$
returns hidden excursions.

For $(x(0), y(0)) = (1, 0)$, the exact retained coordinate is $(1 + e^{-2t})/2$. The dashed curve e^{-t} solves the equation obtained by deleting the hidden coordinate rather than eliminating it.

Projection can destroy the semigroup law

Let $R(t) = (1 + e^{-2t})/2$, the response to this fixed initial preparation. At $t = \log 2$,

$$R(t) = \frac{5}{8}, \qquad R(2t) = \frac{17}{32}, \qquad R(2t) - R(t)^2 = \frac{9}{64}.$$

The full two-state propagator is a semigroup, but this retained scalar response is not. Restarting it as a scalar model silently resets the hidden coordinate, which generally carries information from the first interval.

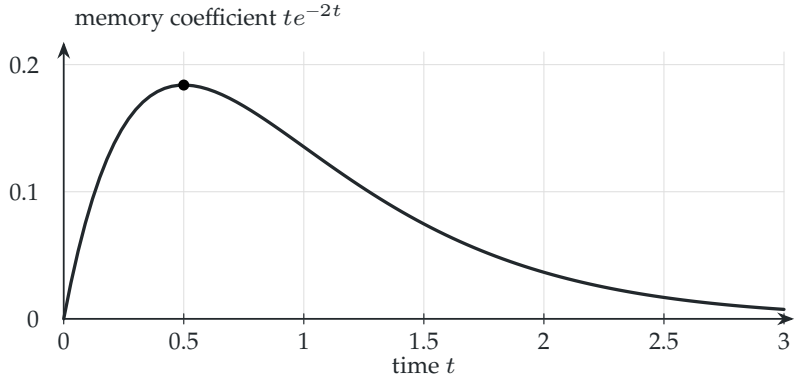
The appendix verifies the full differential equation, initial condition, integral memory equation, and Laplace resolvent in this model. Its kernel is e^{-t}, whose transform is the self-energy on Plate VI.21.

Read this as: Exact reduction retains a record of the eliminated state through convolution and initial forcing. A memoryless approximation must justify the information it removes.

Plate VI.23 / NONDIAGONAL HIDDEN DYNAMICS / POLYNOMIAL EXPONENTIALS

A repeated pole remembers a Jordan chain

Chapter VI, Part I: Theorem 13.2 and Section 15. Functional calculus must retain nilpotent data.



Now use a two-dimensional hidden block

$$J = -2I + N, \qquad N = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad N^2 = 0.$$

Choose the entrance column $V = (0,1)^{\mathsf{T}}$ and exit row $U = (1,0)$. The hidden exponential is not $e^{-2t}I$:

$$e^{tJ} = e^{-2t}(I + tN), \qquad K_{\text{mem}}(t) = Ue^{tJ}V = te^{-2t}.$$

The nilpotent link carries an input from the second hidden coordinate to the first.

$$J = -2I + N, \quad N^2 = 0$$

$$e^{tJ} = e^{-2t}(I + tN)$$

$$\widehat{K}(z) = \frac{1}{(z+2)^2}$$

A repeated pole carries a jet.

The memory kernel starts at zero, becomes positive, and peaks at $t = 1/2$. A rule that retained the eigenvalue -2 but discarded the Jordan chain would predict the zero kernel for these entrance and exit maps.

The transfer function sees pole order

The exact transform is

$$U(zI - J)^{-1}V = \frac{1}{(z+2)^2} = \int_0^\infty te^{-(z+2)t}\,dt, \qquad \operatorname{Re} z > -2.$$

The repeated pole and the polynomial factor t are the same information in two domains. For a longer nilpotent chain, higher powers of t occur with factorial denominators.

A zero value $K_{\text{mem}}(0)$ does not make the entire kernel zero. Nor do stable eigenvalues alone specify every transient contribution: entrance maps, exit maps, and nilpotent structure matter. Here the full kernel is nevertheless elementary, so its peak and transform can be checked without numerical fitting.

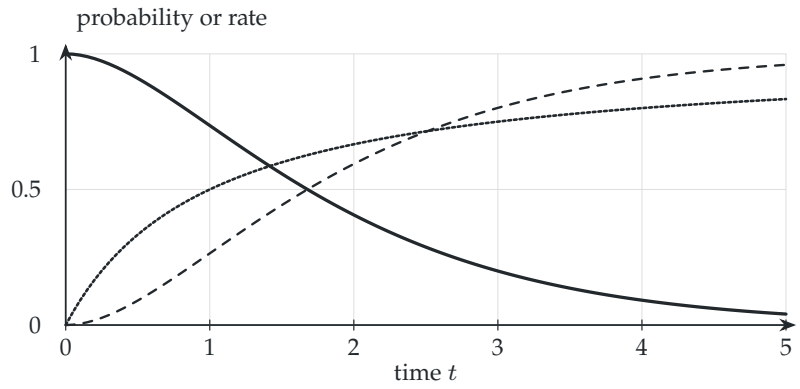
This page is an explicit finite realization. It does not show that an arbitrary continuum memory kernel admits a finite-dimensional representation of this form.

> **Read this as:** Repeated eigenvalues may carry directional information through Jordan chains. Keep the finite jet of the functional calculus, not just its values on the spectrum.

Plate VI.24 / PHASE-TYPE SURVIVAL / TWO SUCCESSIVE STAGES

A zero initial hazard can still lead to certain exit

Chapter VI, Part I: Theorem 14.1. Survival, density, hazard, and moments have distinct meanings.



Let a transient process move through two successive rate-one stages, then leave the system. With column probabilities, the transient generator and starting vector are

$$T = \begin{pmatrix} -1 & 0 \\ 1 & -1 \end{pmatrix}, \qquad p(0) = e_0.$$

Thus $p(t) = e^{-t}(1, t)^{\mathsf{T}}$. Its total remaining mass, exit density, and hazard are

$$S(t) = (1 + t)e^{-t}, \qquad f(t) = te^{-t}, \qquad h(t) = \frac{t}{1 + t}.$$

The initial hazard is zero because an exit needs two stages, not one.

Survival falls from one to zero, while absorbed mass $1 - S$ rises to one. The dotted hazard is an instantaneous rate, not a probability, even though it shares the displayed numerical scale. Time is measured in inverse stage-rate units.

Missing transient mass is absorbed mass

The column sums of T are 0 and -1. The exit-rate row is therefore $(0, 1)$, and $f(t) = (0, 1)p(t)$. Adding an absorbing state restores a three-state probability vector with total mass one.

Exact integration gives

$$\int_0^\infty f(t)\, dt = 1, \qquad \mathbb{E}[\tau] = 2, \qquad \mathbb{E}[\tau^2] = 6, \qquad \mathrm{Var}(\tau) = 2.$$

Equivalently, the mean is $\mathbf{1}^{\mathsf{T}}(-T)^{-1}e_0$. A single exponential waiting time with mean two would have constant hazard $1/2$ and variance four, so matching the mean alone would not reproduce this distribution.

The hazard formula is used where $S(t) > 0$. The model has that property for every finite $t \geq 0$. No division by an already vanished survival mass is required.

Read this as: Survival tracks mass, density tracks exits per unit time, and hazard conditions on survival. Equal means or equal initial rates do not identify a waiting-time law.

Plate VI.25 / HOLOMORPHIC CALCULUS / A RECTANGULAR COMPARISON

Naturality also transports derivatives

Chapter VI, Part I: Theorem 15.1. Exact intertwining passes to the specified functional calculus.

Consider a fine operator, a coarse operator, and a rectangular map

$$A_f = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 9 \end{pmatrix}, \qquad A_c = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}, \qquad C_r = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

Direct multiplication gives $C_r A_f = A_c C_r$. For $F(z) = 1/(1+z)$, which is defined at both spectra, compute the matrices by inversion:

$$F(A_f) = \begin{pmatrix} 1/3 & -1/9 & 0 \\ 0 & 1/3 & 0 \\ 0 & 0 & 1/10 \end{pmatrix}.$$

A_f

2	1	0
0	2	0
0	0	9

$F(A_f)$ for $F(z) = (1+z)^{-1}$

$\frac{1}{3}$	$-\frac{1}{9}$	0
0	$\frac{1}{3}$	0
0	0	$\frac{1}{10}$

$$F(2) = 1/3$$

$$F'(2) = -1/9$$

The dashed block is $F(A_c)$, not just $F(2)I$.

The discarded eigenvalue 9 contributes $1/10$ only on the fine side. On the retained Jordan block, the off-diagonal entry is $F'(2) = -1/9$, not zero. The rectangular comparison preserves that entry.

Why spectral values are not enough

On the retained block $A_c = 2I + N$, with $N^2 = 0$, one has

$$F(A_c) = F(2)I + F'(2)N = \tfrac{1}{3}I - \tfrac{1}{9}N.$$

Hence $C_r F(A_f) = F(A_c) C_r$. Replacing the block by $F(2)I$ would lose the nonzero derivative term and no longer give the actual inverse of $I + A_c$.

For polynomials, naturality follows by transporting every operator power. The manuscript's finite holomorphic statement uses finite Taylor data at each primary block and the corresponding nilpotent orders. This example verifies a rational instance with an actual inverse rather than asserting that arbitrary scalar substitutions are meaningful.

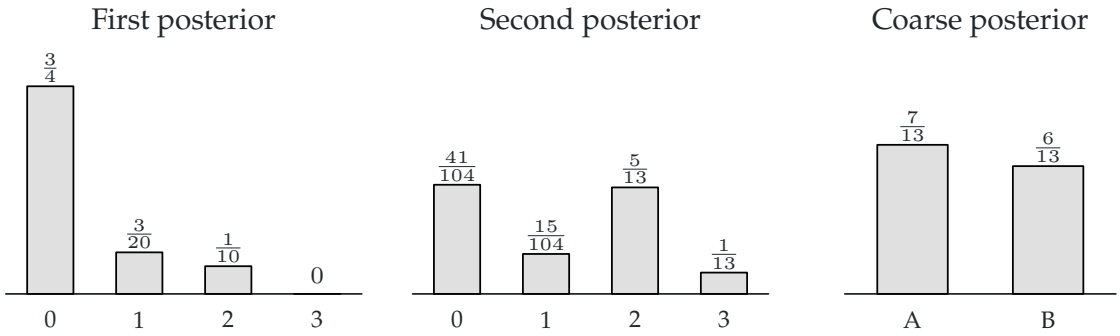
The same mechanism explains why the Jordan memory kernel on Plate VI.23 contains te^{-2t}. Exponentiation also has nonzero derivatives at repeated spectral values.

Read this as: A functional calculus acts on operators, including their nilpotent parts. Exact intertwining transports that full action, not merely a list of scalar eigenvalue images.

Plate VI.26 / END-TO-END MODEL / TWO OBSERVATIONS

One complete coarse filter

Chapter VI, Part I: Proposition 9.3 with Theorems 5.1 and 8.2. Markov closure and likelihood sufficiency are separate.



Use the four-state kernel K and aggregation C from Plate VI.5, starting at $p_0 = e_0$. Observe two likelihood vectors constant inside both packets:

$$\lambda^{(1)} = (3/4, 3/4, 1/4, 1/4), \qquad \lambda^{(2)} = (1/2, 1/2, 1, 1).$$

Predict, then update at each observation. The fine calculation gives

$$p_1 = \tfrac{1}{20}(15, 3, 2, 0)^{\mathsf{T}}, \qquad p_2 = \tfrac{1}{104}(41, 15, 40, 8)^{\mathsf{T}}.$$

Evidence $Z_1 = 5/8$, $Z_2 = 13/20$, and $Z_1 Z_2 = 13/32$

Within-packet probabilities change during the two observations, but the packet totals agree exactly with an independent two-state filter. The second coarse posterior is $(7/13, 6/13)$.

Check the normalizers, not only the final vector

The first and second predictive evidences are

$$Z_1 = \frac{5}{8}, \qquad Z_2 = \frac{13}{20}, \qquad Z_1 Z_2 = \frac{13}{32}.$$

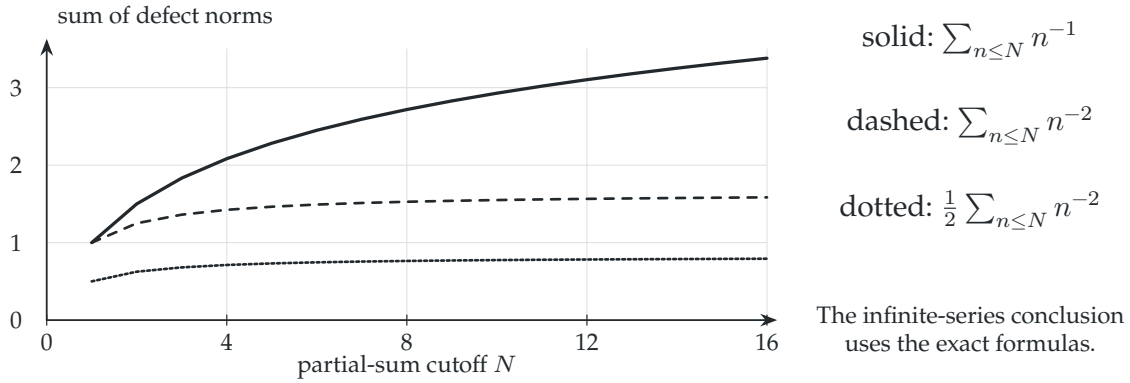
The unnormalized product $D_2 K D_1 K p_0$ has mass $13/32$ and normalizes to p_2. Because the likelihood entries here lie in $[0, 1]$, they can serve as probabilities of the specified observations. This makes the product their joint evidence in the stated model.

Two distinct equalities justify the coarse computation. First, $CK = K_c C$ transports prediction. Second, the likelihood is constant on each packet, so $CD_r = \overline{D}_r C$ transports observation weighting. Their composition preserves both the posterior packet totals and the evidence factors.

The coarse filter does not recover the within-packet shape. If a later observation distinguishes states inside a packet, those missing probabilities can become necessary, as the counterexample on Plate VI.10 shows.

> **Read this as:** Exact filtering at a coarse level needs both dynamical lumpability and observation sufficiency. Agreement under one step does not excuse testing the other.

Plate VI.27 / REFINEMENT LIMITS / WHAT THE FINITE MODELS DO NOT PROVE



Small at each level is not summable across levels

Chapter VI, Part I: Corollary 10.5 and Section 17. Summability and uniform control are additional data.

For each $n \geq 1$, compare the two scalar operators $A_n = 0$ and $B_n = 1/n^2$ through the identity. Their ordinary defects have sizes $1/n^2$, while their square-root defects have sizes $1/n$:

$$\sum_n |A_n - B_n| < \infty, \qquad \sum_n |A_n^{1/2} - B_n^{1/2}| = \infty.$$

These are independent scalar comparisons, not a constructed inverse system. They isolate an error-scale obstruction without claiming a coherent refinement tower.

Partial sums through $n = 16$ illustrate the contrast. The convergence and divergence statements follow from the displayed series, not from the finite plot. A common positive gap gives the third, summable upper bound.

A uniform hypothesis can change the conclusion

Replace the pair by $A_n = 1$ and $B_n = 1 + 1/n^2$. Then

$$\left|B_n^{1/2} - A_n^{1/2}\right| = \frac{1/n^2}{\sqrt{1 + 1/n^2} + 1} \leq \frac{1}{2n^2}.$$

This is the elementary form of the uniform-gap mechanism on Plate VI.16. Without such information, transferring a summable generator-defect budget through a fractional function can fail.

The formal contract keeps three research questions separate: realization of broader transfer semigroups, uniform stochastic-refinement control, and latent packet closure. The exact finite examples here do not settle their existence, domain, topology, or uniformity requirements.

Likewise, exact hidden-state elimination only yields the finite memory models that were supplied. It does not establish a finite latent realization for every memory law. A complete list of matrix identities can still leave an infinite-dimensional approximation problem untouched.

Read this as: A finite example can expose a missing hypothesis. It cannot supply a projective-limit construction, a uniform constant, or a continuum realization merely by passing at several levels.

Plate VI.28 / READER'S GUIDE / CALCULATION, DRAWING, AND FORMAL CONTRACT

How to use the evidence

Chapter VI formal companion: thirty-three-result correspondence and reproduction record.

Plates VI.1–VI.28 develop the finite worked models corresponding to Part I. The references beneath their titles use Part I's theorem numbers. Plates VI.29–VI.42 address the broader results in Part II.

The formal contract covers 33 scoped results, with 341 supporting theorem declarations in 47 proof modules and a saved audit of 782 namespace declarations. These counts describe the recorded formal development rather than independent new mathematical discoveries. The three conjectures retain their stated status.

Read each kind of evidence at its actual strength

Evidence	What is checked here	What it does not establish
Exact matrices	Stochasticity, intertwining, projector identities, inverse formulas, and specific defects.	The same properties for arbitrary partitions or unbounded operators.
Rational algebra	Posterior/evidence identities, polynomial integrals, nodal errors, and complete finite path sums.	An unstated observation model or a continuum convergence theorem.
Symbolic formulas	The displayed exponentials, Laplace transforms, derivatives, and finite spectral powers under stated conditions.	A general-purpose formal proof of every analytic identity.
Vector drawings	Reproducible geometry and sampled curves from the explicit models.	Numerical quadrature certificates or an exhaustive infinite-time experiment.
Saved Lean records	The original contract, source files, dependency pins, and earlier verification logs.	Fresh kernel verification of this editorial addition.

Reproduce a calculation before adapting it

The accompanying files contain the mathematical models, drawing generator and exact-example verifier, with execution instructions. The recorded symbolic suite passed 204 exact or symbolic assertions and rejected 11 deliberately false controls. Its separate execution record is identified on Plate VI.42 and names every check and its finite scope.

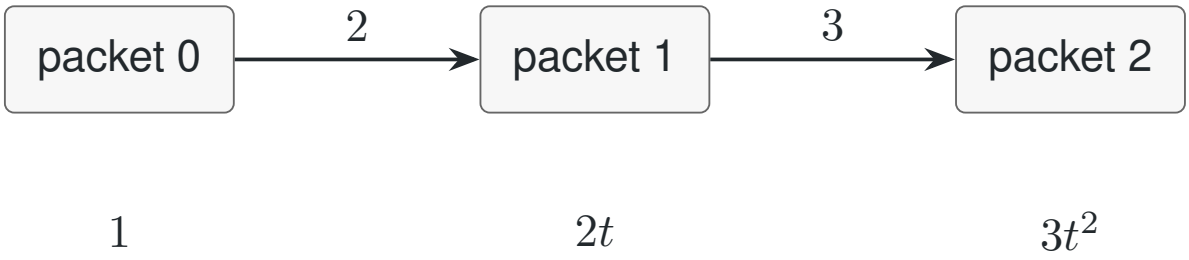
The finite families are explicit: three-step Feynman–Kac paths are fully enumerated, selected rational priors are checked exhaustively within their stated denominator bound, and Green inverses are checked on four named grids. No finite count is used as a substitute for a general theorem.

To change a model, specify the state convention, partition, likelihood meaning, topology, and domain first. Then rerun the calculations and inspect the regenerated drawings. A preserved formula with changed assumptions is not automatically a preserved result.

> **Read this as:** Use the guide to see why a hypothesis matters and to compute a small case. Use the manuscript and its formal map for the scope of the general claim.

Plate VI.29 / DIRECTED TRANSFER / A FINITE DYSON EXAMPLE

Acyclic paths stop after finitely many transfers



Chapter VI, Part II: Theorem E2.8 and Corollary E2.9. Acyclicity concerns the transfer graph.

Let three scalar packets form the directed chain $0 \to 1 \to 2$, with transfer coefficients 2 and 3. The generator and its powers are

$$A = \begin{pmatrix} 0 & 0 & 0 \\ 2 & 0 & 0 \\ 0 & 3 & 0 \end{pmatrix}, \qquad A^2 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 6 & 0 & 0 \end{pmatrix}, \qquad A^3 = 0.$$

Therefore the exponential is the exact polynomial

$$e^{tA} = I + tA + \frac{t^2}{2}A^2.$$

At $t = 1$: $(1, 2, 3)$ At $t = 2$: $(1, 4, 12)$

Only the empty path, one-edge paths, and the two-edge path exist. The coefficient $3t^2$ includes both the edge product $2 \cdot 3$ and the ordered-time simplex area $t^2/2$.

Path length counts transfers, not elapsed time

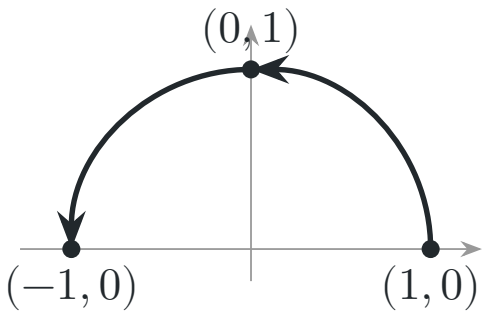
Starting at e_0, the complete state is $(1, 2t, 3t^2)^{\mathsf{T}}$. No fourth packet or repeated cycle can contribute. Direct differentiation gives $x'(t) = Ax(t)$, including the relation $x_2'(t) = 3x_1(t)$.

If nonzero diagonal generators are added, a path acquires an integral of the within-packet evolutions between its transfer times. Acyclicity still bounds the number of transfers. It does not make the diagonal exponential factors polynomial in time.

This is a linear transfer example. The columns of A do not sum to zero. The total of the displayed state is $1 + 2t + 3t^2$. It is consequently not a Markov probability model. Positivity of off-diagonal coefficients alone does not imply conservation of probability.

> **Read this as:** An acyclic packet graph terminates the transfer expansion. Nilpotence makes this particular full exponential polynomial. The two statements have different hypotheses.

Plate VI.30 / REFINEMENT / A PERSISTENT RANGE EXCURSION



Convergence does not close the dynamics

Chapter VI, Part II: Theorem E4.8 and Example E4.10. Summability and closure are different tests.

Let the coarse space be $\mathbb{R}$ and every finer space be $\mathbb{R}^2$. The first connecting maps are $C(x,y) = x$ and $Rx = (x,0)$. All later maps are identities. Let the coarse evolution be the identity and all fine evolutions be rotations:

$$T(t) = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}, \qquad U_n(t) = CT(t)R = \cos t \quad (n \geq 1).$$

The reconstructed sequence is already constant above its first level. Only one adjacent defect is nonzero, so its defect sum is finite on every bounded time interval.

full two-step return: -1

project after each step: 0

The full state returns to the coarse line with negative sign after two quarter turns. Resetting the hidden coordinate after the first quarter turn loses the returning contribution.

A limit can fail the semigroup identity

At $s = t = \pi/2$,

$$U(s)U(t) = 0, \qquad U(s+t) = -1.$$

Write $P = RC = \operatorname{diag}(1,0)$. The exact algebraic difference is

$$U(s)U(t) - U(s+t) = CT(s)(P - I)T(t)R.$$

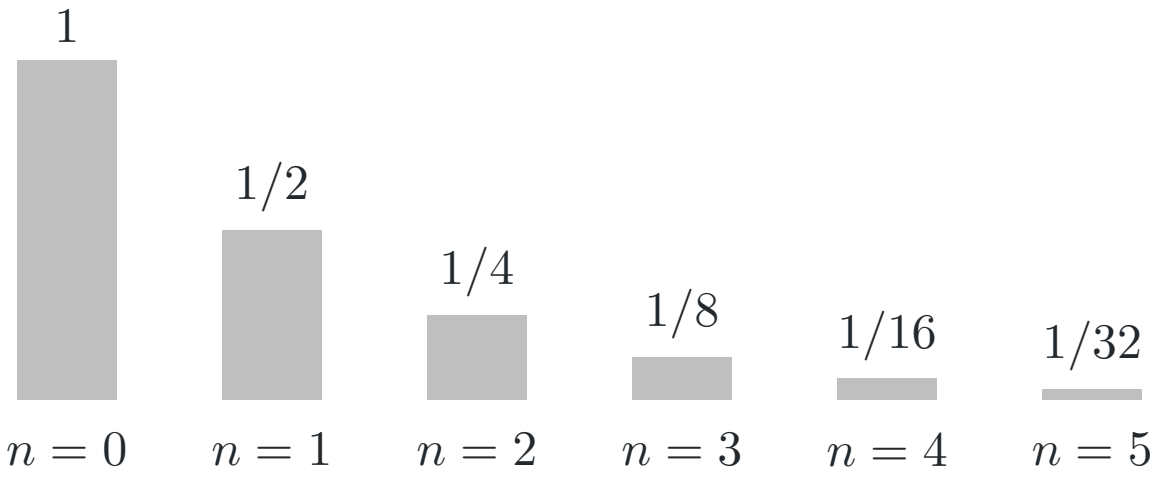
Its value is 1 at these times, matching the missing hidden excursion. This is a failure of closure, not a failure of convergence.

The strengthened closure theorem asks for the corresponding excursion norm to tend to zero with refinement, uniformly on bounded time intervals. Generator control of range leakage supplies a sufficient condition in its stated contractive setting. The present rotation example never meets that vanishing condition.

> **Read this as:** A convergent sequence of reconstructed evolutions need not converge to a semigroup. The limit must also forget no excursion that can later return.

Plate VI.31 / SUMMABLE DEFECTS / A SCALAR COMPLETION

A tail bound states what refinement buys



Chapter VI, Part II: Theorem E4.5 and Corollary E4.7. This example has identity connecting maps.

Take $X_n = \mathbb{R}$, $C_n = R_n = 1$, and

$$a_n = 1 - 2^{-n}, \qquad A_n = -a_n, \qquad T_n(t) = e^{-a_n t} \quad (n \geq 0).$$

Each semigroup is contractive for $t \geq 0$. The exact adjacent generator-defect magnitude is

$$|A_{n+1} - A_n| = 2^{-(n+1)}, \qquad \sum_{j=n}^{\infty} |A_{j+1} - A_j| = 2^{-n}.$$

The bars show the certified tail 2^{-n} at horizon $T = 1$. They are bounds on a whole time interval, not errors sampled at the right endpoint.

The estimate follows before any graph is drawn

For $0 \leq t \leq T$, the derivative of $a \mapsto e^{-at}$ has absolute value at most T when $a \geq 0$. Thus

$$\sup_{0 \leq t \leq T} |T_n(t) - e^{-t}| \leq T 2^{-n}.$$

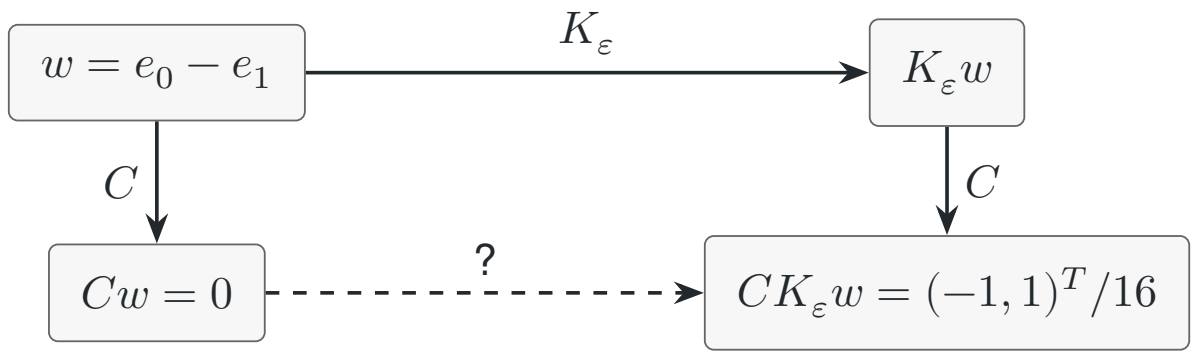
The limit is e^{-t}, which does have the semigroup law. Here every reconstruction is the identity, so the hidden-range excursion is identically zero. That closure fact is additional to the tail estimate.

In a general tower, the weighted estimate includes norms of composed connecting and reconstruction maps. Dropping those weights without contraction or another uniform bound can change a convergent error budget into an invalid one. Even a small defect at each individual level does not control the sum over all levels.

> **Read this as:** A summable tail gives an explicit stopping rule for a fixed horizon. It does not remove weights, supply uniformity on all time, or prove closure without its own hypotheses.

Plate VI.32 / MARKOV DESCENT / TEST THE AGGREGATION KERNEL

The obstruction lives in the forgotten directions



Chapter VI, Part II: Theorem E5.3 and Corollary E5.4. A quotient criterion with a concrete witness.

Return to the four-state model of Plate VI.4 and the perturbed stochastic matrix K_ε of Plate VI.6. Let

$$C = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix}, \qquad w = e_0 - e_1.$$

The vector w changes the fine distribution inside the first packet without changing its mass: $Cw = 0$. Yet

$$CK_\varepsilon w = \begin{pmatrix} -1/16 \\ 1/16 \end{pmatrix} \neq 0.$$

No linear coarse map can make this step: 0 must map to 0.

The coarse input cannot see w. The next coarse output can. Therefore no linear coarse operator can reproduce this fine step for every input.

Why one witness rules out every coarse matrix

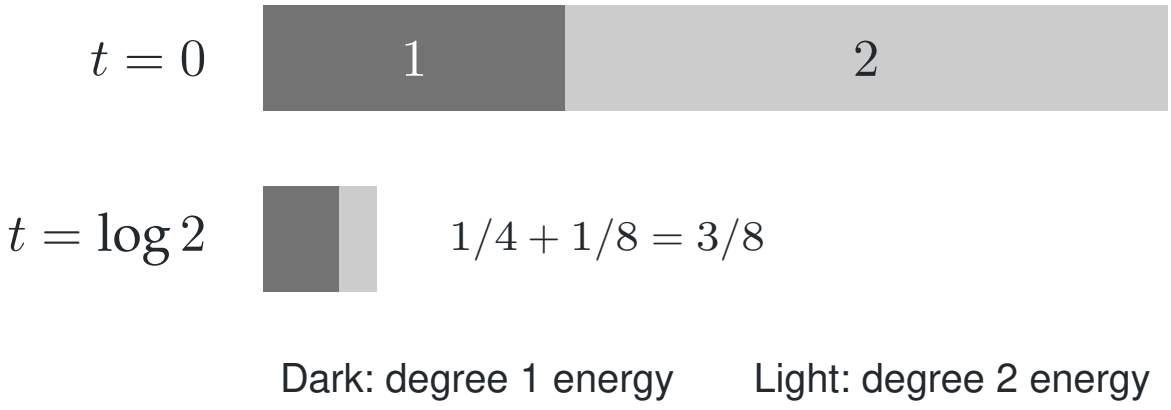
If some $\bar{K}$ satisfied $CK_\varepsilon = \bar{K}C$, then $CK_\varepsilon w = \bar{K}Cw = 0$, contradicting the displayed vector. The failure is not repaired by fitting a different coarse transition matrix to selected priors.

More generally, for a surjective aggregation map C, a linear map M descends exactly if CM vanishes on $\ker C$. The descended map is defined by $\bar{M}(Cx) = CMx$. The kernel condition makes this independent of the representative x.

For a deterministic partition of a finite stochastic system, differences $e_i - e_j$ within the same source block span the forgotten directions. Testing them gives the familiar equality of aggregate columns. Nonnegativity and column sums of the descended stochastic matrix then follow from the fine stochastic matrix and the partition structure.

> **Read this as:** The canonical obstruction is the action on information that aggregation discards. A nonzero witness in that kernel rules out exact descent at once.

Plate VI.33 / ORNSTEIN–UHLENBECK / HERMITE ENERGY



Gaussian packets have separate clocks

Chapter VI, Part II: Theorem E7.1 and Corollaries E7.2, E7.4, and E7.5. Standard Gaussian measure.

In $L^2(\gamma)$ for the standard Gaussian law on $\mathbb{R}$, use the probabilists' Hermite polynomials

$$H_1(x) = x, \qquad H_2(x) = x^2 - 1, \qquad H_4(x) = x^4 - 6x^2 + 3.$$

The Ornstein–Uhlenbeck generator is $\mathcal{L}f = f'' - xf'$. Direct polynomial differentiation gives $\mathcal{L}H_n = -nH_n$ for these three polynomials. Their squared norms are $n!$ and different Hermite degrees are orthogonal.

For $f = H_1 + H_2$, the two bars are its separate squared-energy contributions. At $t = \log 2$, their sum is $3/8$, below the spectral-gap bound $3/4$.

Reconstruction preserves the modes as time changes their weights

The semigroup sends $f = H_1 + H_2$ to

$$T(t)f = e^{-t}H_1 + e^{-2t}H_2, \qquad \|T(t)f\|_2^2 = e^{-2t} + 2e^{-4t}.$$

Its mean is zero. The Gaussian gap bounds this by $e^{-2t}\|f\|_2^2 = 3e^{-2t}$. It need not be an equality when multiple degrees are present.

For the nonnegative operator $-\mathcal{L}$, a square-root evolution replaces rate n by $\sqrt{n}$. On $g = H_1 + H_4$, the coefficients at $t = \log 2$ are $1/2$ and $1/4$, whereas ordinary OU evolution gives $1/2$ and $1/16$. The eigenfunctions agree. The rates differ.

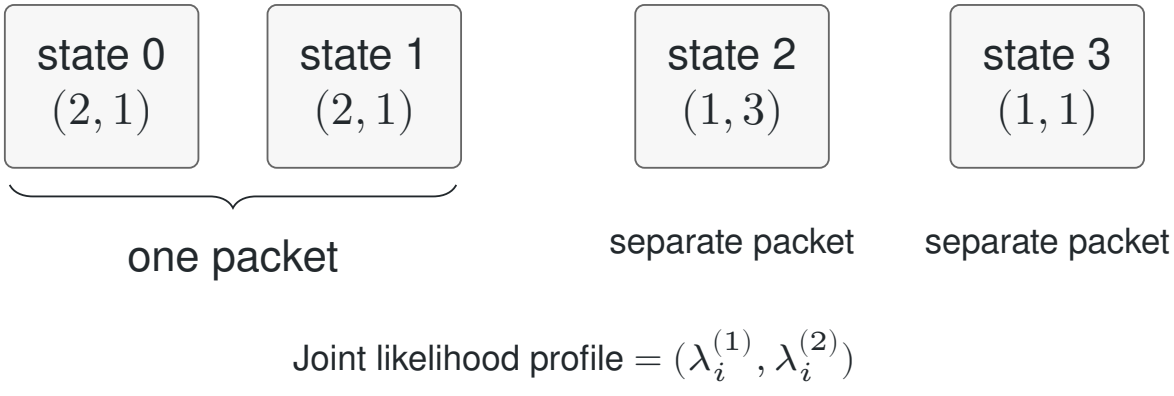
These calculations concern polynomial elements of Gaussian L^2. The general expansion and generator-domain statements belong to the traditional proof. A finite list of Hermite checks does not establish completeness of the basis.

> **Read this as:** Orthogonal packets make the energy accounting exact. A fractional generator alters the spectral clock while keeping the same Gaussian modes.

Plate VI.34 / FIXED LIKELIHOODS / JOINT PROFILES

Several observations determine one sufficient partition

Chapter VI, Part II: Theorem E9.3. A finite family of strictly positive likelihoods.



On four states, consider two likelihoods

$$\lambda^{(1)} = (2, 2, 1, 1), \qquad \lambda^{(2)} = (1, 1, 3, 1).$$

Two states may share a packet in the coarsest partition on which every listed likelihood is constant exactly when their entire likelihood profiles agree. The profiles are

$$(2, 1),\ (2, 1),\ (1, 3),\ (1, 1),$$

so the partition is $\{0, 1\}, \{2\}, \{3\}$.

The first observation alone allows the last two states to be merged. The second observation distinguishes them. The shared partition must respect both likelihoods.

A complete two-stage calculation

Start from the uniform prior. The coarse prior is $(1/2, 1/4, 1/4)$. After the first likelihood, it becomes $(2/3, 1/6, 1/6)$. After the second, it is

$$(1/2, 3/8, 1/8).$$

The direct fine update multiplies the likelihoods componentwise, giving weights $(2, 2, 3, 1)$ and posterior $(2, 2, 3, 1)/8$. Its packet masses are precisely the displayed coarse posterior.

The individual evidences are $Z_1 = 3/2$ and $Z_2 = 4/3$, and their product is 2, the direct evidence of the product likelihood. These are relative likelihood weights, so evidence larger than one is allowed.

This partition supplies fixed coarse likelihoods that work for every prior. A single-packet aggregation always gives posterior (1). That mass-only commutation does not identify likelihood profiles. A prior-dependent conditional average can summarize one update on a coarser partition, but requires the within-packet information that a fixed sufficient rule avoids.

> **Read this as:** Equal full likelihood profiles determine the coarsest partition on which every listed likelihood is constant. This partition admits fixed sufficient update rules.

Plate VI.35 / RELATIVE ENTROPY / COARSE AND CONDITIONAL TERMS

Information loss has an exact location

Chapter VI, Part II: Theorem E9.8 and Corollary E9.9. Positive reference masses in this example.

Take

$$p = (1/2, 1/4, 1/8, 1/8), \qquad q = (1/4, 1/4, 1/4, 1/4)$$

and group the first two and last two states. Their coarse laws are $P = (3/4, 1/4)$ and $Q = (1/2, 1/2)$. Define $D(p\|q) = \sum_i p_i \log(p_i/q_i)$ with natural logarithms.

$$D(p\|q) = \tfrac{1}{4}\log 2$$

coarse information
$\frac{3}{4}\log 3 - \log 2$

conditional information
$\frac{5}{4}\log 2 - \frac{3}{4}\log 3$

The bar lengths use the displayed exact formulas evaluated for illustration. The split is an identity: coarse information plus posterior-weighted conditional information. It is not a fitted allocation.

The chain rule identifies exactly what aggregation removes

Inside packet A, the conditional laws are $(2/3, 1/3)$ and $(1/2, 1/2)$. Inside B they agree. Hence

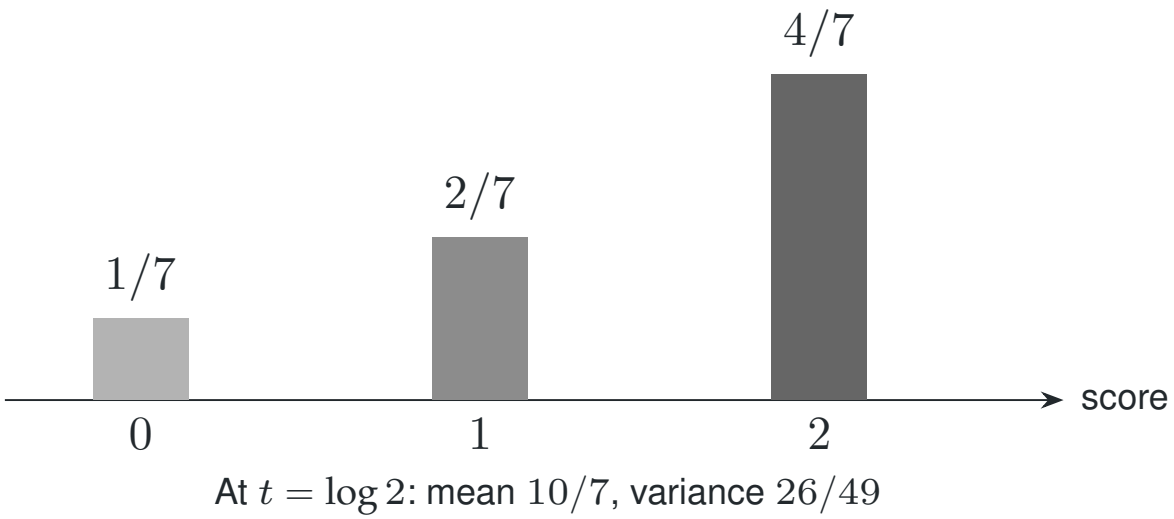
$$\begin{aligned} D(p\|q) &= \tfrac{1}{4}\log 2, \\ D(P\|Q) &= \tfrac{3}{4}\log 3 - \log 2, \\ \sum_a P_a D(p(\cdot \mid a)\|q(\cdot \mid a)) &= \tfrac{5}{4}\log 2 - \tfrac{3}{4}\log 3. \end{aligned}$$

Adding the last two lines recovers the first. Every conditional term is nonnegative, so aggregation cannot increase relative entropy. Equality holds precisely when the occupied packets have the same conditional laws, under the stated support convention.

The weighting is by the packet mass P_a from the first argument of $D(p\|q)$. Replacing it by Q_a generally breaks the identity. Likewise, forgetting zero-mass conventions or allowing a positive p_i over a zero q_i changes which expressions are finite.

> **Read this as:** Coarse relative entropy measures distinguishability that survives aggregation. The conditional term records exactly the distinguishability removed inside the packets.

Plate VI.36 / BAYESIAN FLOW / EVIDENCE CUMULANTS



The score rises because it has variance

Chapter VI, Part II: Theorems E10.1 and E10.2. Exponential tilting of a fixed finite prior.

Start with equal prior masses on scores $u = (0, 1, 2)$ and likelihood e^{tu}. Put $q = e^t$. The evidence and tilted distribution are

$$Z(t) = \frac{1 + q + q^2}{3}, \qquad p(t) = \frac{(1, q, q^2)}{1 + q + q^2}.$$

At $t = \log 2$, they are $Z = 7/3$ and $p = (1, 2, 4)/7$.

The score values stay fixed. Their probabilities change. The rising mean score is a property of this tilted family, not an increase in the individual scores.

Two derivatives have different statistical meanings

The first derivative of log evidence is the current mean score, and the second is its variance:

$$\frac{d}{dt} \log Z(t) = \mathbb{E}_{p(t)} u, \qquad \frac{d^2}{dt^2} \log Z(t) = \mathrm{Var}_{p(t)}(u) \geq 0.$$

At $q = 2$ the exact values are

$$\mathbb{E}u = \frac{10}{7}, \qquad \mathbb{E}u^2 = \frac{18}{7}, \qquad \mathrm{Var}(u) = \frac{26}{49}.$$

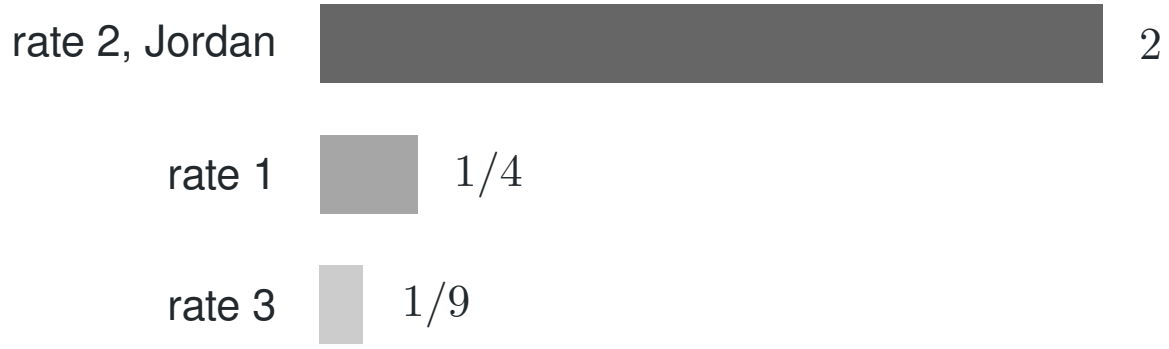
Thus the derivative of the mean is $26/49$ at this time. The flow equation $p_i' = (u_i - \mathbb{E}u)p_i$ gives derivatives $(-10, -6, 16)/49$, which sum to zero.

As $t \to \infty$, mass concentrates on the largest score present in the initial support. A score with zero initial prior mass is never created by multiplication. If several occupied states tie for the maximum, their relative prior proportions remain unchanged within that maximal packet.

Read this as: Log evidence is a cumulant generator for the tilted law. Its curvature is variance, so the mean score is monotone even though the flow is nonlinear.

Plate VI.37 / MEMORY COMPRESSION / AN OPTIMIZATION WITH A DEFINED COST

Keep blocks by their certified contribution



Chapter VI, Part II: Theorem E15.1 and Corollary E15.2. Stable primary blocks. Block count is the budget.

Consider the scalar memory kernel

$$\mathcal{K}(t) = \tfrac{1}{4}e^{-t} + (3+2t)e^{-2t} + \tfrac{1}{3}e^{-3t}.$$

It has three primary blocks. The middle block carries a Jordan term and must be retained or omitted as a whole for this selection rule. Their certified integrated weights are

$$w_1 = \frac{1}{4}, \qquad w_2 = \frac{3}{2} + \frac{2}{2^2} = 2, \qquad w_3 = \frac{1/3}{3} = \frac{1}{9}.$$

With one primary block retained, choose the middle block and certify omitted weight $13/36$. With two retained, add the rate-one block and the remaining certificate is $1/9$.

The slowest eigenvalue is not necessarily the largest effect

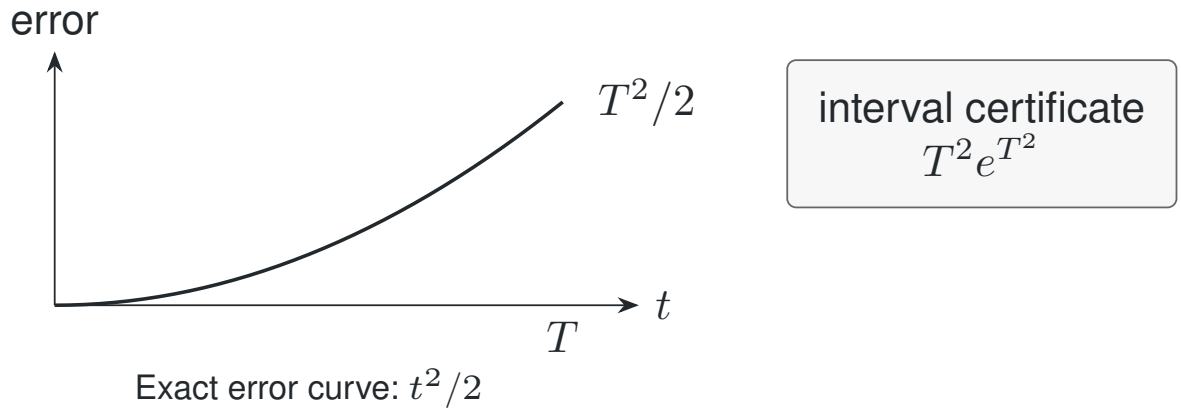
The rate-two block has the greatest weight because its couplings and nilpotent contribution dominate. Retaining the slowest rate alone would omit weight $2 + 1/9$, a much larger certificate.

The descending order is $2, 1/4, 1/9$. A target tolerance $1/8$ needs two blocks according to this bound: one block leaves $13/36 > 1/8$, while two leave $1/9 \le 1/8$. Every term in this particular scalar kernel is nonnegative, so its omitted integral equals the certificate.

In general matrix kernels, cancellations can make the true error smaller. The theorem optimizes the sum of omitted block weights, not every possible approximation error. Moreover, a Jordan block may cost several state dimensions. A fixed budget in total hidden dimension is a different optimization problem from a fixed number of primary blocks.

> **Read this as:** The largest-weight rule is exact for its stated certificate and block-count budget. It is not a claim of globally optimal model reduction.

Plate VI.38 / VOLTERRA STABILITY / SAME INITIAL DATA AND FORCING



A kernel certificate becomes a trajectory certificate

Chapter VI, Part II: Theorem E15.6. Norms and a finite time horizon are explicit.

Let $N = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, so $N^2 = 0$ and $\|N\|_2 = 1$. On $[0, T]$, compare the memory kernels $K(t) = N$ and $\widetilde{K}(t) = 0$, with identity free semigroup, no forcing, and initial state $x_0 = e_1 = (0, 1)^\mathsf{T}$. The equations are

$$x'(t) = \int_0^t N x(r)\, dr, \qquad \tilde{x}'(t) = 0.$$

Their exact solutions are $x(t) = (t^2/2, 1)^\mathsf{T}$ and $\tilde{x}(t) = (0, 1)^\mathsf{T}$.

The first-coordinate error is exactly $t^2/2$. The certificate bounds its maximum on the entire interval. The bound is deliberately shown separately from the trajectory.

Track every constant before applying the estimate

Here $M_T = 1$, $B = \sup \|\tilde{x}\| = 1$, and

$$L = \|K\|_{L^1(0,T)} = T, \qquad \varepsilon = \|K - \widetilde{K}\|_{L^1(0,T)} = T.$$

The theorem yields

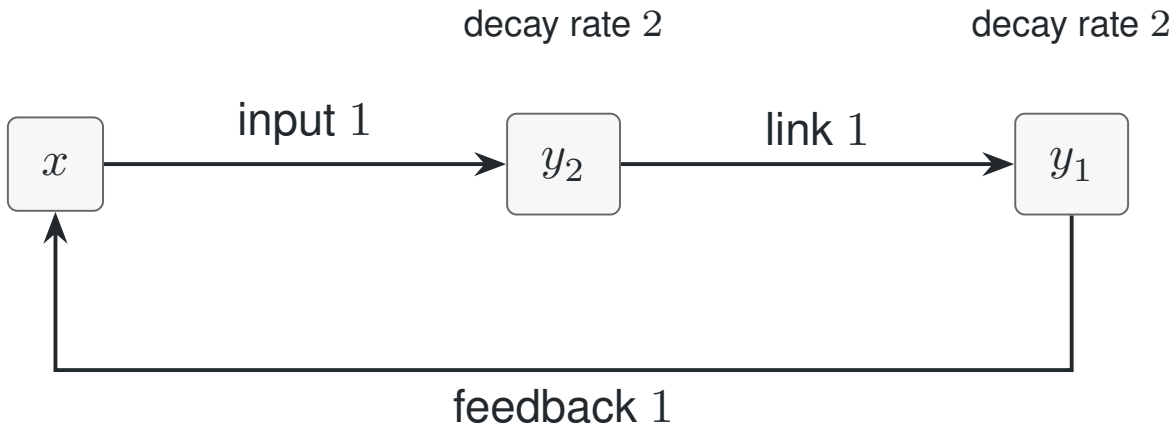
$$\sup_{0 \le t \le T} \|x(t) - \tilde{x}(t)\| = \frac{T^2}{2} \le T^2 e^{T^2}.$$

At $T = 1/2$, the exact error is $1/8$ and the certificate is $e^{1/4}/4$. Nilpotence makes this example polynomial. It does not remove the time horizon from the general theorem.

The two solutions share initial state, free semigroup, and forcing. If those are changed as well, their errors need additional terms. An integrated kernel error alone does not automatically control a trajectory on an infinite horizon.

> **Read this as:** The compression estimate transports an L^1 kernel budget into a finite-horizon state bound, using an explicit bound on the comparison trajectory.

Plate VI.39 / FINITE REALIZATION / AN EXACT DIFFERENTIAL MODEL



Two auxiliary states realize a repeated pole

Chapter VI, Part II: Corollaries E15.4 and E15.5. This is a supplied rational realization.

The kernel $K(t) = te^{-2t}$ from Plate VI.23 has transform $1/(z+2)^2$. It is realized by two auxiliary states:

$$\begin{aligned} \dot{y}_1 &= -2y_1 + y_2, \quad y_1(0) = 0, \\ \dot{y}_2 &= -2y_2 + x, \quad y_2(0) = 0, \\ \dot{x} &= ax + y_1. \end{aligned}$$

With $D = \begin{pmatrix} -2 & 1 \\ 0 & -2 \end{pmatrix}$, $B = (1, 0)$, and $C = (0, 1)^{\mathsf{T}}$, the feedback kernel is $Be^{tD}C = te^{-2t}$.

An input first enters y_2, transfers to y_1, and then returns to x. The two equal decay rates produce a repeated pole through the intervening link.

Elimination recovers the convolution, including its preparation

Variation of constants gives

$$y(t) = e^{tD}y(0) + \int_0^t e^{(t-r)D}Cx(r)\,dr,$$

so the retained equation is

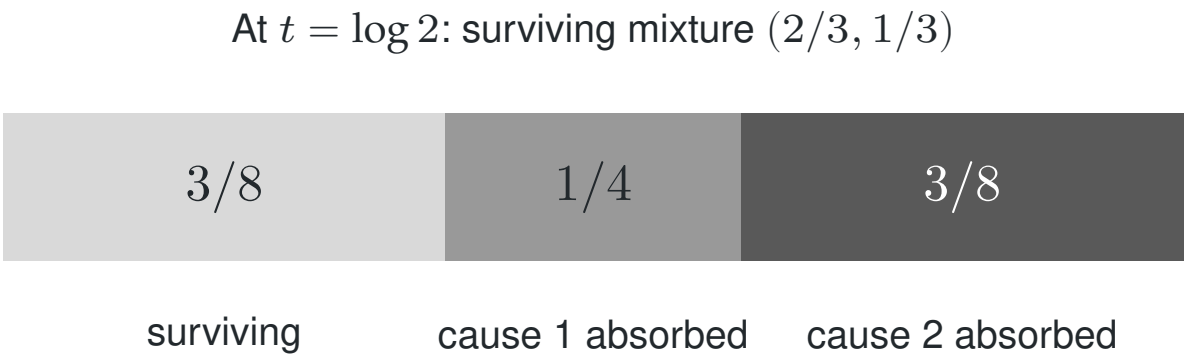
$$\dot{x}(t) = ax(t) + Be^{tD}y(0) + \int_0^t (t-r)e^{-2(t-r)}x(r)\,dr.$$

The convolution-only version is exact for $y(0) = 0$. For a nonzero preparation, $Be^{tD}y(0) = e^{-2t}(y_1(0) + ty_2(0))$ is an additional forcing.

The highest pole coefficient is nonzero in this example. A hidden Jordan block can become invisible to a transfer function if its entrance or exit coupling annihilates that coefficient. Pole order is therefore bounded by hidden Jordan depth, with equality requiring a visible highest term.

> **Read this as:** A polynomial-exponential kernel has a concrete finite state realization when the matrices are supplied. This does not realize every possible memory law with finitely many states.

Plate VI.40 / COMPETING RISKS / RESIDUAL LIFE



Survivors have a different mixture of causes

Chapter VI, Part II: Proposition E16.4 and Theorem E16.5. This example is stable and absorbs surely.

Two transient states have no internal transitions. Their exit rates are 1 and 2, their initial masses are both $1/2$, and the two states exit by distinct causes. Thus

$$A = \operatorname{diag}(-1, -2), \qquad S(t) = \tfrac{1}{2}e^{-t} + \tfrac{1}{2}e^{-2t},$$

with cause densities $f_1(t) = e^{-t}/2$ and $f_2(t) = e^{-2t}$.

At $t = \log 2$, surviving mass is $3/8$. Cause 1 has accumulated probability $1/4$ and cause 2 has accumulated probability $3/8$. The three pieces sum to one.

Condition on survival before restarting the clock

At this time the transient masses are $(1/4, 1/8)$, so the conditional distribution of survivors is $(2/3, 1/3)$. Consequently

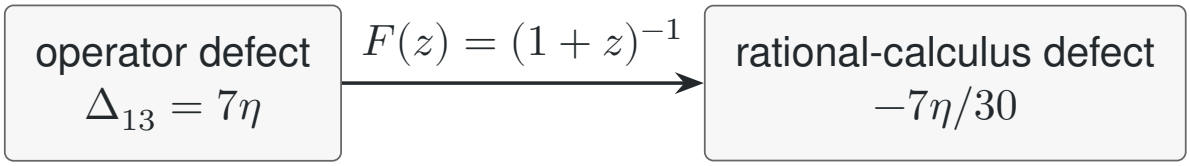
$$\frac{S(t+s)}{S(t)} = \frac{2}{3}e^{-s} + \frac{1}{3}e^{-2s}, \qquad \mathbb{E}[\tau - t \mid \tau > t] = \frac{2}{3} + \frac{1}{6} = \frac{5}{6}.$$

The original mean lifetime was $\frac{1}{2} \cdot 1 + \frac{1}{2} \cdot \frac{1}{2} = 3/4$. Surviving longer changes the mixture toward the slower state. It does not restart the original mixture.

The cause densities at $t = \log 2$ both equal $1/4$, so the cause-specific hazards are both $2/3$ and total hazard is $4/3$. Hazards are rates and need not lie in $[0, 1]$. Each eventual cause probability is $1/2$, obtained by integrating its density. Stability of the subgenerator is part of that eventual-absorption statement.

> **Read this as:** Residual life restarts the same transient semigroup from the conditional surviving distribution. Cause probabilities, densities, and hazards answer different questions.

Plate VI.41 / FUNCTIONAL CALCULUS / AN EXACT RATIONAL TEST



An operator substitution transports the defect too

Chapter VI, Part II: Theorem E3.4; compare Chapter VI, Part I, Theorem 15.1, and Plate VI.25.

Use the operators from Plate VI.25, but perturb the rectangular comparison map:

$$A = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 9 \end{pmatrix}, \quad B = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}, \quad C_\eta = \begin{pmatrix} 1 & 0 & \eta \\ 0 & 1 & 0 \end{pmatrix}.$$

The generator defect is $\Delta = C_\eta A - BC_\eta$, with only one nonzero entry, $\Delta_{13} = 7\eta$ (matrix indices begin at one).

Left inverse factor $1/3$ Right inverse factor $1/10$ Sign $-$

At $\eta = 0$: both defects vanish exactly

The perturbation lets the discarded eigenvalue enter the comparison. Exact naturality holds at $\eta = 0$. A nonzero defect is transformed, not erased, by the rational calculus.

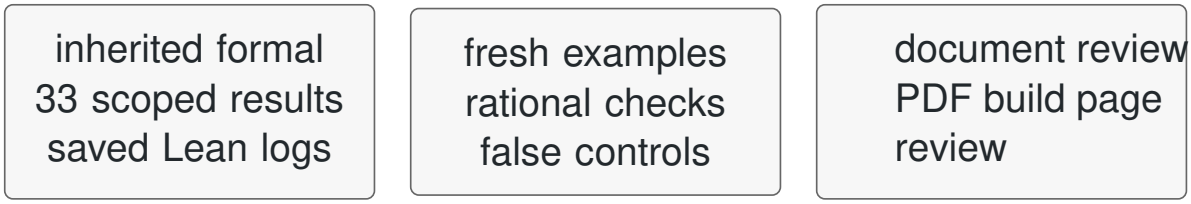
A resolvent identity supplies the sign and both inverse factors

For $F(z) = 1/(1+z)$, all required inverses exist, and

$$C_\eta F(A) - F(B)C_\eta = -(I+B)^{-1}\Delta(I+A)^{-1} = \begin{pmatrix} 0 & 0 & -7\eta/30 \\ 0 & 0 & 0 \end{pmatrix}.$$

This follows by multiplying the difference by $I+B$ on the left and $I+A$ on the right. The middle numerator is $(I+B)C_\eta - C_\eta(I+A) = -\Delta$.

The retained Jordan block still contributes $F'(2) = -1/9$, as on Plate VI.25. The new third-column discrepancy compares $F(9) = 1/10$ with $F(2) = 1/3$, multiplied by η.



The general holomorphic defect formula integrates the corresponding resolvent defect under its contour and spectral assumptions. This rational example verifies an actual matrix inverse identity. It does not remove those analytic hypotheses or establish a calculus for arbitrary unbounded operators.

> **Read this as:** Exact intertwining gives exact naturality. When intertwining fails, the functional calculus has a structured defect whose factors can be computed.

Plate VI.42 / EVIDENCE MAP / FORMAL RECORDS AND FINITE EXAMPLES

How to read the evidence

Chapter VI formal companion: source, execution, and example records.

The three evidence tracks have distinct scopes. The formal contract, exact examples, and PDF assembly have separate verification records.

Read the records without adding incompatible counts

The recorded symbolic suite reports 204 exact or symbolic checks and 11 rejected false controls for its 28-page atlas. The scripts and saved report remain available. The recorded monograph review reran the original symbolic suite with SymPy and mpmath. Its recorded inputs, outputs, resource limits, and execution logs accompany the current result.

The recorded monograph review also reran the separate standard-library exact checker for Plates VI.29–VI.41. It uses rational matrices, finite polynomial algebra, Gaussian moments, and rational coefficients of logarithms. It checks the stated finite examples and rejects deliberately false alternatives. Its report records 120 assertions and 8 rejected false controls. A separate recorded verification reran 182 rational assertions and 4 rejected false controls for selected inherited models. That narrower check overlaps the full symbolic replay and remains separate from its count.

The new checks do not numerically certify improper integrals, all time horizons, or every analytic theorem. For example, the integrated memory weights use the stated exponential-integral formula. The checker verifies its coefficients and finite selection problem. Gaussian polynomial checks do not prove Hermite completeness. Rational entropy coefficient identities do not replace the general support-sensitive chain rule.

The formal and editorial boundaries stay separate

The inherited Lean record covers 33 scoped results with 341 supporting theorem declarations in 47 proof modules. This guide neither enlarges that denominator nor claims a fresh kernel build. Traditional Part II retains broader written proofs. Part III retains earlier complementary results and the operator-substitution material migrated from Chapter IV. The formal companion maps their relationship to the formal baseline.

All 40 plates are editable vector sources: the 26 original plates plus 14 editorial plates. The portable build compiles the shipped geometry without needing symbolic regeneration. The supplied models and Python generators were used to regenerate all forty plates. Geometry samples remain drawing coordinates rather than additional analytic proofs.

> Read this as: Read every proof, verification record and finite computation at its stated scope.

CHAPTER VII

Quantum Seeds and Effective Dynamics

Symmetry, geometric transport, quantum channels, and bounded refinement towers

The transfer viewpoint is now developed in quantum settings with their own algebraic and dynamical assumptions.

Quantum seeds generate spaces through an operator grammar. Symmetry, circuits, geometric transport and quantum channels lead to finite effective dynamics and bounded refinement questions.

IN THIS CHAPTER

Mathematical text 660

Visual studies 772

Formal companion 2054

Sources and references 2681

Scope

The finite formal contract does not certify the full continuum physics program. Anomaly-free refinement, uniform Feshbach control, Lorentzian reconstruction and the proposed gravitational limits remain open.

The next chapter turns to algorithms, separating exact structural reductions from numerical and hardware questions.

How to use this volume

Part I. The finite quantum seed calculus develops the packet language and states the precise scope of the archived formal proof.
Part II. The strengthened development extends this language through seventy-nine theorem, proposition, lemma, and corollary proofs.
Part III. Six supplements give the detailed mathematical constructions behind the formal proofs, followed by three alternative derivations.
Part IV. Forty worked visual pages connect the formulas to finite models and identify the hypotheses needed at each continuum boundary.

Reading this chapter

A seed is useful only together with the operators allowed to act on it. Chapter VII follows that principle through symmetry packets, quantum circuits, moving projectors, channels, effective dynamics, and refinement. The finite calculus in Part I supplies the common language. The strengthened development in Part II gives broader bounded constructions and limit criteria. Part III supplies the detailed proof completions.

The finite results use the prefix I. The bounded development uses II, and the supplementary constructions use III. This local numbering distinguishes their hypotheses and provides stable references throughout the chapter. Some constructions appear in more than one setting because the ambient spaces and conclusions differ.

The formal companion covers nineteen scoped manuscript items through 323 supporting Lean theorem declarations in twenty-five modules. The bounded development in Part II is outside that contract for nineteen items. The companion states the exact hypotheses, source declarations and verification provenance.

Five explicitly named conjectures remain open in the finite core: anomaly-free refinement, uniform Feshbach control, Lorentzian reconstruction, the Einstein infrared limit, and massless spin-two packets. Bounded direct limits and norm limits provide useful criteria. Each physical target still needs the additional structure stated in its conjecture.

Four distinctions to keep in view

A seed's algebraic orbit is different from a unitary state-preparation orbit. Compression is different from an effective resolvent. A normalized channel is different from an unnormalized error family. A finite spectrum is different from a continuum particle interpretation. Keeping these distinctions visible makes the later results easier to use.

Read Part I first for the packet grammar and the finite statements. Turn to Part II for bounded operator transport, spectral and channel constructions, and refinement towers. Use Part III when the geometric bundle construction or a formal specialization needs more detail. The visual atlas follows the same topics through explicit examples. It illustrates the statements with finite data and does not replace their proofs.

Part I Finite quantum seed calculus

A route through this section

The finite core starts with seed rank, then resolves symmetry and circuit transfer into packets. Its geometric statements use the actual range bundle, including the Lie-bracket term. Its channel and Feshbach statements keep normalization and invertibility visible. The three examples below introduce those distinctions with exact finite data.

Three exact finite models

A seed remembers multiplicity support

For $M_2(\mathbb{C}) \otimes I_3$, a coefficient matrix with rank one generates an orbit of dimension two. A matrix of rank two generates an orbit of dimension four. Neither single seed spans the full space of dimension six, because a 2×3 matrix cannot have rank three. Two seeds can nevertheless cover all three multiplicity coordinates together. The example illustrates the finite seed rank formula with $d = 2$ and $m = 3$.

Seed rank measures the available multiplicity support

```
C1 = [[1, 0, 0], [0, 0, 0]]

C2 = [[1, 0, 0], [0, 1, 0]]

C3 = [[0, 0, 1], [0, 0, 0]]

C2 and C3 cover all 3 columns.
```

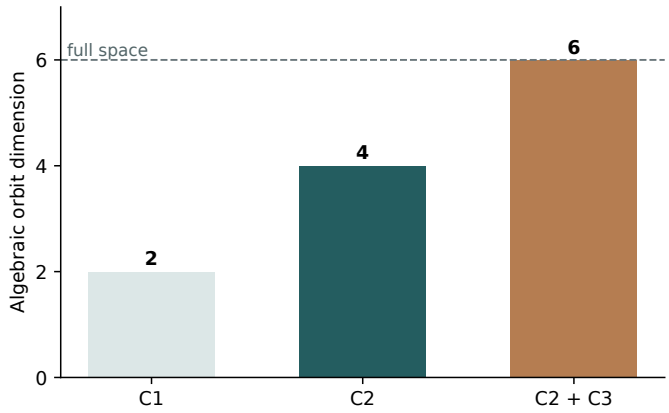


Figure 1. The figure displays exact coefficient matrices for $d = 2$, $m = 3$. The combined row support of two seeds has rank three. The bar heights record algebraic orbit dimensions and should not be read as probabilities of unitary state preparation.

An eliminated coordinate still contributes

Take $H = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 3 \end{smallmatrix}\right)$ and retain its first coordinate. The eliminated block is invertible and the Schur complement of H is $2 - 1/3 = 5/3$. Its inverse is $3/5$, exactly the retained entry of H^{-1}. Inverting the compressed entry alone gives $1/2$. The difference records the contribution of a path through the eliminated coordinate. Direct compression omits that contribution, while block inversion retains it.

Block inversion includes the discarded coordinate

```
H = [[2, 1], [1, 3]]

Schur complement of H:

2 - 1/3 = 5/3

Retained entry of H inverse:

(5/3) inverse = 3/5
```

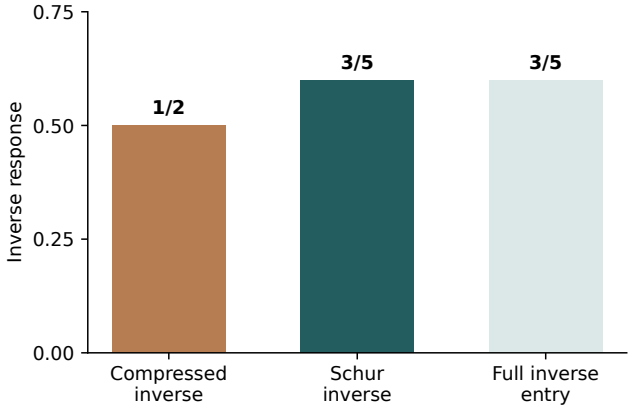

Figure 2. This rational model uses two coordinates to illustrate block inversion. Both the eliminated block and the full operator are invertible, and the plotted values are exact fractions. The example shows why direct compression and resolvent elimination give different results.

Normalization changes the map

Let $P = |0\rangle\langle 0|$ on $\mathbb{C}^2$ and $Z = \mathrm{diag}(1, -1)$. The normalized Kraus family $\sqrt{3/4}\, I$, $\sqrt{1/4}\, Z$ satisfies $\sum_j K_j^* K_j = I$ and maps P to P. The unnormalized family $\sqrt{3}\, I$, Z satisfies $\sum_j E_j^* E_j = 4I$ and maps P to $4P$. The two families have the same relative weights, but their total normalization differs. Both outputs are proportional to the same projector, but their traces differ.

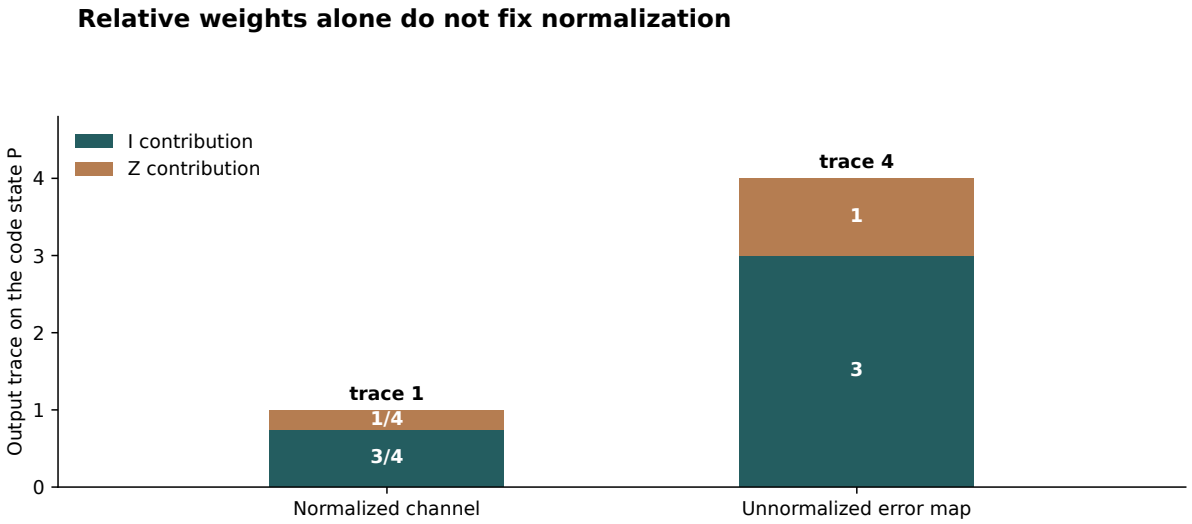

Figure 3. The figure shows exact weights for one supported code state. The normalized map preserves trace one, while the unnormalized positive map has output trace four. The illustration records this finite scaling distinction and does not assert a general recovery construction.

I.1 The quantum seed realization

Conventions. Unless the zero space is explicitly included as a boundary case, quantum state spaces are nonzero complex Hilbert spaces of finite dimension. A complete packet family is a finite collection satisfying

$$P_\alpha^* = P_\alpha, \qquad P_\alpha P_\beta = \delta_{\alpha\beta} P_\alpha, \qquad \sum_\alpha P_\alpha = I.$$

All operator norms in the analytic estimates are induced by the norm on the Hilbert space. The estimates do not use the entrywise maximum norm or the Frobenius norm. We write $[A, B] = AB - BA$ and use units with $\hbar = 1$. Parameter derivatives are real derivatives. A matrix X is supported on a code projector P when $PXP = X$.

The common operator sequence of the series becomes

quantum seed $\longrightarrow$ gate or observable address $\longrightarrow$ symmetry projection $\longrightarrow$ packet transfer $\longrightarrow$ constraint $\longrightarrow$ refinement $\longrightarrow$ reconstruction

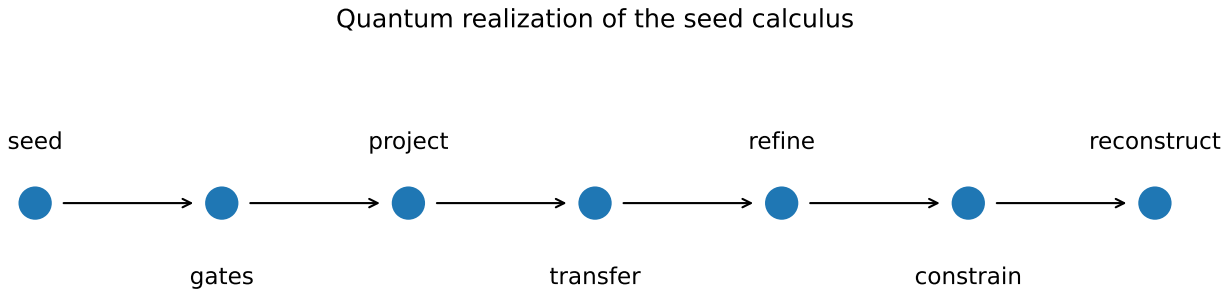

Figure 4. The diagram shows the quantum realization of the common sequence of operators in the seed calculus. The same finite packet language describes states, gates, Hamiltonians, channels, geometric projectors, and effective dynamics.

Definition I.1.1 (Finite quantum seed system)**.** A finite quantum seed system is a tuple

$$\mathfrak{Q} = \left(\mathcal{H}, \psi_0, \mathcal{O}, \mathcal{R}, \{P_{\ell,\alpha}\}, H, \tau\right),$$

where $\mathcal{H}$ is a finite-dimensional Hilbert space, $\psi_0 \in \mathcal{H}$ is a nonzero seed, $\mathcal{O}$ is the declared operator grammar, $\mathcal{R}$ is a collection of algebraic or physical constraints, $\{P_{\ell,\alpha}\}$ is an exact packet system at each refinement level, $H = H^*$ is a Hamiltonian when dynamics are present, and τ specifies the topology used in a later completion.

The generated state space is

$$\mathcal{H}(\psi_0; \mathcal{O}) = \operatorname{span}\left\{O_r \cdots O_1 \psi_0 : O_j \in \mathcal{O},\ r \geq 0\right\}.$$

The quantum seed is cyclic for the grammar when

$$\mathcal{H}(\psi_0;\mathcal{O}) = \mathcal{H}.$$

This is a statement about the pair $(\psi_0, \mathcal{O})$, not about the vector alone. A state may be cyclic for the full matrix algebra and noncyclic for a restricted physical gate set.

I.2 Quantum seed rank and cyclicity

I.2.1 Finite observable algebras

Let a finite-dimensional unital $*$-subalgebra of operators act in its standard multiplicity form

$$\mathcal{A} \cong \bigoplus_{i=1}^{r} \left(M_{d_i}(\mathbb{C}) \otimes I_{m_i} \right)$$

on

$$\mathcal{H} \cong \bigoplus_{i=1}^{r} \left(\mathbb{C}^{d_i} \otimes \mathbb{C}^{m_i} \right).$$

Here every d_i is a positive integer and every multiplicity m_i is a nonnegative integer. An empty block family represents the zero space and has seed rank zero. The maximum over an empty block family is also assigned the value zero. A vector $\psi_i \in \mathbb{C}^{d_i} \otimes \mathbb{C}^{m_i}$ is identified with a $d_i \times m_i$ coefficient matrix C_i.

Theorem I.2.1 (Orbit dimension of one quantum seed). *For integers $d \geq 1$ and $m \geq 0$, consider the action of $M_d(\mathbb{C}) \otimes I_m$ on $\mathbb{C}^d \otimes \mathbb{C}^m$. Let C be the coefficient matrix of a vector ψ. Then*

$$\boxed{\dim \operatorname{span}\{(A \otimes I_m)\psi : A \in M_d(\mathbb{C})\} = d \operatorname{rank} C.}$$

The seed is cyclic if and only if $\operatorname{rank} C = m$*, which is possible only when $m \leq d$.*

Proof. Under the identification by coefficient matrices, $(A \otimes I_m)\psi$ corresponds to AC. Every row of AC lies in the row space of C. Conversely, any $d \times m$ matrix whose rows lie in the row space of C equals AC for a suitable A: choose each row of A to produce the desired row combination. The orbit therefore consists of all matrices with d independently chosen rows in the $\operatorname{rank} C$-dimensional row space of C, and has dimension $d \operatorname{rank} C$. It equals the full dm-dimensional space exactly when $\operatorname{rank} C = m$. □

Theorem I.2.2 (Quantum seed-rank formula). *For*

$$\mathcal{A} = \bigoplus_i (M_{d_i}(\mathbb{C}) \otimes I_{m_i}) \quad \text{on} \quad \mathcal{H} = \bigoplus_i (\mathbb{C}^{d_i} \otimes \mathbb{C}^{m_i}),$$

the minimum number of seeds required to generate $\mathcal{H}$ is

$$\boxed{\operatorname{srank}_{\mathcal{A}}(\mathcal{H}) = \max_i \left\lceil \frac{m_i}{d_i} \right\rceil.}$$

Proof. Each seed contributes a coefficient matrix of rank at most d_i in the ith block. Thus k seeds can cover at most a kd_i-dimensional subspace of the multiplicity factor $\mathbb{C}^{m_i}$, so $k \geq \lceil m_i/d_i \rceil$ for every i.

For the converse, take

$$k = \max_i \left\lceil \frac{m_i}{d_i} \right\rceil .$$

In each block, partition a basis of $\mathbb{C}^{m_i}$ into at most k groups of size at most d_i. Choose the coefficient matrix of seed a so that its nonzero rows span the ath group. The combined row spaces of the k seeds then span $\mathbb{C}^{m_i}$ in every block. The preceding theorem shows that their $\mathcal{A}$-orbits generate the whole direct sum. □

Corollary I.2.3 (Local orbit and Schmidt rank)**.** *Let $\psi \in \mathcal{H}_A \otimes \mathcal{H}_B$, with $\dim \mathcal{H}_A = d_A \geq 1$, and let r be its Schmidt rank. The reduced positive operator on B is $\rho_B = \mathrm{Tr}_A(|\psi\rangle\langle\psi|)$. Normalization of ψ does not affect its support. Then*

$$\boxed{\dim \mathrm{span}\{(A \otimes I_B)\psi : A \in M_{d_A}(\mathbb{C})\} = d_A r.}$$

In particular, local operators on A generate the complete bipartite Hilbert space exactly when the reduced state on B has full support.

Proof. A Schmidt decomposition of length r gives a coefficient matrix of rank r. Applying Theorem I.2.1 gives the orbit dimension $d_A r$. The range of ρ_B is the span of the r Schmidt vectors on B, so full support is equivalent to $r = \dim \mathcal{H}_B$. Because $d_A > 0$, this is equivalent to the orbit having the full bipartite dimension. □

The conclusion concerns the algebraic span obtained from arbitrary local operators. A normalized unitary gate orbit need not contain every vector, and the span statement does not supply a deterministic protocol for preparing arbitrary remote states. Entanglement controls the multiplicity support appearing in that algebraic span.

I.2.2 A computational-basis seed

Theorem I.2.4 (One seed for the computational basis)**.** *For an integer $n \geq 0$, let*

$$\psi_0 = |0\rangle^{\otimes n}$$

and let X_j denote the Pauli X operator on qubit j. Then

$$\{X_1^{a_1} \cdots X_n^{a_n} \psi_0 : (a_1, \ldots, a_n) \in \{0,1\}^n\}$$

is the complete computational basis. Hence the seed is cyclic under the algebra generated by the X_j.

Proof. For a binary address $a = (a_1, \ldots, a_n)$,

$$X_1^{a_1} \cdots X_n^{a_n} |0 \cdots 0\rangle = |a_1 \cdots a_n\rangle .$$

Distinct binary addresses produce distinct orthonormal basis vectors. There are 2^n of them, equal to the dimension of the Hilbert space. □

Recorded Numerical Check I.2.5 (Three-qubit seed orbit). The original numerical implementation generated all eight computational basis states from $|000\rangle$ using the three local X address operators. It reported an orbit rank of $8/8$.

I.3 Cyclic symmetry packets

I.3.1 Character projectors

Let $N \geq 1$ be an integer, and let S be a unitary symmetry whose order divides N:

$$S^N = I.$$

Set $\omega = e^{2\pi i/N}$.

Theorem I.3.1 (Cyclic quantum projectors). *The operators*

$$\boxed{P_j = \frac{1}{N}\sum_{r=0}^{N-1} \omega^{-jr} S^r, \qquad 0 \leq j < N,}$$

are self-adjoint, pairwise orthogonal projectors satisfying

$$P_j P_k = \delta_{jk} P_j, \qquad \sum_{j=0}^{N-1} P_j = I, \qquad S P_j = \omega^j P_j.$$

Proof. Using $S^{r+s} = S^{r+s \bmod N}$ and the finite character orthogonality relation,

$$\frac{1}{N}\sum_{r=0}^{N-1} \omega^{(k-j)r} = \delta_{jk},$$

we obtain $P_j P_k = \delta_{jk} P_j$. Summing over j cancels every term indexed by $r \neq 0$ and retains the $r = 0$ term, which proves completeness. Unitarity and the change of residue $r \mapsto -r$ give

$$P_j^* = \frac{1}{N}\sum_{r=0}^{N-1} \omega^{jr} S^{-r} = P_j.$$

Finally, multiplication by S shifts the summation index and contributes the factor ω^j. □

For parity,

$$S = Z^{\otimes n}, \qquad P_{\text{even}} = \frac{I+S}{2}, \qquad P_{\text{odd}} = \frac{I-S}{2}.$$

I.3.2 Tensor refinement

Fix $N \geq 1$. Suppose every factor a has a complete orthogonal family $P_0^{(a)}, \dots, P_{N-1}^{(a)}$. The fine tensor packets are

$$P_{\mathbf{j}}^{\text{fine}} = P_{j_1}^{(1)} \otimes \cdots \otimes P_{j_m}^{(m)}.$$

Theorem I.3.2 (Tensor/polyphase refinement). *For each residue $r \in \mathbb{Z}/N\mathbb{Z}$, define*

$$\boxed{P_r^{\text{coarse}} = \sum_{j_1+\cdots+j_m \equiv r \pmod N} P_{j_1}^{(1)} \otimes \cdots \otimes P_{j_m}^{(m)}.}$$

Then the P_r^{coarse} are complete orthogonal projectors, and every coarse packet is the exact sum of its fine descendants.

Proof. The fine tensor projectors are mutually orthogonal and sum to the identity. Grouping the fine addresses by their total residue partitions the full address set. Sums over disjoint sets of orthogonal projectors remain orthogonal projectors, and the union of the residue classes is the full fine address set. □

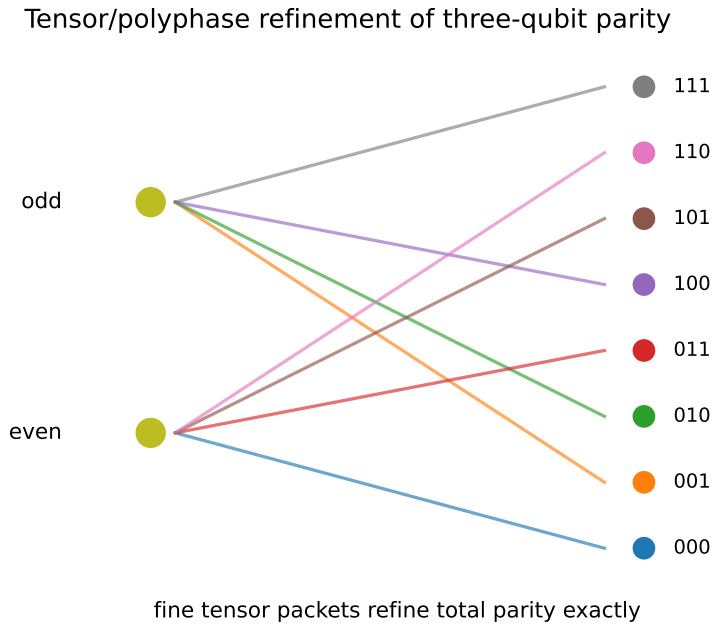

Figure 5. The eight computational packets of three qubits refine the two total-parity packets exactly.

Recorded Numerical Check I.3.3 (Exact parity refinement). For three qubits, the local computational projectors were grouped by the parity of their Hamming weight. The resulting coarse projectors agreed with $(I \pm Z^{\otimes 3})/2$ with residual 0.

I.4 Quantum circuits as packet paths

Let

$$U = U_m U_{m-1} \cdots U_1$$

be a circuit with $m \geq 1$, and let $\{P_\alpha\}$ be a complete packet system. For the empty circuit $m = 0$, set $U = I$. Its boundary block is $P_\beta P_\alpha = \delta_{\beta\alpha} P_\alpha$.

Theorem I.4.1 (Exact circuit path expansion). *For source packet α_0 and target packet α_m,*

$$\boxed{P_{\alpha_m} U P_{\alpha_0} = \sum_{\alpha_1,\ldots,\alpha_{m-1}} P_{\alpha_m} U_m P_{\alpha_{m-1}} \cdots P_{\alpha_1} U_1 P_{\alpha_0}.}$$

Summing over the source and target packets reconstructs the complete circuit operator.

Proof. Insert the identity resolution $I = \sum_\alpha P_\alpha$ between every adjacent pair of gates. Distributing the finite sums gives the path expansion. Summing the left and right boundary projectors reconstructs U. □

Theorem I.4.2 (Packetwise unitarity conservation). *If U is unitary and $U_{\beta\alpha} = P_\beta U P_\alpha$, then*

$$\boxed{\sum_\beta U^*_{\beta\alpha} U_{\beta\gamma} = \delta_{\alpha\gamma} P_\alpha.}$$

Similarly,

$$\sum_\alpha U_{\beta\alpha} U^*_{\delta\alpha} = \delta_{\beta\delta} P_\beta.$$

Proof. Using completeness and unitarity,

$$\sum_\beta U^*_{\beta\alpha} U_{\beta\gamma} = P_\alpha U^* \left(\sum_\beta P_\beta \right) U P_\gamma = P_\alpha P_\gamma.$$

For the second identity, sum over the source packets and use unitarity in the reverse order. □

Example I.4.3 (Bell seed circuit). In this example only, H denotes the Hadamard gate, not a Hamiltonian. Starting from $|00\rangle$,

$$(H \otimes I)\,|00\rangle = \frac{|00\rangle + |10\rangle}{\sqrt{2}},$$

and then

$$\mathrm{CNOT}(H \otimes I)\,|00\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}}.$$

The parity packets show that the final state lies entirely in the even sector, while the intermediate circuit path passes through both even and odd addresses.

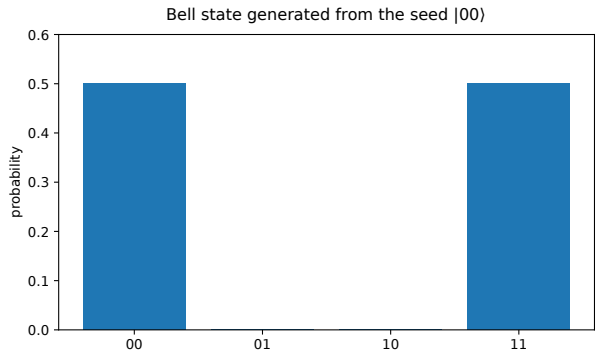

Figure 6. The Bell state generated from the seed $|00\rangle$.

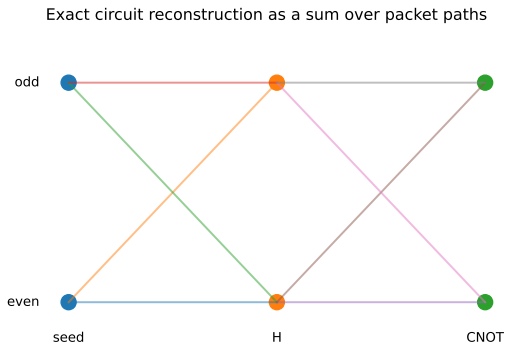

Figure 7. Circuit reconstruction as a sum over packet paths.

Recorded Numerical Check I.4.4 (Bell and path reconstruction). The original numerical implementation reported residuals of 0 for both the Bell state and its complete reconstruction from parity paths.

I.5 Symmetry-resolved Hamiltonians and leakage

Let $H = H^*$ and let P be a packet projector. If $[H, P] = 0$, then $P\mathcal{H}$ is invariant under e^{-itH}.

Theorem I.5.1 (Exact symmetry packets). *If $[H, P_\alpha] = 0$ for every packet, then*

$$H = \sum_\alpha P_\alpha H P_\alpha$$

and

$$e^{-itH} = \sum_\alpha P_\alpha e^{-itH} P_\alpha.$$

No amplitude transfers between distinct packets.

Proof. The commutation relation gives $P_\beta H P_\alpha = 0$ for $\beta \neq \alpha$. Every polynomial in H has the same block form, and the finite-dimensional exponential is the norm limit of its polynomial series. □

For two qubits and real parameters J, h, consider

$$H = JX \otimes X + h(Z \otimes I + I \otimes Z).$$

In the ordered even basis $\{|00\rangle, |11\rangle\}$ and odd basis $\{|01\rangle, |10\rangle\}$,

$$H_{\text{even}} = \begin{pmatrix} 2h & J \\ J & -2h \end{pmatrix}, \qquad H_{\text{odd}} = \begin{pmatrix} 0 & J \\ J & 0 \end{pmatrix}.$$

Therefore

$$\operatorname{Spec} H_{\text{even}} = \{\pm\sqrt{4h^2 + J^2}\}, \qquad \operatorname{Spec} H_{\text{odd}} = \{\pm J\}.$$

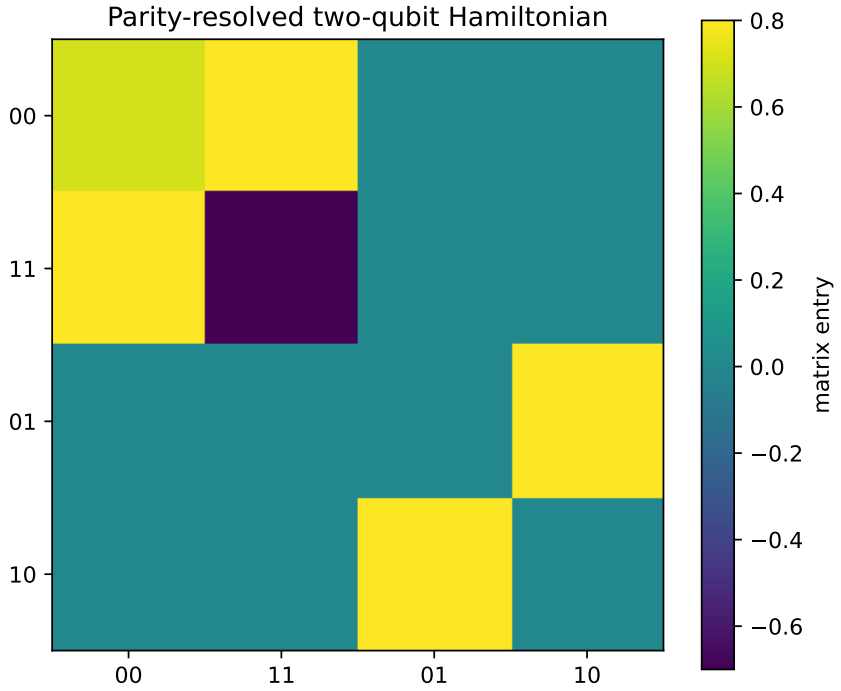

Figure 8. The Hamiltonian becomes exactly block diagonal when the even and odd basis vectors are grouped.

I.5.1 Leakage under broken symmetry

Set $Q = I - P$.

Theorem I.5.2 (Commutator leakage bound). *For every self-adjoint H, orthogonal projector P, and real time t,*

$$\boxed{\left\|Qe^{-itH}P\right\| \le |t|\ \|[H,P]\|\,.}$$

In particular, exact commutation gives zero leakage for all time.

Proof. Set $F(s) = e^{isH}Pe^{-isH}$. Differentiating the exponential gives

$$F'(s) = i\,e^{isH}[H,P]e^{-isH}, \qquad F(0) = P.$$

Unitary conjugation preserves the operator norm, so $\|F'(s)\| = \|[H,P]\|$. The mean-value estimate on the interval between 0 and t yields

$$\|F(t) - P\| \le |t|\,\|[H,P]\|.$$

Finally, $e^{itH}Qe^{-itH}P = (P - F(t))P$ and $\|P\| \le 1$. Left multiplication by e^{itH} preserves the norm and gives the desired inequality. This argument includes positive, negative and zero time. □

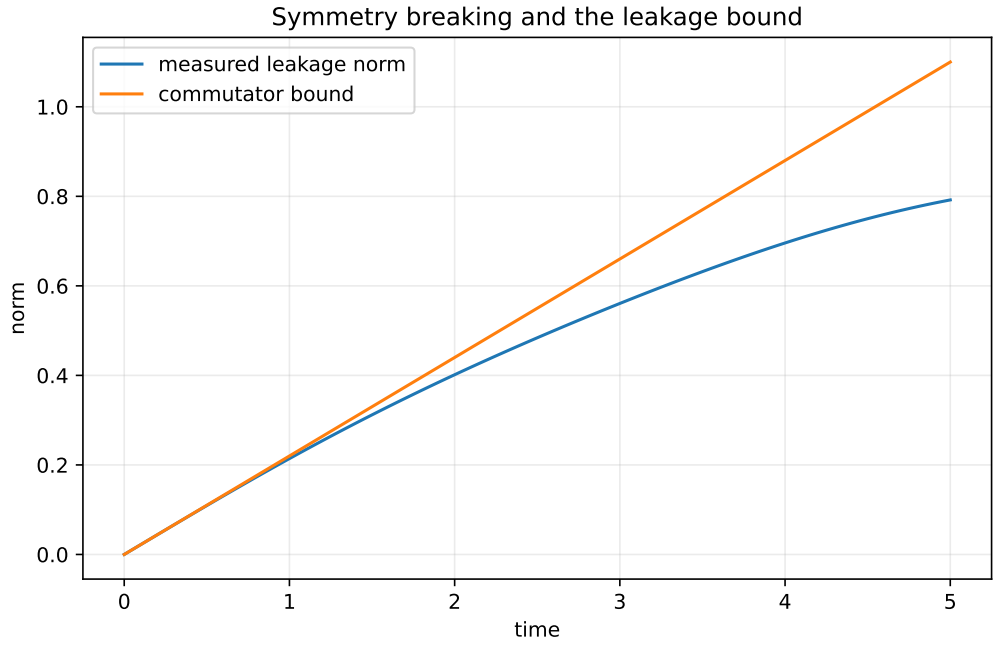

Figure 9. A perturbation that breaks parity creates nonzero transfer between the packets. The measured leakage remains below the commutator bound.

Recorded Numerical Check I.5.3 (Symmetry and negative control). For the Hamiltonian that preserves parity, the norm of the block between distinct packets and the maximum measured leakage were both 0. Adding an $X \otimes I$ perturbation broke parity and produced a maximum leakage of approximately 0.79196. The maximum violation of the proved bound remained 0.

I.6 Moving packets, connections, and curvature

I.6.1 Moving quantum coordinates

Theorem I.6.1 (Moving-frame Hamiltonian). *Let $U(t)$ and $\psi(t)$ be differentiable on an open real time interval, let $U(t)$ be unitary, and let $H(t) = H(t)^*$. Suppose*

$$i\dot{\psi}(t) = H(t)\psi(t).$$

Writing

$$\psi(t) = U(t)y(t)$$

gives

$$\boxed{i\dot{y}(t) = \big(U(t)^*H(t)U(t) - iU(t)^*\dot{U}(t)\big)\, y(t).}$$

Both the connection term $-iU^*\dot{U}$ and the effective Hamiltonian $U^*HU - iU^*\dot{U}$ are Hermitian.

Proof. Differentiate $\psi = Uy$:

$$i\dot{U}y + iU\dot{y} = HUy.$$

Multiplying by U^* gives the formula. Differentiating $U^*U = I$ shows $U^*\dot{U}$ is skew-Hermitian, so $-iU^*\dot{U}$ is Hermitian. □

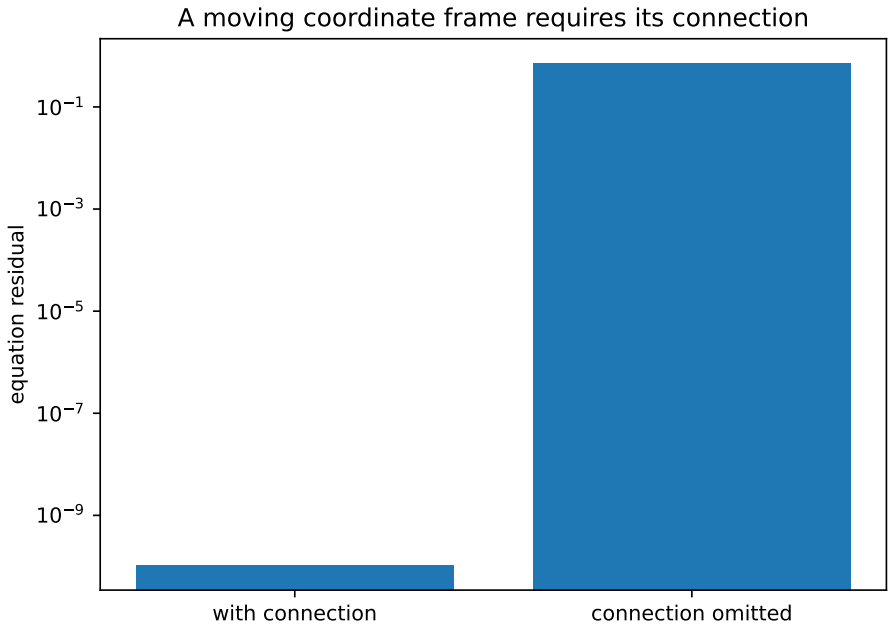

Figure 10. The equation in the moving frame holds to numerical precision only when the connection term is retained.

Recorded Numerical Check I.6.2 (Moving-frame correction). The reported residual for the complete equation in the moving frame was 1.0645×10^{-10}. Omitting the connection increased the residual to 0.7000.

I.6.2 A canonical projector connection

Let $P_1(t), \dots, P_m(t)$ be differentiable on an open real time interval, with $P_a(t)^* = P_a(t)$ and

$$P_a P_b = \delta_{ab} P_a, \qquad \sum_a P_a = I.$$

Theorem I.6.3 (Canonical packet connection). *Define*

$$\boxed{C(t) = \frac{1}{2}\sum_a [\dot{P}_a(t), P_a(t)] = \sum_a \dot{P}_a(t) P_a(t).}$$

Then

$$C(t)^* = -C(t)$$

and

$$\boxed{[C(t), P_b(t)] = \dot{P}_b(t)}$$

for every packet b.

Proof. Differentiating $P_a^2 = P_a$ gives

$$\dot{P}_a P_a + P_a \dot{P}_a = \dot{P}_a.$$

Summing over a and using $\sum_a \dot{P}_a = 0$ yields

$$\sum_a P_a \dot{P}_a = -\sum_a \dot{P}_a P_a,$$

which proves both displayed formulas for C and its skew-Hermiticity.

For fixed b,

$$C P_b = \dot{P}_b P_b.$$

When $a \neq b$, differentiating $P_b P_a = 0$ gives

$$P_b \dot{P}_a = -\dot{P}_b P_a.$$

Hence

$$P_b C = \sum_a P_b \dot{P}_a P_a = -\dot{P}_b (I - P_b),$$

and subtraction gives $[C, P_b] = \dot{P}_b$. □

The connection generates infinitesimal transport of the moving packet frame. The packet family determines it directly, so its construction does not require a basis inside any packet.

I.6.3 Projector curvature

Classical Input I.6.4 (Projected connection). Let M be a smooth finite-dimensional real manifold without boundary, let V be a finite-dimensional real normed vector space, and let $P : M \to \mathrm{End}_{\mathbb{R}}(V)$ be smooth with $P(x)^2 = P(x)$. In the quantum application, V is the underlying real space of a finite complex Hilbert space and P is an orthogonal complex-linear projector.

The rank of P is locally constant. On each open rank region, its ranges form a smooth vector bundle. For a smooth range section s, so that $Ps = s$, define

$$\nabla_X s = P\, ds(X).$$

This is a connection on smooth range sections. For smooth vector fields X, Y, its curvature satisfies

$$\boxed{(\nabla_X \nabla_Y - \nabla_Y \nabla_X - \nabla_{[X,Y]})s = P[dP(X), dP(Y)]P\, s.}$$

Equivalently, its endomorphism-valued curvature is

$$\boxed{F = P(dP \wedge dP)P.}$$

No global frame or globally constant rank is required, and the vector fields need not commute. The geometric formalization concerns real smooth structures. It does not cover complex analytic manifolds or extensions to a boundary.

Proof. Range coordinates. Fix $a \in M$ and put

$$T_a(x) = P(x)P(a) + (I - P(x))(I - P(a)).$$

Then $T_a(a) = I$ and $P(x)T_a(x) = T_a(x)P(a)$. Invertibility is open, so on a neighborhood of a, $T_a(x)$ restricts to an isomorphism from Ran $P(a)$ to Ran $P(x)$. This proves local constancy of rank. The local coordinates and their transitions are

$$(x, v) \longmapsto (x, T_a(x)^{-1}v), \qquad u \longmapsto T_b(x)^{-1}T_a(x)u.$$

Their smoothness follows from smoothness of P and inversion. The transition maps satisfy the cocycle identity by cancellation. These charts construct the smooth range bundles on the open rank regions, including when different connected components have different ranks.

Connection rules. The smoothness of $P\,ds(X)$ and the identity $P^2 = P$ show that $\nabla_X s$ is a smooth range section. Differentiation and projection give

$$\begin{aligned} \nabla_{X+Y}s = \nabla_X s + \nabla_Y s, \qquad \nabla_{fX}s = f\nabla_X s, \\ \nabla_X(s+t) = \nabla_X s + \nabla_X t, \quad \nabla_X(fs) = f\nabla_X s + (Xf)s \end{aligned}$$

for smooth real f. The range coordinates above identify ambient smooth range sections with smooth sections of the constructed bundle.

Curvature. Differentiating $P^2 = P$ gives $P(dP(X))P = 0$. Write $D_X s = ds(X)$. For ambient smooth sections,

$$D_X D_Y s - D_Y D_X s - D_{[X,Y]}s = 0.$$

Expansion of the projected derivatives therefore leaves

$$R(X, Y)s = P(dP(X))D_Y s - P(dP(Y))D_X s.$$

Since $Ps = s$, differentiation gives $D_Y s = (dP(Y))s + PD_Y s$. The terms with a middle P vanish. Thus

$$R(X, Y)s = P\big(dP(X)dP(Y) - dP(Y)dP(X)\big)P\,s.$$

This expression is alternating and bilinear in the tangent vectors, and it preserves the range. The ordinary chain rule and the transformation law for the Lie bracket make the local calculations agree on chart overlaps, which gives the global formula. □

For an orthogonal rank-one complex projector, use the scalar connection convention $A = -i\langle u, du\rangle$ in a local unit frame. The associated scalar curvature density is

$$\mathcal{F}_{\mu\nu} = -i\,\mathrm{Tr}\left(P[\partial_\mu P, \partial_\nu P]\right).$$

On the Bloch sphere,

$$P(\theta, \phi) = \frac{1}{2}\left(I + \mathbf{n}(\theta, \phi)\cdot\sigma\right),$$

where

$$\mathbf{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta).$$

The Pauli multiplication law gives

$$[\partial_\theta P, \partial_\phi P] = \frac{i}{2}(\partial_\theta \mathbf{n} \times \partial_\phi \mathbf{n})\cdot\sigma.$$

Using $\operatorname{Tr}(P\,\mathbf{a}\cdot\sigma)=\mathbf{n}\cdot\mathbf{a}$ therefore yields

$$\boxed{\mathcal{F}_{\theta\phi}=\frac{1}{2}\mathbf{n}\cdot(\partial_\theta\mathbf{n}\times\partial_\phi\mathbf{n})=\frac{1}{2}\sin\theta.}$$

The scalar sign changes if the opposite convention for A is chosen. This explicit calculation is not a separate entry among the 19 items in the Lean register.

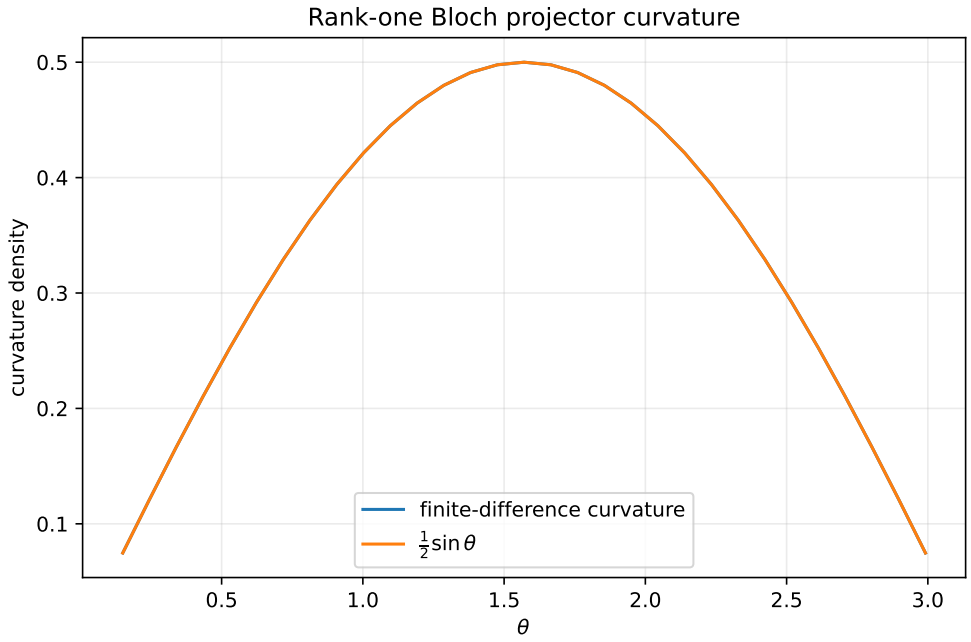

Figure 11. The curvature of the Bloch projector, evaluated by finite differences, is compared with the exact density $\frac{1}{2}\sin\theta$.

Recorded Numerical Check I.6.5 (Geometric packet identities). The canonical connection reconstructed every packet derivative with residual 0. The maximum residual for the Bloch curvature was 2.0803×10^{-11}.

I.7 Measurements and quantum channels

I.7.1 Packet measurements

Let ρ be a density matrix and let $\{E_k\}$ be a POVM:

$$E_k\geq 0,\qquad \sum_k E_k=I.$$

The outcome probabilities are

$$p_k=\operatorname{Tr}(E_k\rho).$$

Theorem I.7.1 (Block-diagonal measurement invariance). *Let $\{P_\alpha\}$ be a complete packet family, and suppose every measurement effect is packet diagonal:*

$$E_k = \sum_\alpha P_\alpha E_k P_\alpha.$$

Define the packet-dephased state

$$\mathcal{D}_P(\rho) = \sum_\alpha P_\alpha \rho P_\alpha.$$

Then

$$\boxed{\mathrm{Tr}(E_k\rho) = \mathrm{Tr}(E_k \mathcal{D}_P(\rho))}$$

for every outcome k.

Proof. Insert the packet decomposition of E_k and use cyclicity of the trace:

$$\mathrm{Tr}(E_k\rho) = \sum_\alpha \mathrm{Tr}(P_\alpha E_k P_\alpha \rho) = \sum_\alpha \mathrm{Tr}(E_k P_\alpha \rho P_\alpha).$$

□

The theorem identifies which coherences a declared measurement can detect. Observables that are diagonal in the packet decomposition cannot detect coherence between distinct packets. Coherence within a packet remains available to such observables.

I.7.2 Kraus transfer

A quantum channel can transfer both populations and coherences between packet addresses. A Kraus representation describes this transfer by summing the contributions of its individual branches. The normalization of those branches ensures that the total trace is preserved.

Classical Input I.7.2 (Finite Kraus channel). Let $K_1, \dots, K_r$ satisfy

$$\sum_a K_a^* K_a = I.$$

Then

$$\boxed{\Phi(\rho) = \sum_a K_a \rho K_a^*}$$

is completely positive and trace preserving.

Proof. Trace preservation follows from

$$\mathrm{Tr}\,\Phi(\rho) = \mathrm{Tr}\left(\rho \sum_a K_a^* K_a\right) = \mathrm{Tr}\,\rho.$$

For any auxiliary dimension and positive matrix X, each term

$$(I \otimes K_a) X (I \otimes K_a)^*$$

is positive, so their sum is positive. This is complete positivity. □

Packet superoperator blocks are defined by

$$\Phi_{\alpha\beta;\gamma\delta}(X) = P_\alpha \Phi(P_\gamma X P_\delta) P_\beta.$$

Summing all four packet indices reconstructs $\Phi(X)$ exactly.

For amplitude damping with a real parameter $0 \le \gamma \le 1$,

$$K_0 = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{1-\gamma} \end{pmatrix}, \qquad K_1 = \begin{pmatrix} 0 & \sqrt{\gamma} \\ 0 & 0 \end{pmatrix}.$$

The excited state becomes

$$\Phi(|1\rangle\langle 1|) = \gamma\,|0\rangle\langle 0| + (1-\gamma)\,|1\rangle\langle 1|\,.$$

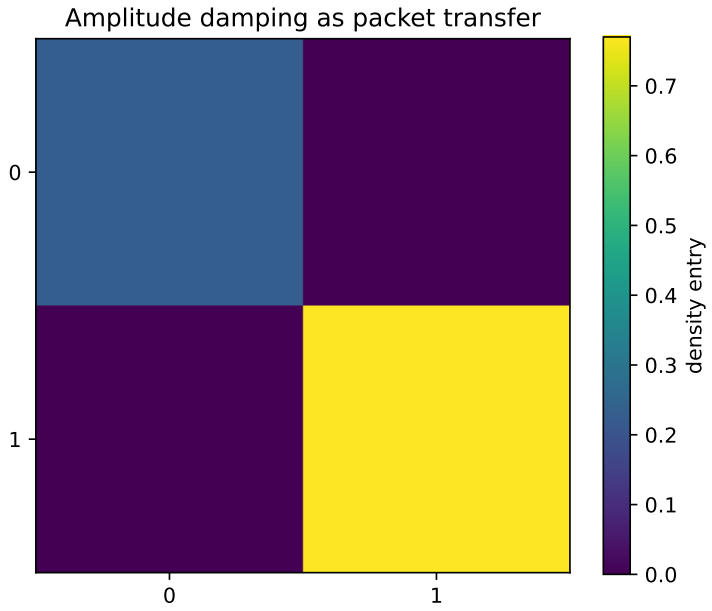

Figure 12. Amplitude damping transfers population from the excited packet to the ground packet while preserving trace and positivity.

Recorded Numerical Check I.7.3 (Channel reconstruction). For $\gamma = 0.23$, the residuals for Kraus completeness and the output trace were 0. The computed output from $|1\rangle\langle 1|$ was $\mathrm{diag}(0.23, 0.77)$. In the Bell state test, packet dephasing left every measurement probability in the computational basis unchanged.

I.8 Quantum error correction as obstruction-packet annihilation

Let $P = P^* = P^2$ project onto a code space $\mathcal{C} \subset \mathcal{H}$, and let $E_1, \dots, E_r$ be a finite family of complex error matrices. Neither a nonzero code nor channel normalization is assumed unless stated. The operators

$$PE_a^* E_b P$$

are the obstruction packets on the code. If they retain information about the logical state beyond one scalar multiple of P, the environment can distinguish logical states and exact correction is impossible.

We call a recovery complete when it is a Kraus map

$$\mathcal{R}(X) = \sum_j K_j X K_j^*, \qquad \sum_j K_j^* K_j = I.$$

The family is *exactly correctable* when one such recovery works for every coherent error combination $A_w = \sum_a w_a E_a$: for every w there is a real $t_w \geq 0$, independent of the logical input, such that

$$PXP = X \quad \Longrightarrow \quad \mathcal{R}(A_w X A_w^*) = t_w X.$$

The coefficient is an unnormalized weight. It is not necessarily a probability for an arbitrary matrix A_w.

Classical Input I.8.1 (Finite Knill–Laflamme criterion). The finite error family is exactly correctable in the sense just defined if and only if there is a positive semidefinite complex matrix $C = (c_{ab})$ such that

$$\boxed{PE_a^* E_b P = c_{ab} P \qquad \text{for every } a, b.}$$

If $\sum_a E_a^* E_a = I$, the equivalent normalized-channel formulation is the existence of a complete recovery satisfying

$$\mathcal{R}\left(\sum_a E_a X E_a^*\right) = X \quad \text{for every } X \text{ with } PXP = X.$$

The zero code and an empty error family are included. An empty family cannot define a channel that preserves trace on a nonzero ambient space.

Proof. Necessity. Fix an error E_a and let $L_j = K_j E_a P$. Perfect recovery on rank-one code operators gives

$$\sum_j |L_j\psi\rangle \langle L_j\psi| = t_a |\psi\rangle \langle\psi| \qquad (\psi \in \mathcal{C}).$$

For every vector orthogonal to ψ, the quadratic form on the left is a sum of nonnegative squared absolute values and equals zero. Each $L_j\psi$ therefore lies in the span of ψ. A linear operator that preserves every line in $\mathcal{C}$ is scalar there: apply it to two independent vectors and their sum. The one-dimensional case is immediate, and the claim is vacuous for the zero code. Consequently

$$K_j E_a P = d_{ja} P.$$

Recovery completeness now gives

$$PE_a^*E_bP = \sum_j (K_jE_aP)^*(K_jE_bP)$$
$$= \left(\sum_j \overline{d_{ja}}d_{jb}\right) P.$$

The coefficients form a Gram matrix, hence are positive semidefinite. For a normalized channel, apply the same rank-one argument to all composite branches K_jE_aP at once to obtain the necessary condition.

Sufficiency. Diagonalize $C = U\,\mathrm{diag}(\lambda_r)U^*$ with U unitary and $\lambda_r \geq 0$. Define compressed transformed errors

$$F_r = \sum_a U_{ar}E_aP.$$

Then $F_rP = F_r$ and $F_r^*F_s = \lambda_r\delta_{rs}P$. If $\lambda_r = 0$, $F_r^*F_r = 0$ forces $F_r = 0$. For positive eigenvalues only, set $V_r = F_r/\sqrt{\lambda_r}$. These satisfy

$$V_rP = V_r, \qquad V_r^*V_s = \delta_{rs}P.$$

Let $S = \sum_{\lambda_r>0} V_rV_r^*$. Orthogonality makes S an orthogonal projector. Use the recovery branches

$$K_r = V_r^*, \qquad K_{\text{unused}} = I - S.$$

They are complete on the whole ambient space because

$$\sum_r K_r^*K_r + K_{\text{unused}}^*K_{\text{unused}} = S + (I-S)^2 = I.$$

The inverse unitary change of coordinates reconstructs each E_aP from the F_r. Every recovery branch of a coherent combination is therefore scalar on the code, while the branch for the unused space vanishes. For all supported matrices, the resulting recovery is

$$\mathcal{R}(A_wXA_w^*) = (w^*Cw)X.$$

This establishes the statement for arbitrary families without assuming normalization. Under $\sum_a E_a^*E_a = I$ and $P \neq 0$, summing the diagonal KL equations gives $\mathrm{Tr}\,C = 1$, so the normalized-channel output is X. When $P = 0$, every supported X is zero and the conclusion is automatic. The recovery is trace preserving by completeness and completely positive at every finite ancillary dimension by the Kraus calculation in Classical Input I.7.2. □

For the three-qubit bit-flip code,

$$|0_L\rangle = |000\rangle\,, \qquad |1_L\rangle = |111\rangle\,,$$

and the error family is

$$I, \quad X\otimes I\otimes I, \quad I\otimes X\otimes I, \quad I\otimes I\otimes X.$$

The four error images of the code are pairwise orthogonal two-dimensional syndrome packets whose projectors sum to the identity on the eight-dimensional Hilbert space.

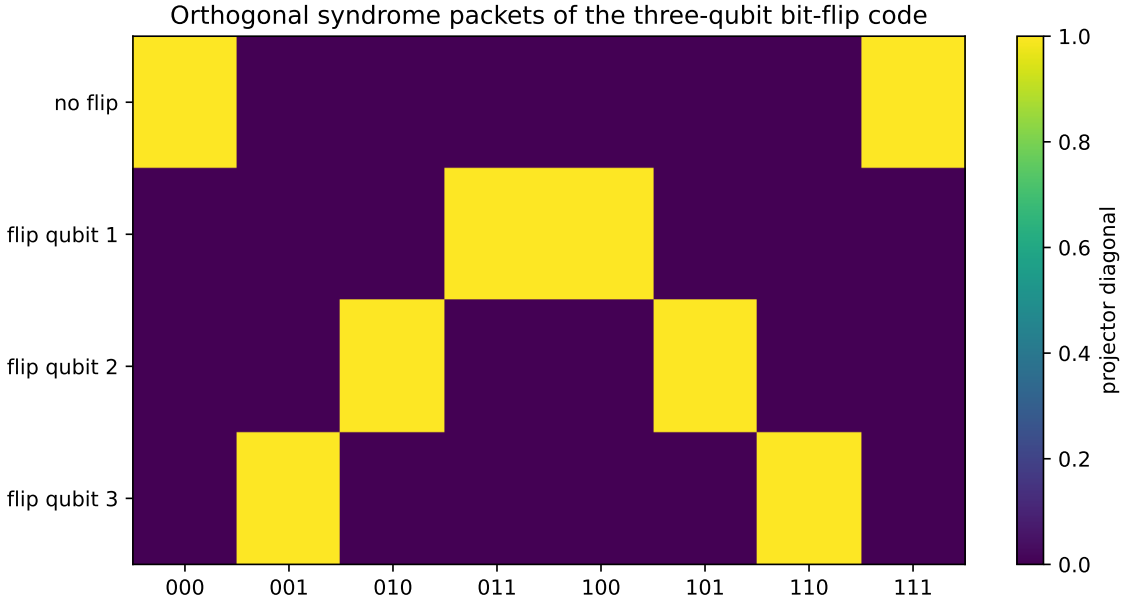

Figure 13. The four orthogonal syndrome packets of the three-qubit bit-flip code. Each packet identifies one correctable error without resolving the encoded logical state.

Recorded Numerical Check I.8.2 (Exact bit-flip correction). The residuals for the Knill–Laflamme condition and completeness of the syndrome packets were both 0. A mixed channel of single bit flip errors, applied to a nontrivial logical superposition, was reversed with a residual of 1.0385×10^{-16} in the density matrix.

I.9 Exact effective dynamics

I.9.1 Schur–Feshbach reduction

Let P be a retained packet projector and $Q = I - P$. In packet coordinates,

$$H = \begin{pmatrix} H_{PP} & H_{PQ} \\ H_{QP} & H_{QQ} \end{pmatrix}.$$

Theorem I.9.1 (Exact Feshbach resolvent). *Assume that both $zI_Q - H_{QQ}$ and $zI - H$ are invertible. Define*

$$\boxed{H_{\text{eff}}(z) = H_{PP} + H_{PQ}(z - H_{QQ})^{-1} H_{QP}.}$$

Then

$$\boxed{P(z - H)^{-1} P = \left(z - H_{\text{eff}}(z)\right)^{-1}}$$

where the left side is restricted to $P\mathcal{H}$, the right side is an inverse on that retained space, and both are written in the same orthonormal basis. Here $z - H_{QQ}$ and $z - H_{\text{eff}}$ abbreviate the appropriately sized scalar matrices minus the indicated blocks.

Proof. The block in the lower right corner of $z - H$ is $z - H_{QQ}$. Gaussian block elimination produces the Schur complement

$$z - H_{PP} - H_{PQ}(z - H_{QQ})^{-1}H_{QP}.$$

The assumed invertibility of this block and of the full matrix implies that the Schur complement is invertible. The block in the upper left corner of the full inverse is the inverse of that Schur complement, which is exactly the displayed operator. □

The second premise cannot be dropped: at $z = 0$ and $H = \mathrm{diag}(0, -1)$, the eliminated block is 1 but $zI - H$ is singular. This counterexample is also included in the Lean module.

The self-energy

$$\Sigma_P(z) = H_{PQ}(z - H_{QQ})^{-1}H_{QP}$$

contains the complete influence of the eliminated packet. Bare truncation drops $\Sigma_P(z)$ and is therefore exact only when the coupling between packets vanishes or the self-energy cancels for another stated reason.

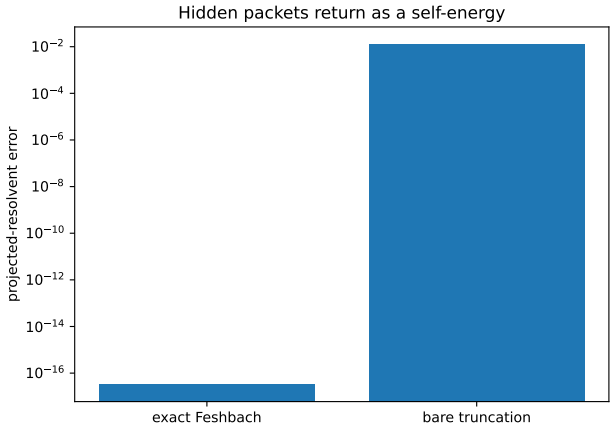

Figure 14. Exact Feshbach reduction versus bare truncation.

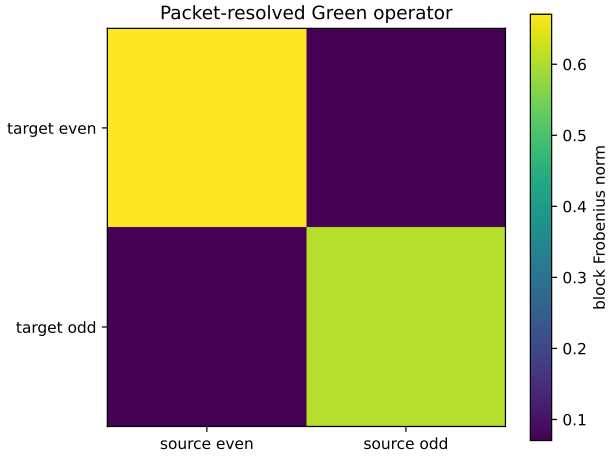

Figure 15. Norms of packet Green-function blocks.

Recorded Numerical Check I.9.2 (Effective resolvent). In the reported test with a random Hermitian matrix of dimension six, the exact Feshbach residual was 3.2291×10^{-17}. The corresponding residual for bare truncation was 1.3091×10^{-2}.

I.9.2 The hidden packet as memory

For a time-independent finite Hamiltonian H and fixed projectors P, Q, write $\psi = x + y$, with $x = P\psi$ and $y = Q\psi$. Then

$$i\dot{x} = H_{PP}x + H_{PQ}y,$$
$$i\dot{y} = H_{QP}x + H_{QQ}y.$$

Solving the second equation gives

$$y(t) = e^{-itH_{QQ}}y(0) - i\int_0^t e^{-i(t-s)H_{QQ}}H_{QP}x(s)\,ds.$$

Substitution yields the exact Volterra equation

$$\boxed{\begin{aligned} i\dot{x}(t) &= H_{PP}x(t) + H_{PQ}e^{-itH_{QQ}}y(0) \\ &\quad - i\int_0^t K(t-s)x(s)\,ds, \end{aligned}}$$

with memory kernel

$$\boxed{K(t) = H_{PQ}e^{-itH_{QQ}}H_{QP}.}$$

The influence of the eliminated degrees of freedom is therefore retained in a self-energy that depends on frequency, or equivalently in an exact memory term. For forward evolution the integral is causal. When the Hamiltonian depends on time, the corresponding propagator between two times replaces the stationary exponential used here. This Volterra derivation is not a separate entry in the finite Lean register.

I.10 Finite quantum geometry

I.10.1 A projector-resolved geometry

At resolution ℓ, define

$$\boxed{\mathfrak{Q}_\ell = \left(\mathcal{A}_\ell, \mathcal{H}_\ell, D_\ell, \{P_{\ell,\alpha}\}, E_\ell, C_\ell, \Pi_\ell^{\mathrm{phys}}, T_\ell\right).}$$

In order, the entries specify the observable algebra, Hilbert space, geometric or Dirac-type operator, packet projectors, embedding into the fine space, reconstruction onto the coarse space, physical constraint projector, and transfer operator. The maps have types $E_\ell : \mathcal{H}_\ell \to \mathcal{H}_{\ell+1}$ and $C_\ell : \mathcal{H}_{\ell+1} \to \mathcal{H}_\ell$. The left inverse relation $C_\ell E_\ell = I$ alone does not imply $C_\ell = E_\ell^*$ or make the embedding isometric.

A coherent refinement should satisfy

$$C_\ell E_\ell = I$$

and

$$\boxed{P_{\ell,\alpha} = C_\ell \left(\sum_{\beta \succ \alpha} P_{\ell+1,\beta}\right) E_\ell.}$$

For an operator D, define the refinement defect

$$\Delta_\ell(D) = C_\ell D_{\ell+1} E_\ell - D_\ell.$$

Exact resolution independence is $\Delta_\ell(D) = 0$. When exact equality is too strong, the correct continuum problem is to prove convergence of the resolvents and uniform control of the effective self-energies.

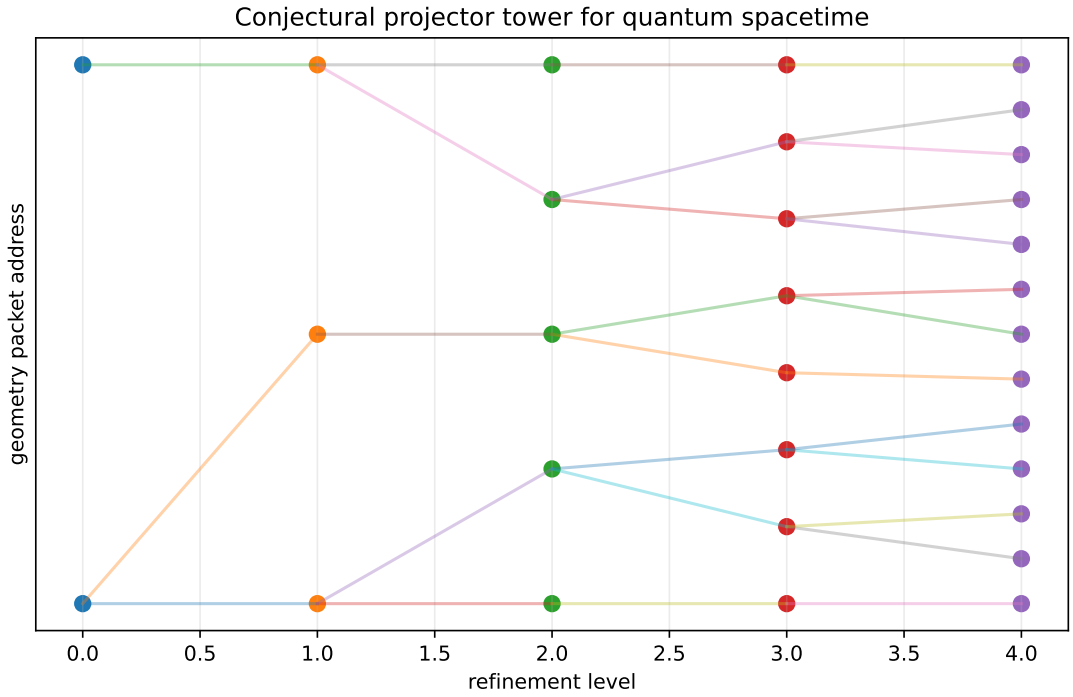

Figure 16. The diagram organizes a conjectural nested packet tower for quantum geometry. It does not provide a numerical reconstruction of physical spacetime.

I.10.2 Euclidean transfer

Theorem I.10.1 (Finite Euclidean transfer). *Let H be Hermitian on a nonzero finite-dimensional Hilbert space. For all real $\tau, \sigma \geq 0$,*

$$T(\tau) = e^{-\tau(H - E_0 I)}, \qquad E_0 = \min \operatorname{Spec} H,$$

is positive definite and satisfies

$$\boxed{T(\tau + \sigma) = T(\tau)T(\sigma).}$$

Its spectrum is contained in $(0, 1]$.

Proof. Diagonalize $H = \sum_j E_j P_j$. Then

$$T(\tau) = \sum_j e^{-\tau(E_j - E_0)} P_j.$$

Every eigenvalue is strictly positive and at most one. Multiplication adds the exponents, proving the semigroup law and $T(0) = I$. Positivity here is operator positivity, not an assertion that every matrix entry is nonnegative. □

The paper tests a controlled volume-state model

$$H_{nn} = 2\kappa + V(n), \qquad H_{n,n+1} = H_{n+1,n} = -\kappa,$$

with $\kappa > 0$ and a real confining potential. This is a finite transfer-matrix test only. Operator positivity alone is not reflection positivity of a Euclidean field measure. It is not derived from a gravitational path integral and is not evidence for a unique microscopic spacetime dynamics.

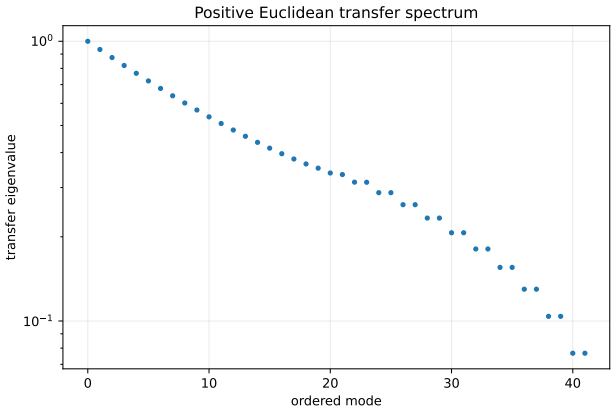

Figure 17. Positive spectrum of the Euclidean transfer operator.

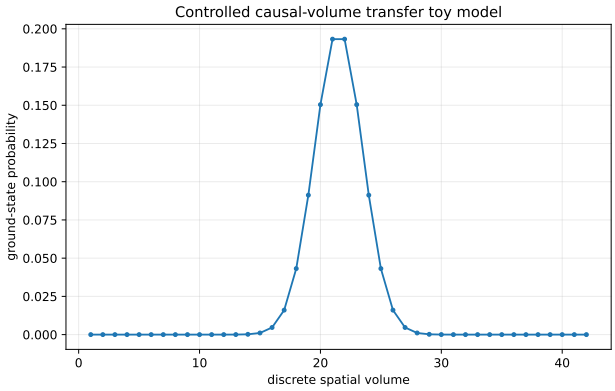

Figure 18. Ground-state volume packet in the controlled toy model.

Recorded Numerical Check I.10.2 (Finite transfer model). The minimum transfer eigenvalue was 0.0767054, the semigroup residual was 0, and reconstruction from four volume-residue packets had residual 0.

I.11 Spectral dimension and continuum diagnostics

Let $L \geq 0$ be a finite Laplacian on $N \geq 1$ states, with eigenvalues λ_j and at least one zero eigenvalue. For diffusion time $\tau > 0$, define the normalized heat trace

$$K(\tau) = \frac{1}{N} \sum_j e^{-\tau \lambda_j}$$

and the scale-dependent spectral dimension

$$\boxed{d_s(\tau) = -2 \frac{d \log K(\tau)}{d \log \tau}.}$$

For a finite system, $d_s(\tau)$ is a diagnostic, not a topological invariant. Indeed, finite differentiation gives

$$d_s(\tau) = 2\tau \frac{\sum_j \lambda_j e^{-\tau \lambda_j}}{\sum_j e^{-\tau \lambda_j}}.$$

It tends to zero as $\tau \downarrow 0$ and, under the stated assumption of a zero mode, as $\tau \to \infty$. If a general positive operator has no zero mode, its behavior at large times is instead asymptotic to $2\tau\lambda_{\min}$. The conclusion for operators with a zero mode therefore does not apply to that case. Inferring a geometric dimension requires a stable intermediate window and a controlled refinement limit.

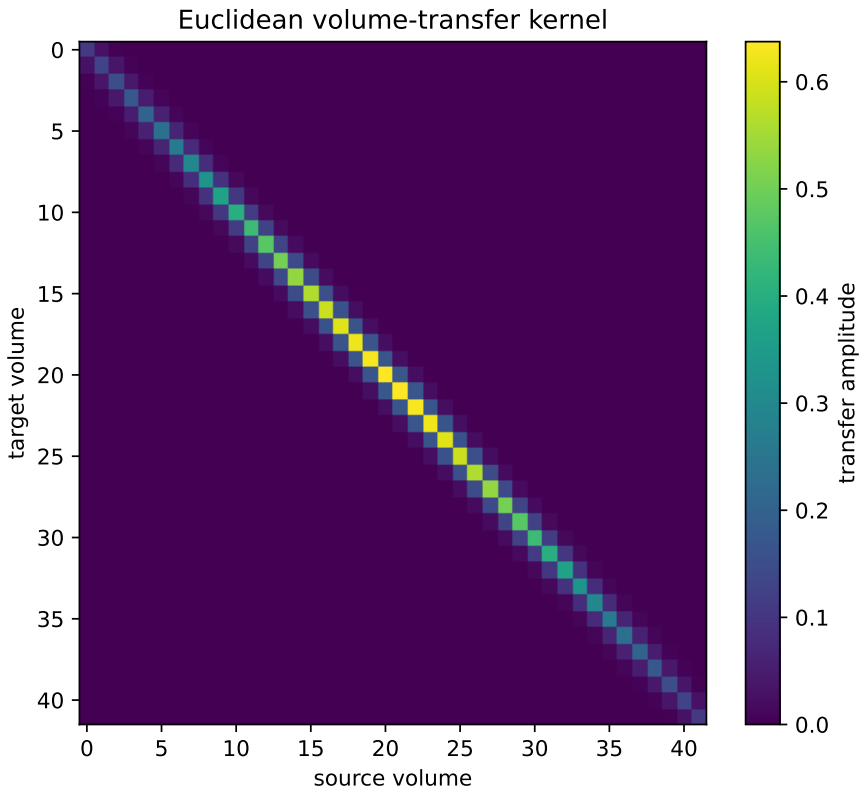

Figure 19. The figure shows the finite Euclidean kernel for volume transfer. Positivity and semigroup composition hold exactly in the finite model. Its gravitational interpretation remains provisional.

I.11.1 The circle dispersion bound

For a periodic grid with spacing $h > 0$ and physical wave number $k \in \mathbb{R}$,

$$\lambda_{k,h} = \frac{4}{h^2} \sin^2\left(\frac{kh}{2}\right).$$

Theorem I.11.1 (Low-mode second-order bound). *For every real k and every nonzero real h, define $\lambda_{k,h} = 4h^{-2}\sin^2(kh/2)$. Then*

$$\boxed{0 \le k^2 - \lambda_{k,h} \le \frac{k^4 h^2}{12}.}$$

Proof. Put $x = kh/2$. The inequalities $|\sin x| \le |x|$ and $|x - \sin x| \le |x|^3/6$, which hold for every real argument, give

$$0 \le x^2 - \sin^2 x = |x - \sin x|\,|x + \sin x| \le \frac{|x|^3}{6}\, 2|x| = \frac{x^4}{3}.$$

Multiplying by $4/h^2$ proves both bounds. The estimate holds for every frequency. Its interpretation as convergence of second order keeps k fixed while $h \to 0$, so it does not assert a uniformly small relative error across all grid modes. □

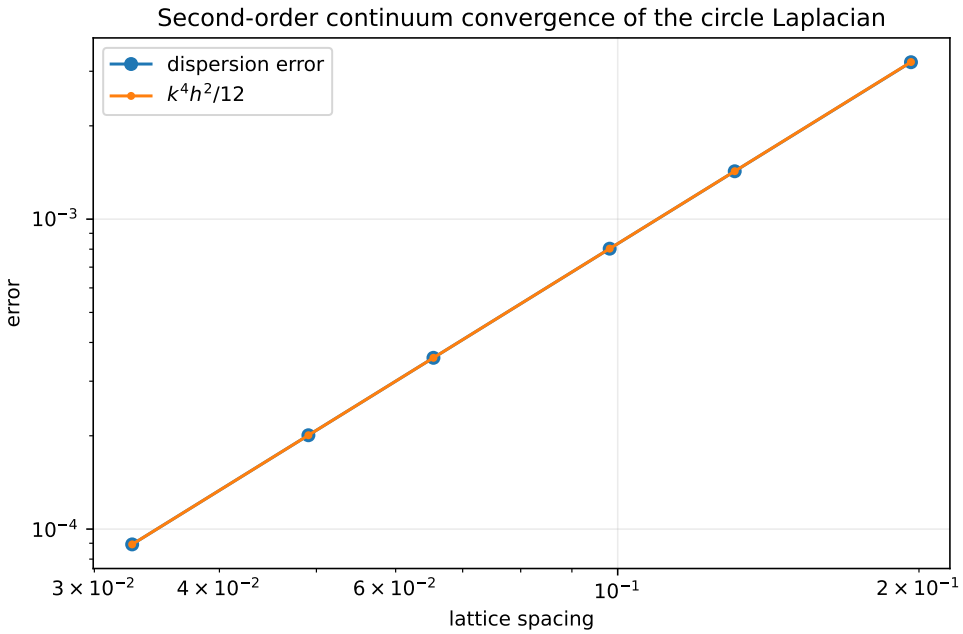

Figure 20. The first nonzero circle mode converges at second order and remains below the proved dispersion bound.

Recorded Numerical Check I.11.2 (Continuum dispersion). The reported convergence order was 1.99936. For every tested mode, the error was below the bound, so none of those tests violated the theorem.

I.11.2 One- and two-dimensional plateaus

At intermediate diffusion times, a finite cycle and a finite torus can exhibit plateaus near the dimensions of their underlying geometries. The following figure and numerical certificate show the reported behavior for these two examples. The plateaus occur between the small and large time regimes in which the spectral dimension returns to zero.

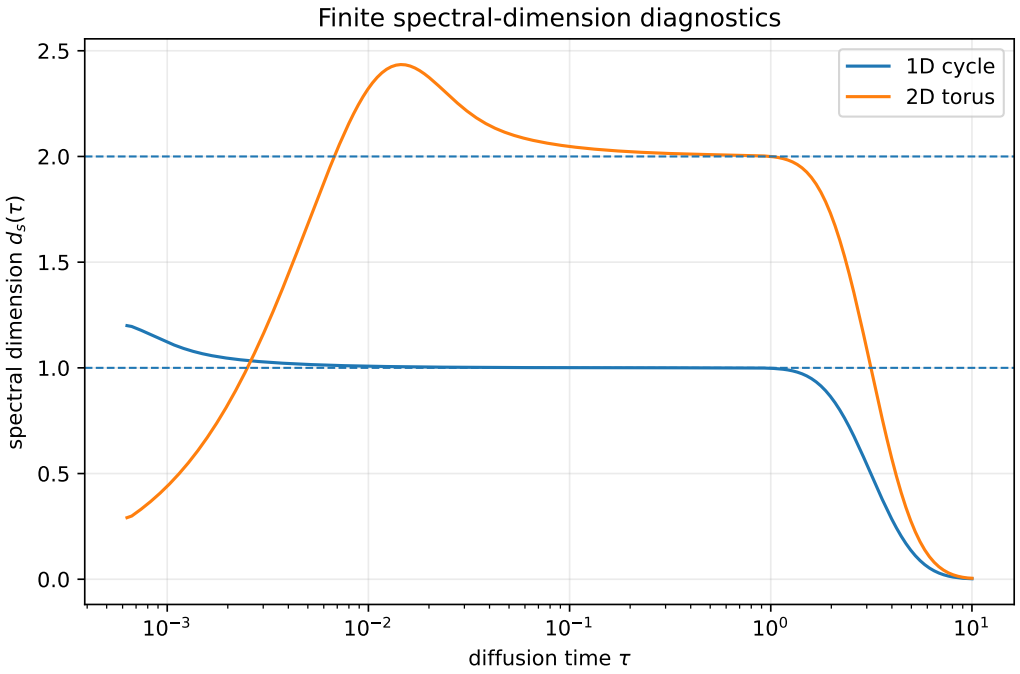

Figure 21. The curves show intermediate windows of spectral dimension for a finite cycle and a finite two-dimensional torus. Departures in the ultraviolet and infrared reflect the finite size of the models rather than additional dimensions.

Recorded Numerical Check I.11.3 (Spectral dimension). The median intermediate plateaus were

$$d_s^{(1)} = 1.00062, \qquad d_s^{(2)} = 2.03781.$$

These tests recover the expected dimensions of the chosen finite geometries. They do not select a physical theory of quantum spacetime.

I.12 Constraint packets and the quantum-spacetime boundary

At one finite level, let $\widehat{C}_A$ be a finite family of matrix constraints, with fixed scalar structure coefficients, and let Π^{phys} be the orthogonal projector onto their exact common kernel. If the classical constraint algebra has structure coefficients $f_{AB}^{\ C}$, define the anomaly operator

$$\boxed{\mathfrak{A}_{AB} = [\widehat{C}_A, \widehat{C}_B] - i \sum_C f_{AB}^{\ C} \widehat{C}_C.}$$

Its physical packet is

$$\Pi^{\text{phys}} \mathfrak{A}_{AB} \Pi^{\text{phys}}.$$

In this exact finite setting, $\widehat{C}_C \Pi^{\text{phys}} = 0$ for every C. Associativity gives

$$\mathfrak{A}_{AB} \Pi^{\text{phys}} = 0, \qquad \Pi^{\text{phys}} \mathfrak{A}_{AB} \Pi^{\text{phys}} = 0$$

automatically. This compression therefore cannot certify operator closure away from the physical range. A nonzero measured compression contradicts the exact-kernel assumptions or indicates an approximation or implementation error. For example, $C_1 = \operatorname{diag}(1, 0, 0)$ and $C_2 = E_{12} + E_{21}$ annihilate the same third coordinate, while their commutator $E_{12} - E_{21}$ is nonzero. With zero proposed structure coefficients, the anomaly is nonzero but its physical compression vanishes.

The closure target must be stated at the operator level, not inferred from that automatic compression. Unbounded constraints additionally require a specified common invariant domain. Neither such a domain theory nor gravitational structure functions are supplied by the finite check.

Conjecture I.12.1 (Anomaly-free refinement)**.** For a specified nontrivial quantum-geometric constraint model, there exists a coherent packet tower with nonzero physical spaces, compatible physical projectors and exact operator closure

$$\mathfrak{A}_{AB}^{(\ell)} = 0$$

at every finite level. The compatible physical compression then vanishes as a consequence, not as a substitute for closure.

The substantive research target is the operator condition. The earlier condition stated only in terms of compression was too weak. A choice of model, dynamics, and refinement maps is still needed before this program becomes a fully specified physical existence problem.

Conjecture I.12.2 (Uniform Feshbach control)**.** For the same specified tower, the self-energies from exact elimination of fine packets admit bounds uniform in cutoff and volume on a common spectral domain. Together with consistent identifications of the Hilbert spaces and a proved resolvent convergence criterion, they yield a nontrivial continuum limit in the strong resolvent sense. Uniform boundedness alone is not asserted to imply convergence.

Conjecture I.12.3 (Lorentzian reconstruction)**.** The Euclidean packet theory satisfies a positivity or reconstruction principle strong enough to produce a Lorentzian Hilbert space with causal propagation and positive physical norm.

Conjecture I.12.4 (Einstein infrared limit)**.** There exist semiclassical packet states $\Psi_{g,\ell}$ such that the effective action converges to

$$\frac{1}{16\pi G}\int \sqrt{-g}\,(R-2\Lambda)\,d^4x$$

with controlled higher-order corrections.

Conjecture I.12.5 (Massless spin-two sector)**.** The continuum two-point function possesses a positive transverse-traceless massless spin-two pole, while all unphysical packet sectors are removed by the constraints.

The exact finite identities establish none of these physical conclusions, and no formal theorem of logical independence is claimed. Exact packet reconstruction provides a kinematic and computational advantage. It does not determine the physical action, prove existence of the continuum theory, or guarantee the limit of general relativity.

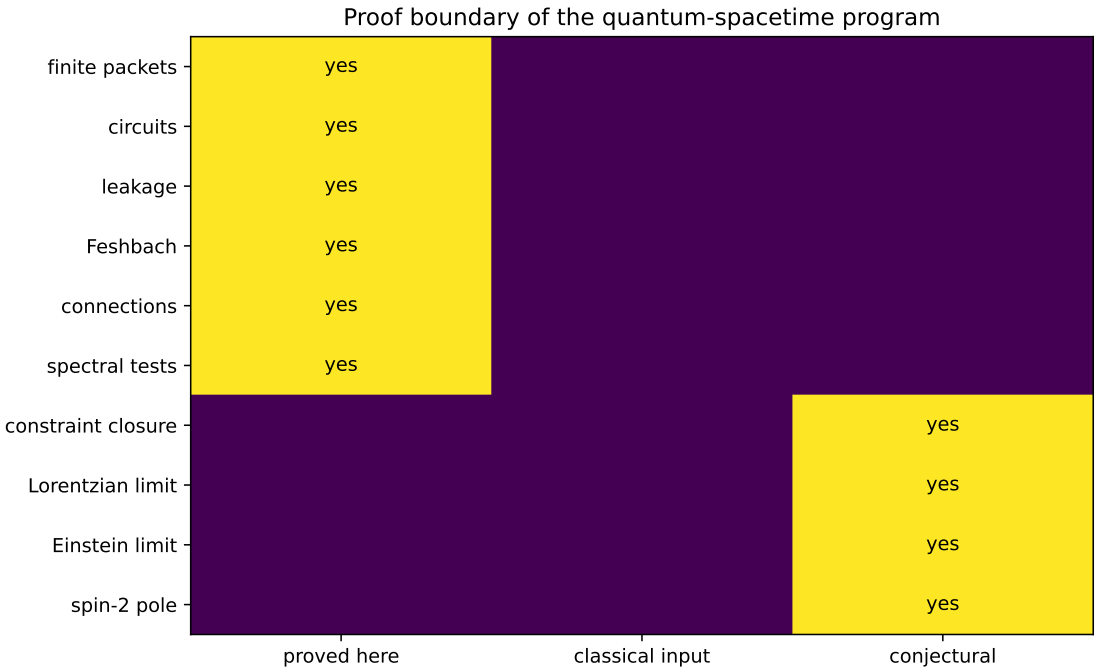

Figure 22. The proof boundary. Finite packet, circuit, leakage, Feshbach, connection, and spectral identities are established here. Constraint closure and the physical continuum claims remain conjectural.

I.13 Numerical certificates

The numerical study reports CPU experiments and a suite of 22 tests. The values below come from the accompanying numerical record. They are separate from the 323 supporting declarations in the formal companion. A displayed floating-point residual of zero describes the reported computation and does not independently prove equality in exact arithmetic.

Table 1. Recorded finite numerical checks.

Certificate	Value
Bell-state residual	0
Three-qubit seed-orbit rank	$8/8$
Parity off-block norm	0
Circuit path reconstruction residual	0
Exact-symmetry maximum leakage	0
Maximum leakage-bound violation	0
Feshbach projected-resolvent residual	3.2291×10^{-17}
Bare-truncation projected-resolvent residual	1.3091×10^{-2}
Moving-frame residual with connection	1.0645×10^{-10}
Moving-frame residual without connection	7.0000×10^{-1}
Canonical packet-connection residual	0
Bloch-curvature residual	2.0803×10^{-11}
Kraus completeness residual	0
Output trace residual	0
Knill–Laflamme residual	0
Bit-flip recovery residual	1.0385×10^{-16}
Tensor parity-refinement residual	0
Circle low-mode convergence order	1.99936
One-dimensional spectral plateau	1.00062
Two-dimensional spectral plateau	2.03781
Minimum Euclidean-transfer eigenvalue	0.0767054
Transfer semigroup residual	0
Volume-packet reconstruction residual	0

The recorded test count is

$$\boxed{22/22 \text{ recorded numerical tests presented here.}}$$

The 19 original figures are retained from the recovered numerical companion. The separate visual guide supplies a reading route through these constructions and the later strengthened results.

I.15 Conclusion

The quantum realization of the seed calculus begins with a primitive state and a declared operator grammar. Symmetry projectors resolve the state and every operator into exact packets. In these coordinates, circuit products become sums over packet paths, and Hamiltonian symmetry appears as a diagonal block structure. When that symmetry is broken, the resulting transfer is measured by the leakage estimates.

Moving packets carry a canonical connection and curvature. Channels and measurements act on the corresponding operator packets, while the conditions for error correction become statements about compression to the code. Exact elimination retains the influence of hidden sectors through self-energy and memory.

The finite theory therefore provides a coherent language for

$$\boxed{\begin{array}{c}\text{seed reachability} + \text{symmetry resolution} + \text{circuit paths} \\ +\text{effective dynamics} + \text{geometric transport} + \text{constraint diagnostics}\end{array}}$$

A physical continuum theorem remains open. The next required results are anomaly-free refinement, uniform control of effective operators, Lorentzian reconstruction, the Einstein infrared limit, and a positive massless spin-two sector. Each requires its own hypotheses and proof. Agreement in a finite numerical model cannot replace those arguments.

Part II Strengthened quantum packet calculus and continuum towers

A route through this section

This part broadens the packet calculus while keeping its hypotheses explicit. Read each result with its assumptions about nonzero spaces, a common ambient space, self-adjointness, finite address sets, and trace class operators. Its bounded limits do not establish the five open physical continuum targets.

II.1 Introduction

Quantum mechanics repeatedly uses the same operation. A Hilbert space is split into sectors, an operator is resolved between those sectors, and the pieces are propagated or recombined. Symmetry sectors, eigenspaces, syndrome spaces, adiabatic subspaces, and retained model spaces are familiar examples. This article treats them as instances of one finite packet calculus.

The elementary coordinate object is a complete family of orthogonal projectors

$$P_a P_b = \delta_{ab} P_a, \qquad \sum_{a \in I} P_a = I.$$

Every vector has packet coordinates $P_a \psi$. Every operator has transfer blocks

$$A_{ba} = P_b A P_a.$$

These identities are simple. Their value appears when the same coordinates are used across representation theory, circuits, channels, error correction, effective dynamics, and geometric limits.

Quantum information and operator theory in finite dimensions provide the standard background [18, 27, 3]. Finite group projectors come from character theory [23, 9]. Moving spectral subspaces and geometric phase originate in the work of Kato, Berry, Wilczek, and Zee [12, 13, 2, 28]. Completely positive maps and quantum dynamical semigroups are treated in [24, 5, 15, 16]. Exact error correction is governed by the Knill–Laflamme condition [14, 22, 1]. Projection methods and hidden state memory are linked by the Feshbach, Nakajima, and Zwanzig constructions [8, 17, 29, 4].

The first part begins with quantum seeds. A state is cyclic only relative to a declared observable algebra. For an algebra in multiplicity form, the local orbit dimension is controlled by the rank of a coefficient matrix. This recovers the relation between Schmidt rank and the dimension reached by local operations. The finite group section then constructs central isotypic projectors. Cyclic symmetry gives a sharper charge selection rule. An operator with charge q can move a state only from packet j to packet $j + q$.

A circuit is resolved by inserting the identity between successive gates. This produces a sum over packet paths. The target probability contains diagonal path terms and interference between distinct

paths. Symmetry can remove entire path families before any matrix multiplication is performed. Unitarity gives exact row and column relations among the transfer blocks.

The moving packet section treats time dependent projectors. The canonical generator

$$K(t) = \sum_a \dot{P}_a(t) P_a(t)$$

is skew adjoint and transports every packet. In the moving frame, the physical Hamiltonian acquires the geometric term $-\mathrm{i}W(t)^*\dot{W}(t)$. The leakage estimate must account for the motion of the packet itself. The physical coupling QHP is therefore replaced by

$$Q(t)(H(t) - \mathrm{i}K(t))P(t).$$

This is the exact finite distinction between following a moving subspace and remaining in a fixed one.

Density matrices require separate packet labels for their output and input coordinates. The superoperators

$$\mathcal{P}_{ab}(X) = P_a X P_b$$

form a complete orthogonal packet system on Hilbert–Schmidt operator space. Dephasing is the diagonal projection. Every channel has input and output superblocks, with the same composition law as ordinary matrix blocks. A covariant channel preserves the isotypic packets of the conjugation action. In the cyclic case these are coherence orders. The Choi matrix carries the equivalent symmetry under $U \otimes \overline{U}$.

Error correction is expressed through compression to a code. Let P be the code projector. The class of PAP modulo scalar multiples of P measures the obstruction to making A undetectable within the code. The Knill–Laflamme criterion says that this obstruction vanishes for every product $E_a^* E_b$ from the error family. Diagonalizing the resulting positive coefficient matrix produces orthogonal syndrome packets and an explicit recovery on the error span.

The effective dynamics section returns to ordinary Hilbert space packets. Schur complementation gives the exact retained resolvent and a frequency dependent self energy. The same hidden block gives a causal memory kernel in time. For a self adjoint hidden Hamiltonian, the self energy has a fixed sign in the upper half plane, and the time kernel is positive definite. Uniform spectral separation gives direct bounds that can be carried through a refinement tower.

The geometric part develops two finite constructions. A strictly positive contraction gives a reflection positive Hankel kernel, and its logarithm reconstructs a nonnegative Hamiltonian. A finite Laplacian gives a heat trace from which the spectral dimension is defined at each diffusion scale. The article proves convergence from periodic lattices to the continuum torus at every fixed positive diffusion time. Poisson summation then determines the continuum dimension as diffusion time tends to zero.

Constraint closure needs a different obstruction. If C_a are self adjoint constraints and P_{phys} projects onto their common kernel, then

$$P_{\mathrm{phys}}[C_a, C_b]P_{\mathrm{phys}} = 0$$

holds automatically. This compression cannot test closure. The correct finite obstruction is the class of $[C_a, C_b]$ in the quotient of $\mathrm{End}(\mathcal{H})$ by the span of the constraints. Vanishing means that the constraint span is closed under commutators.

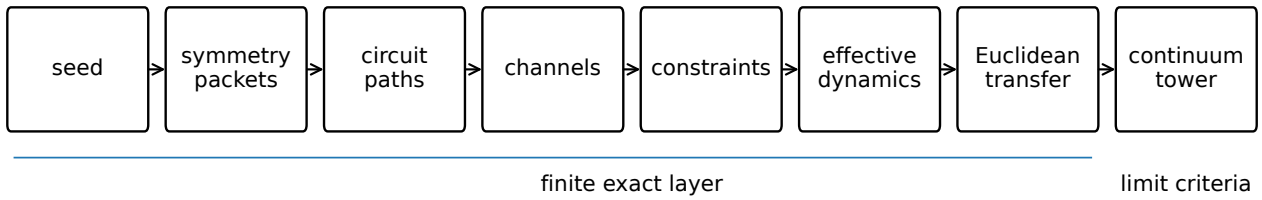

Figure 23. The finite mathematical layers developed in the article and the separate limit criteria needed at the continuum boundary.

Object	Packet coordinate	Exact structural condition
State	$P_a\psi$	completeness of the projector family
Operator	P_bAP_a	block multiplication
Circuit	intermediate packet path	insertion of complete resolutions
Density matrix	$P_a\rho P_b$	two sided operator packets
Channel	superoperator block	complete positivity and covariance when declared
Code	syndrome packet	scalar compression of error products
Effective model	Feshbach map	invertibility of the hidden resolvent
Euclidean model	positive transfer matrix	positivity and self adjointness
Constraint system	quotient obstruction	commutator closure modulo the constraint span
Continuum tower	direct or norm limit	compatibility plus explicit convergence

Table 2. The packet coordinates used in the article.

The last part gives two theorems for towers of bounded Hamiltonians. Exactly compatible finite Hamiltonians with a uniform norm bound define a bounded self adjoint operator on the Hilbert direct limit. When successive bounded self adjoint Hamiltonians on a common Hilbert space have norm summable differences, they converge to a bounded self adjoint limit. Their unitary evolutions, and their Euclidean evolutions under the stated positivity assumption, converge uniformly on bounded time intervals. Reflection positivity and closure with fixed structure coefficients pass to the limit under the stated convergence assumptions.

These results do not construct an interacting continuum quantum field theory. They do not prove anomaly freedom on an unbounded common domain, Osterwalder–Schrader reconstruction for a continuum measure, an Einstein infrared action, or a positive massless spin two sector. Each of those conclusions needs hypotheses absent from the finite calculations.

II.2 Quantum seeds and observable algebras

Definition II.2.1 (Finite quantum seed system)**.** A finite quantum seed system is a triple

$$(\mathcal{H}, \mathcal{A}, S),$$

where $\mathcal{H}$ is a finite dimensional Hilbert space, $\mathcal{A} \subseteq \mathrm{End}(\mathcal{H})$ is a unital star subalgebra, and $S \subseteq \mathcal{H}$ is a finite set. Its generated hull is

$$\mathcal{A}S = \mathrm{span}\{A\psi : A \in \mathcal{A},\ \psi \in S\}.$$

The seed set is cyclic when $\mathcal{A}S = \mathcal{H}$. The quantum seed rank is the least cardinality of a cyclic seed set.

The algebra is part of the data. A vector may be cyclic for $\mathrm{End}(\mathcal{H})$ and fail to be cyclic for a restricted observable or gate algebra.

Let

$$\mathcal{A} \cong \bigoplus_{r=1}^{s} (M_{d_r}(\mathbb{C}) \otimes I_{m_r})$$

act on

$$\mathcal{H} \cong \bigoplus_{r=1}^{s} (\mathbb{C}^{d_r} \otimes \mathbb{C}^{m_r}).$$

Assume $d_r, m_r \geq 1$ for each displayed block. For an empty block family, the seed rank and the displayed finite supremum are defined as zero. A vector in one block is identified with a d_r by m_r coefficient matrix.

Theorem II.2.2 (Orbit dimension of one seed)**.** *For integers $d \geq 1$, $m \geq 0$, and the action of $M_d(\mathbb{C}) \otimes I_m$ on $\mathbb{C}^d \otimes \mathbb{C}^m$, let C_ψ be the coefficient matrix of ψ. Then*

$$\dim \mathrm{span}\{(A \otimes I_m)\psi : A \in M_d(\mathbb{C})\} = d \,\mathrm{rank}\, C_\psi.$$

The vector is cyclic exactly when $\mathrm{rank}\, C_\psi = m$.

Proof. Under the coefficient matrix identification, $(A \otimes I_m)\psi$ corresponds to AC_ψ. Every row of AC_ψ lies in the row space of C_ψ. Conversely, a matrix whose rows lie in that row space equals AC_ψ for a suitable A. There are d independent row choices in a space of dimension $\mathrm{rank}\, C_\psi$. The orbit dimension is therefore $d\,\mathrm{rank}\, C_\psi$. It equals dm exactly when C_ψ has full column rank. □

Theorem II.2.3 (Quantum seed rank)**.** *For the displayed multiplicity decomposition,*

$$\mathrm{srank}_{\mathcal{A}}(\mathcal{H}) = \max_{1 \leq r \leq s} \left\lceil \frac{m_r}{d_r} \right\rceil.$$

Proof. A single seed contributes a row space of dimension at most d_r to the rth multiplicity factor. Hence k seeds cover at most kd_r multiplicity directions, which gives the lower bound.

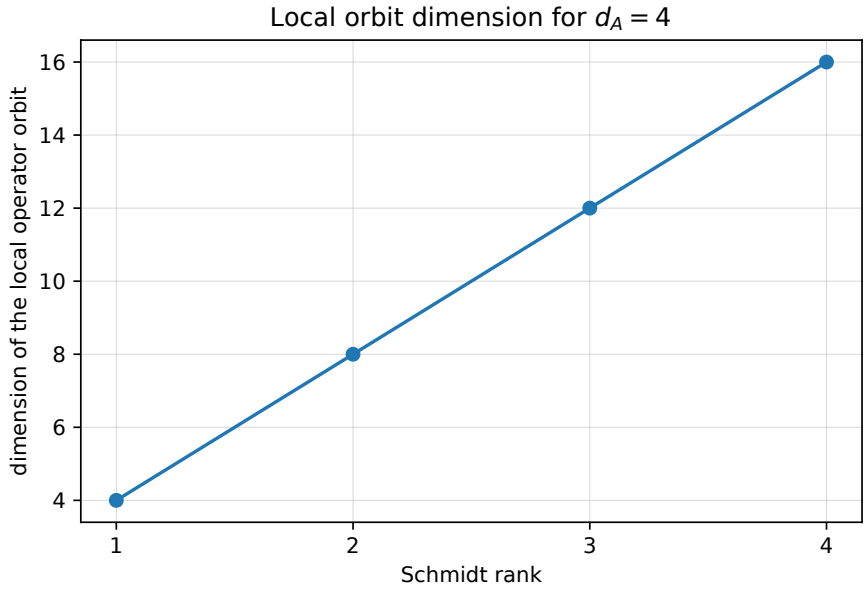

Figure 24. The dimension reached by all local operators is linear in Schmidt rank.

Set

$$k = \max_r \left\lceil \frac{m_r}{d_r} \right\rceil .$$

For each r, partition a basis of $\mathbb{C}^{m_r}$ into at most k groups of size at most d_r. Choose the coefficient matrix of the jth seed so that its row space spans the jth group. The combined row spaces span every multiplicity factor. The preceding theorem then shows that the k seeds generate every summand. □

Corollary II.2.4 (Local orbit and Schmidt rank)**.** *Let $\psi \in \mathcal{H}_A \otimes \mathcal{H}_B$, let $d_A = \dim \mathcal{H}_A \geq 1$, and let r be the Schmidt rank of ψ. Then*

$$\dim \operatorname{span}\{(A \otimes I_B)\psi : A \in \operatorname{End}(\mathcal{H}_A)\} = d_A r.$$

Local operators on A generate the whole bipartite Hilbert space exactly when the reduced state on B has full support.

Proof. The Schmidt rank is the rank of the coefficient matrix in any product basis. Substituting that rank into theorem II.2.2 gives the stated orbit dimension. □

Proposition II.2.5 (Computational address orbit)**.** *For n qubits, let*

$$\psi_0 = |0\rangle^{\otimes n}$$

and let X_j be the Pauli X operator on the jth qubit. Then

$$\{X_1^{a_1} \cdots X_n^{a_n} \psi_0 : (a_1, \ldots, a_n) \in \{0,1\}^n\}$$

is the computational basis.

Proof. The addressed vector is $|a_1 \cdots a_n\rangle$. Distinct binary addresses produce the 2^n distinct basis vectors. □

Remark II.2.6. The seed rank records generation by a declared algebra. It does not measure circuit depth, locality cost, control complexity, or physical reachability under a restricted time dependent Hamiltonian.

II.3 Symmetry packets and selection rules

Let G be a finite group and let

$$U : G \longrightarrow \mathcal{U}(\mathcal{H})$$

be a unitary representation. Write $\widehat{G}$ for the set of irreducible unitary representations. For $\lambda \in \widehat{G}$, let d_λ and χ_λ denote its dimension and character.

Theorem II.3.1 (Finite group isotypic projectors)**.** *The operators*

$$P_\lambda = \frac{d_\lambda}{|G|} \sum_{g \in G} \overline{\chi_\lambda(g)} U(g)$$

are orthogonal projectors. They satisfy

$$P_\lambda P_\mu = \delta_{\lambda\mu} P_\lambda, \qquad \sum_{\lambda \in \widehat{G}} P_\lambda = I_{\mathcal{H}}.$$

The range of P_λ is the λ isotypic component of $\mathcal{H}$.

Proof. Complete reducibility gives a unitary decomposition

$$\mathcal{H} \cong \bigoplus_{\mu \in \widehat{G}} V_\mu \otimes M_\mu, \qquad U(g) \cong \bigoplus_{\mu} \pi_\mu(g) \otimes I_{M_\mu}.$$

On the μ summand, the displayed average is central in the irreducible representation π_μ, so it is a scalar by Schur's lemma. Taking its trace and applying character orthogonality shows that the scalar is one when $\mu = \lambda$ and zero otherwise. The asserted identities follow on the direct sum. □

The central projectors separate irreducible types but do not choose coordinates inside the representation factor. Matrix units provide that finer resolution.

Theorem II.3.2 (Representation matrix units). *Fix an irreducible unitary representation $\pi_\lambda : G \to U(d_\lambda)$ and an orthonormal basis of its representation space. Define*

$$E_{ij}^{\lambda} = \frac{d_\lambda}{|G|} \sum_{g \in G} \big[\pi_\lambda(g^{-1})\big]_{ji} U(g).$$

Then

$$E_{ij}^{\lambda} E_{k\ell}^{\mu} = \delta_{\lambda\mu}\delta_{jk} E_{i\ell}^{\lambda}, \qquad \big(E_{ij}^{\lambda}\big)^{*} = E_{ji}^{\lambda},$$

and

$$P_\lambda = \sum_{i=1}^{d_\lambda} E_{ii}^{\lambda}.$$

Proof. Apply the matrix coefficient form of Schur orthogonality to the two group averages. It gives the matrix unit multiplication law. Unitarity gives the adjoint relation after replacing g by g^{-1}. Summing the diagonal coefficients gives the character average in theorem II.3.1. □

II.3.1 Cyclic charge packets

Let $N \geq 1$ be an integer, S unitary with $S^N = I$, and $\omega = \mathrm{e}^{2\pi \mathrm{i}/N}$.

Corollary II.3.3 (Cyclic charge projectors). *The operators*

$$P_j = \frac{1}{N} \sum_{r=0}^{N-1} \omega^{-jr} S^r, \qquad j \in \mathbb{Z}/N\mathbb{Z},$$

form a complete orthogonal packet system and satisfy

$$S P_j = \omega^j P_j.$$

Proof. Apply theorem II.3.1 to the cyclic group. Its irreducible representations are the one dimensional characters $r \mapsto \omega^{jr}$. □

Definition II.3.4 (Operator charge). An operator $A \in \mathrm{End}(\mathcal{H})$ has cyclic charge $q \in \mathbb{Z}/N\mathbb{Z}$ when

$$S A S^{*} = \omega^q A.$$

Theorem II.3.5 (Charge selection rule). *If A has charge q, then*

$$P_k A P_j = 0$$

unless $k = j + q$ in $\mathbb{Z}/N\mathbb{Z}$. In fact,

$$A P_j = P_{j+q} A P_j.$$

Proof. For $x \in P_j\mathcal{H}$,

$$S(Ax) = (SAS^{*})Sx = \omega^{q+j} Ax.$$

Thus $Ax \in P_{j+q}\mathcal{H}$. The block statement follows. □

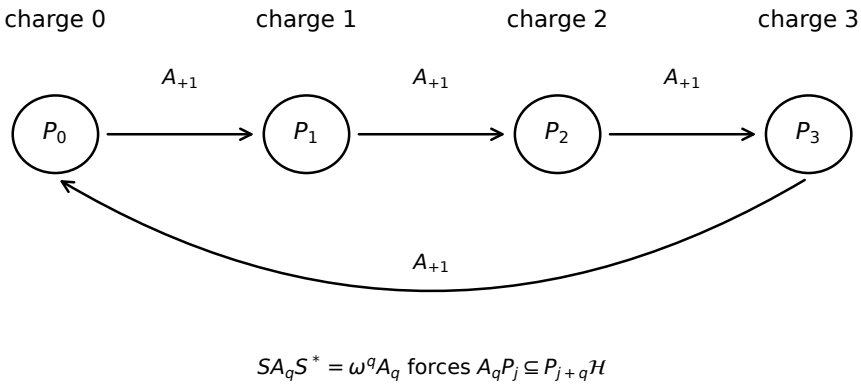

Figure 25. An operator of charge one moves each cyclic packet to the next packet and has no other transfer blocks.

Corollary II.3.6 (Charge addition)**.** *If A and B have charges q and r, then AB has charge $q + r$. The adjoint A^* has charge $-q$.*

Proof. Conjugation by S is a star automorphism. Applying it to AB adds the two charges, while applying it to A^* changes the sign of the charge. □

II.3.2 Tensor refinement

Suppose the ath tensor factor carries a cyclic packet family

$$\left(P_j^{(a)}\right)_{j\in\mathbb{Z}/N\mathbb{Z}}.$$

The fine tensor packets are

$$P_{\boldsymbol{j}}^{\text{fine}} = P_{j_1}^{(1)} \otimes \cdots \otimes P_{j_m}^{(m)}.$$

Theorem II.3.7 (Tensor charge refinement)**.** *For $r \in \mathbb{Z}/N\mathbb{Z}$, define*

$$P_r^{\text{total}} = \sum_{j_1+\cdots+j_m=r} P_{j_1}^{(1)} \otimes \cdots \otimes P_{j_m}^{(m)}.$$

Then the P_r^{total} form a complete orthogonal packet system. Every total charge packet is the exact sum of its fine tensor descendants.

Proof. The fine tensor projectors are mutually orthogonal and sum to the identity. The total residue classes partition the fine address set. Summing the fine projectors over each class gives the result. □

Corollary II.3.8 (Tensor selection rule). *If A_a has local charge q_a, then*

$$A_1 \otimes \cdots \otimes A_m$$

has total charge $q_1 + \cdots + q_m$.

Proof. Conjugate the tensor product by the total cyclic symmetry and multiply the local phase factors. □

Remark II.3.9. For a nonabelian group, tensor products are refined by irreducible fusion multiplicities rather than residue addition. The central isotypic projectors remain exact, but a complete tensor refinement also requires a choice of Clebsch–Gordan intertwiners.

II.4 Quantum circuits as packet paths

Let

$$U = U_m U_{m-1} \cdots U_1$$

be a finite circuit with $m \geq 1$, and let $(P_a)_{a \in I}$ be a complete orthogonal packet family. For the empty circuit, $U = I$ and its transfer block is $P_b P_a = \delta_{ba} P_a$, whose endpoint sum reconstructs I.

Theorem II.4.1 (Exact circuit path expansion). *For source packet a_0 and target packet a_m,*

$$P_{a_m} U P_{a_0} = \sum_{a_1, \ldots, a_{m-1}} P_{a_m} U_m P_{a_{m-1}} \cdots P_{a_1} U_1 P_{a_0}.$$

Summing over a_0 and a_m reconstructs U.

Proof. Insert $I = \sum_a P_a$ between every adjacent pair of gates and distribute the finite sums. Completeness at the two endpoints gives the full operator. □

For a packet path

$$\gamma = (a_0, a_1, \ldots, a_m),$$

write

$$U_\gamma = P_{a_m} U_m P_{a_{m-1}} \cdots P_{a_1} U_1 P_{a_0}.$$

Theorem II.4.2 (Packet unitarity identities). *If U is unitary and $U_{ba} = P_b U P_a$, then*

$$\sum_b U_{ba}^* U_{bc} = \delta_{ac} P_a$$

and

$$\sum_a U_{ba} U_{da}^* = \delta_{bd} P_b.$$

Proof. Use completeness and unitarity:

$$\sum_b U_{ba}^* U_{bc} = P_a U^* \left(\sum_b P_b \right) U P_c = P_a P_c.$$

Summing instead over the source packets and using unitarity in the reverse order gives the second identity. □

Corollary II.4.3 (Probability conservation from one packet)**.** *If $\psi \in P_a\mathcal{H}$, then*

$$\sum_b \|P_bU\psi\|^2 = \|\psi\|^2 .$$

Proof. Take the inner product of the first identity in theorem II.4.2 with ψ and set $c = a$. □

Theorem II.4.4 (Path interference formula)**.** *Fix a source vector $\psi \in P_{a_0}\mathcal{H}$ and a target packet b. Let Γ_b be the set of packet paths from a_0 to b, and set*

$$\eta_\gamma = U_\gamma\psi.$$

Choose any total order on this finite path set. Then

$$\|P_bU\psi\|^2 = \sum_{\gamma\in\Gamma_b} \|\eta_\gamma\|^2 + 2\,\mathrm{Re} \sum_{\substack{\gamma,\gamma'\in\Gamma_b \\ \gamma<\gamma'}} \langle \eta_\gamma, \eta_{\gamma'} \rangle .$$

Consequently,

$$\|P_bU\psi\| \le \sum_{\gamma\in\Gamma_b} \|\eta_\gamma\| .$$

If the path outputs are pairwise orthogonal, the target probability is the sum of the path probabilities.

Proof. The path expansion gives

$$P_bU\psi = \sum_{\gamma\in\Gamma_b} \eta_\gamma.$$

Expanding the squared norm and grouping conjugate cross terms gives the interference formula. The triangle inequality gives the norm bound. When the path outputs are orthogonal, every cross term vanishes and only the individual path probabilities remain. □

Proposition II.4.5 (Charge pruning of circuit paths)**.** *Suppose every gate has a finite charge decomposition*

$$U_r = \sum_q U_r^{(q)}, \qquad SU_r^{(q)}S^* = \omega^q U_r^{(q)}.$$

A term with gate charges $q_1, \dots, q_m$ can contribute from source charge a_0 only to target charge

$$a_m = a_0 + q_1 + \cdots + q_m.$$

Every packet path violating one of the intermediate charge updates vanishes.

Proof. Apply theorem II.3.5 after each gate component. The packet address is forced at every step. □

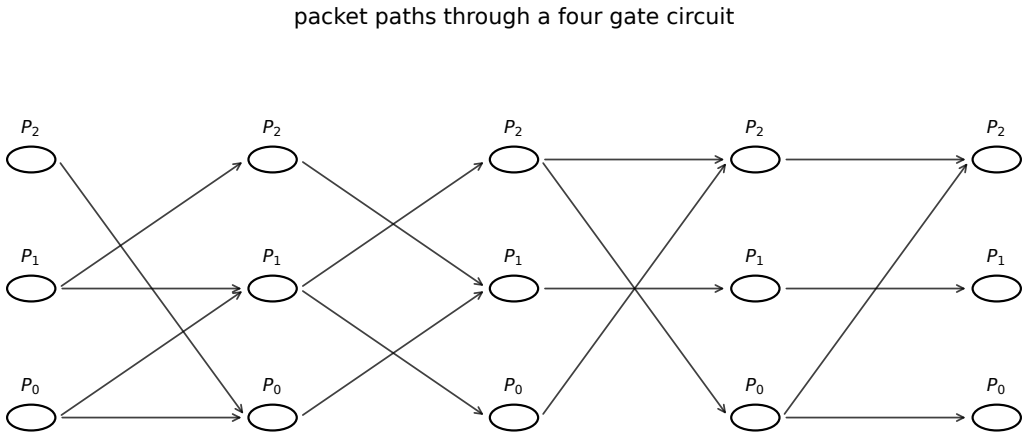

Figure 26. A circuit block is the coherent sum of its allowed packet paths. Selection rules remove forbidden paths before amplitudes are evaluated.

Example II.4.6 (Bell circuit)**.** Starting from $|00\rangle$, apply a Hadamard gate to the first qubit and then a controlled NOT gate. The final state is

$$\frac{|00\rangle + |11\rangle}{\sqrt{2}}.$$

It lies in the even parity packet. The intermediate state has one even and one odd computational contribution, so the final even amplitude is reconstructed by more than one packet path.

II.5 Symmetry resolved dynamics and leakage

Let $H = H^*$ and let $(P_a)_{a\in I}$ be a complete orthogonal packet system.

Theorem II.5.1 (Exact invariant packets)**.** *The following conditions are equivalent:*

1. *The Hamiltonian commutes with each projector:* $[H, P_a] = 0$ *for every* a*.*
2. *Transfer blocks between distinct packets vanish:* $P_b H P_a = 0$ *whenever* $a \neq b$*.*
3. *Every packet* $P_a\mathcal{H}$ *is invariant under* $\mathrm{e}^{-\mathrm{i}tH}$ *for every real* t*.*

When they hold,

$$H = \sum_a P_a H P_a$$

and

$$\mathrm{e}^{-\mathrm{i}tH} = \sum_a P_a \mathrm{e}^{-\mathrm{i}tH} P_a.$$

Proof. Commutation is equivalent to vanishing of every off diagonal block. The same block decomposition passes to polynomials in H, then to the exponential by norm convergence. Invariance of every packet implies invariance under both $\mathrm{e}^{-\mathrm{i}tH}$ and its adjoint. Differentiation at $t = 0$ gives commutation with H. □

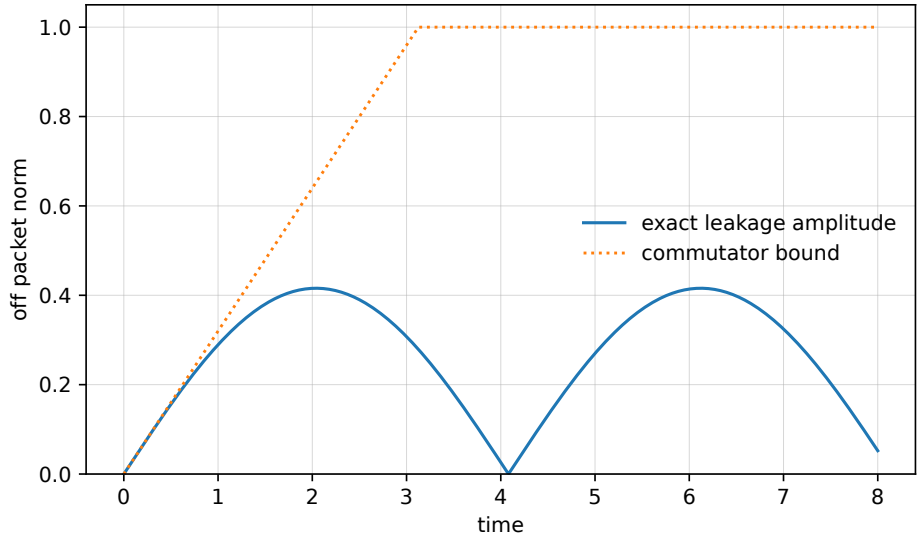

Figure 27. Exact transition amplitude in a two packet model and the linear commutator bound.

Fix one packet projector P and set $Q = I - P$.

Lemma II.5.2 (Off diagonal norm)**.** *For self adjoint H,*

$$\|[H, P]\| = \|QHP\| = \|PHQ\|\,.$$

Proof. Relative to $P\mathcal{H} \oplus Q\mathcal{H}$,

$$[H, P] = \begin{pmatrix} 0 & -PHQ \\ QHP & 0 \end{pmatrix}.$$

Its square has diagonal blocks $-PHQHP$ and $-QHPHQ$. The norm is therefore the largest singular value of QHP. □

Theorem II.5.3 (Fixed packet leakage)**.** *For every real t,*

$$\left\|Q\mathrm{e}^{-\mathrm{i}tH}P\right\| \le |t|\,\|QHP\| = |t|\,\|[H, P]\|\,.$$

Proof. Let

$$H_{\mathrm{d}} = PHP + QHQ, \qquad H_{\mathrm{o}} = PHQ + QHP.$$

The propagator generated by H_{d} preserves $P\mathcal{H}$ and $Q\mathcal{H}$. Duhamel's formula relative to H_{d} gives

$$Q\mathrm{e}^{-\mathrm{i}tH}P = -\mathrm{i}\int_0^t Q\mathrm{e}^{-\mathrm{i}(t-s)H}H_{\mathrm{o}}\mathrm{e}^{-\mathrm{i}sH_{\mathrm{d}}}P\,\mathrm{d}s.$$

Since $H_{\mathrm{o}}P = QHP$ and both propagators are unitary, the norm is at most $|t|\,\|QHP\|$. Use lemma II.5.2 for the last equality. □

Corollary II.5.4 (Leakage probability). *If $\psi \in P\mathcal{H}$ is a unit vector, then*

$$\left\|Q\mathrm{e}^{-\mathrm{i}tH}\psi\right\|^2 \leq t^2 \left\|QHP\right\|^2 .$$

Proof. Apply theorem II.5.3 to the unit vector, then square the resulting nonnegative bound. □

II.6 Moving packets and geometric transport

Let $(P_a(t))_{a\in I}$ be a twice continuously differentiable family of complete orthogonal packet systems on a finite dimensional Hilbert space.

Theorem II.6.1 (Canonical packet connection). *Define*

$$K(t) = \sum_a \dot{P}_a(t) P_a(t).$$

Then

$$K(t)^* = -K(t)$$

and

$$[K(t), P_a(t)] = \dot{P}_a(t)$$

for every a.

Proof. Differentiating $P_a^2 = P_a$ gives

$$\dot{P}_a P_a + P_a \dot{P}_a = \dot{P}_a.$$

Summing over a and using $\sum_a \dot{P}_a = 0$ yields

$$\sum_a P_a \dot{P}_a = -\sum_a \dot{P}_a P_a.$$

This proves skew adjointness. For fixed b,

$$K P_b = \dot{P}_b P_b.$$

Differentiating $P_b P_a = 0$ for $a \neq b$ gives

$$P_b \dot{P}_a = -\dot{P}_b P_a.$$

Hence

$$P_b K = -\dot{P}_b (I - P_b).$$

Subtracting gives $[K, P_b] = \dot{P}_b$. □

Theorem II.6.2 (Exact Kato transport). *Let $W(t)$ solve*

$$\dot{W}(t) = K(t)W(t), \qquad W(0) = I.$$

Then $W(t)$ is unitary and

$$P_a(t)W(t) = W(t)P_a(0)$$

for every packet a.

Proof. Skew adjointness gives

$$\frac{\mathrm{d}}{\mathrm{d}t} W(t)^* W(t) = 0.$$

Thus $W(t)$ is unitary. Next,

$$\frac{\mathrm{d}}{\mathrm{d}t} \left(W(t)^* P_a(t) W(t) \right) = W(t)^* \left(\dot{P}_a - [K, P_a] \right) W(t) = 0.$$

The expression equals $P_a(0)$ at $t = 0$, which proves the intertwining identity. □

Theorem II.6.3 (Moving frame Hamiltonian). *Let $U(t)$ solve*

$$\mathrm{i}\dot{U}(t) = H(t)U(t), \qquad U(0) = I,$$

where $H(t) = H(t)^*$ is continuous on the compact time interval under consideration. Set

$$V(t) = W(t)^* U(t).$$

Then

$$\mathrm{i}\dot{V}(t) = H_{\mathrm{mov}}(t)V(t),$$

where

$$H_{\mathrm{mov}}(t) = W(t)^* H(t) W(t) - \mathrm{i} W(t)^* \dot{W}(t) = W(t)^* (H(t) - \mathrm{i}K(t)) W(t).$$

The moving frame Hamiltonian is self adjoint.

Proof. Differentiate $V = W^* U$. Since $\dot{W} = KW$ and $K^* = -K$,

$$\dot{W}^* = -W^* K.$$

Substitution gives the equation. The first term in H_{mov} is self adjoint. The operator $-\mathrm{i}W^*\dot{W}$ is self adjoint because $W^*\dot{W}$ is skew adjoint. □

Theorem II.6.4 (Moving packet leakage). *Fix a packet $P(t) = P_a(t)$ and put $Q(t) = I - P(t)$. For $0 \le t \le T$,*

$$\|Q(t)U(t)P(0)\| \le \int_0^t \left\| Q(s)(H(s) - \mathrm{i}K(s))P(s) \right\| \mathrm{d}s.$$

In particular, the physical evolution follows the moving packet exactly on $[0, T]$ when the displayed off packet block vanishes for every time in that interval.

Proof. In the Kato frame, $P(0)$ is fixed and

$$Q(t)U(t)P(0) = W(t)Q(0)V(t)P(0).$$

Apply the time dependent version of the Duhamel argument in theorem II.5.3 to $H_{\mathrm{mov}}(t)$. The off diagonal block is

$$Q(0)H_{\mathrm{mov}}(s)P(0) = W(s)^*Q(s)(H(s) - \mathrm{i}K(s))P(s)W(s).$$

Unitary conjugation preserves the norm. □

The exact coupling test therefore includes the geometric term. Even if the Hamiltonian is diagonal in the packet decomposition at every fixed time, its evolution can fail to follow a packet whose range rotates.

II.6.1 Discrete packet transport

Let (P_a) and (Q_a) be two complete packet systems with the same index set. Define

$$S(\mathcal{Q}, \mathcal{P}) = \sum_a Q_a P_a.$$

Theorem II.6.5 (Direct packet rotation). *Assume*

$$\|S(\mathcal{Q}, \mathcal{P}) - I\| < 1.$$

Then $S(\mathcal{Q}, \mathcal{P})$ is invertible. Its unitary polar factor

$$\mathcal{U}(\mathcal{Q}, \mathcal{P}) = S(S^*S)^{-1/2}$$

satisfies

$$Q_a\mathcal{U}(\mathcal{Q}, \mathcal{P}) = \mathcal{U}(\mathcal{Q}, \mathcal{P})P_a$$

for every a.

Proof. The norm condition gives invertibility by the Neumann series. The identity

$$Q_aS = SP_a = Q_aP_a$$

shows that S^*S commutes with every P_a. Its inverse square root also commutes with every P_a. Hence

$$Q_a\mathcal{U} = Q_aS(S^*S)^{-1/2} = SP_a(S^*S)^{-1/2} = \mathcal{U}P_a.$$

The polar factor is unitary because S is invertible. □

Theorem II.6.6 (Convergence of short packet rotations)**.** *Let $(P_a(t))$ be twice continuously differentiable on $[0,T]$. For a partition*

$$0 = t_0 < t_1 < \cdots < t_n = T,$$

let

$$W_\pi = \mathcal{U}(\mathcal{P}(t_n), \mathcal{P}(t_{n-1})) \cdots \mathcal{U}(\mathcal{P}(t_1), \mathcal{P}(t_0)).$$

For sufficiently fine partitions the factors are defined, and

$$\|W_\pi - W(T)\| \le C_T \, |\pi|$$

for a constant depending on the packet path but not on the partition. Here the size of the partition is measured by its mesh, which is the length of its largest subinterval.

Proof. Taylor expansion gives

$$S(\mathcal{P}(t+h), \mathcal{P}(t)) = I + hK(t) + O(h^2)$$

uniformly on $[0,T]$. Since $K(t)^* = -K(t)$,

$$S^*S = I + O(h^2),$$

so the polar factor satisfies

$$\mathcal{U}(\mathcal{P}(t+h), \mathcal{P}(t)) = I + hK(t) + O(h^2).$$

This gives a first order approximation to $\dot{W} = KW$ over a single time step. A telescoping product estimate over the partition gives a total error bounded by a constant times $\sum_j (t_{j+1} - t_j)^2$, which is at most $T\,|\pi|$. □

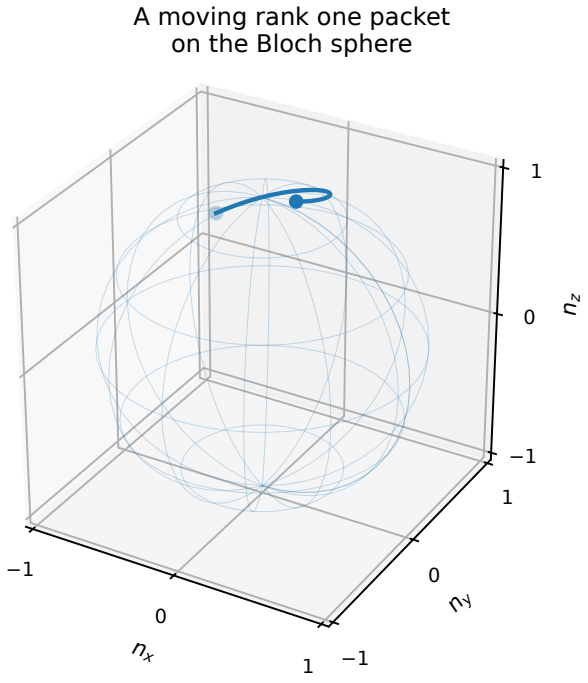

Figure 28. A moving rank one packet on the Bloch sphere. The Kato evolution transports the range without choosing a phase convention for its eigenvector.

II.6.2 Local frames and curvature

Let $P(x)$ be a smooth rank r orthogonal projector over a parameter manifold. Choose a local isometry

$$V(x) : \mathbb{C}^r \longrightarrow \mathcal{H}, \qquad V(x)V(x)^* = P(x).$$

Theorem II.6.7 (Nonabelian packet connection)**.** *The one form with matrix values*

$$\mathcal{A} = V^* \, \mathrm{d}V$$

is skew adjoint. Under a frame change $V' = VG$, where $G(x) \in U(r)$,

$$\mathcal{A}' = G^* \mathcal{A} G + G^* \, \mathrm{d}G.$$

Its curvature

$$\mathcal{F} = \mathrm{d}\mathcal{A} + \mathcal{A} \wedge \mathcal{A}$$

satisfies

$$\mathcal{F} = V^* (\, \mathrm{d}P \wedge \mathrm{d}P) V.$$

Proof. Differentiate $V^*V = I$ to obtain $\mathcal{A}^* = -\mathcal{A}$. The gauge transformation law follows by differentiating VG. Since $P = VV^*$ and $(I - P)\, \mathrm{d}V = \mathrm{d}P\, V$, direct expansion gives

$$\mathrm{d}\mathcal{A} + \mathcal{A} \wedge \mathcal{A} = \mathrm{d}V^* (I - P) \wedge \mathrm{d}V = V^* (\, \mathrm{d}P \wedge \mathrm{d}P) V.$$

□

Corollary II.6.8 (Bloch sphere curvature)**.** *Let*

$$P(\theta,\phi)=\frac{1}{2}\left(I+\boldsymbol{n}(\theta,\phi)\cdot\boldsymbol{\sigma}\right),$$

where

$$\boldsymbol{n}=(\sin\theta\cos\phi,\sin\theta\sin\phi,\cos\theta).$$

With the convention

$$\mathcal{F}_{\theta\phi}=-\mathrm{i}\,\mathrm{Tr}(P[\partial_\theta P,\partial_\phi P]),$$

one has

$$\mathcal{F}_{\theta\phi}=\frac{1}{2}\sin\theta$$

and

$$\frac{1}{2\pi}\int_0^{2\pi}\int_0^{\pi}\mathcal{F}_{\theta\phi}\,\mathrm{d}\theta\,\mathrm{d}\phi=1.$$

Proof. The Pauli identity

$$(\boldsymbol{a}\cdot\boldsymbol{\sigma})(\boldsymbol{b}\cdot\boldsymbol{\sigma})=(\boldsymbol{a}\cdot\boldsymbol{b})I+\mathrm{i}(\boldsymbol{a}\times\boldsymbol{b})\cdot\boldsymbol{\sigma}$$

gives

$$-\mathrm{i}\,\mathrm{Tr}(P[\partial_\theta P,\partial_\phi P])=\frac{1}{2}\boldsymbol{n}\cdot(\partial_\theta\boldsymbol{n}\times\partial_\phi\boldsymbol{n})=\frac{1}{2}\sin\theta.$$

Integrating the displayed curvature over the sphere and applying the stated normalization gives one. □

II.7 Operator packets, measurements, and quantum channels

Density matrices and observables carry both an input packet and an output packet. Equip $\mathrm{End}(\mathcal{H})$ with the Hilbert–Schmidt inner product

$$\langle X,Y\rangle_{\mathrm{HS}}=\mathrm{Tr}(X^*Y).$$

Definition II.7.1 (Two sided operator packet)**.** For a complete orthogonal family (P_a), define

$$\mathcal{P}_{ab}(X)=P_aXP_b.$$

The range

$$\mathcal{B}_{ab}=P_a\,\mathrm{End}(\mathcal{H})P_b$$

is the operator packet with output address a and input address b.

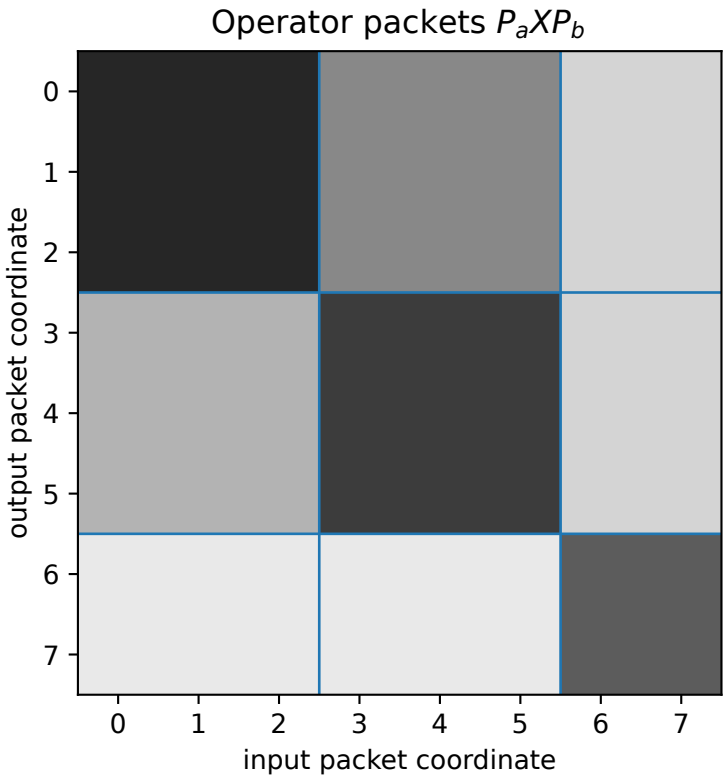

Figure 29. A density matrix or observable carries two packet addresses. Diagonal packets contain populations and internal observables. Off diagonal packets contain coherences.

Theorem II.7.2 (Complete operator packet system)**.** *The superoperators* $(\mathcal{P}_{ab})_{a,b\in I}$ *are mutually orthogonal projections on Hilbert–Schmidt operator space. They satisfy*

$$X = \sum_{a,b} P_a X P_b$$

and

$$\|X\|_{\mathrm{HS}}^2 = \sum_{a,b} \|P_a X P_b\|_{\mathrm{HS}}^2 .$$

Proof. Idempotence and completeness follow from the projector identities. For Hilbert–Schmidt orthogonality,

$$\begin{aligned} \langle P_a X P_b, P_c Y P_d \rangle_{\mathrm{HS}} &= \mathrm{Tr}(P_b X^* P_a P_c Y P_d) \\ &= \delta_{ac}\delta_{bd}\,\mathrm{Tr}(P_b X^* P_a Y P_b). \end{aligned}$$

Since the packets are orthogonal and sum to the original operator, their squared norms add to its squared norm. □

Definition II.7.3 (Packet dephasing)**.** The packet dephasing map is

$$\mathcal{D}_{\mathcal{P}}(X) = \sum_a P_a X P_a.$$

Theorem II.7.4 (Dephasing as conditional expectation)**.** *The map $\mathcal{D}_{\mathcal{P}}$ is completely positive, trace preserving, unital, and idempotent. It is the Hilbert–Schmidt orthogonal projection onto the block diagonal algebra*

$$\mathcal{A}_{\mathcal{P}} = \{X : [X, P_a] = 0 \text{ for every } a\}.$$

In particular,

$$\|\mathcal{D}_{\mathcal{P}}(X)\|_{\mathrm{HS}} \le \|X\|_{\mathrm{HS}}.$$

Proof. The projectors P_a form a Kraus family because $\sum_a P_a^* P_a = I$. Thus the map is completely positive and trace preserving. It is unital for the same reason. Orthogonality and idempotence follow from theorem II.7.2. Its range is the sum of the diagonal operator packets. This is exactly the commutant of the projector family. □

Corollary II.7.5 (Block diagonal measurement invariance)**.** *Let (E_k) be a positive operator valued measurement, and suppose*

$$E_k = \mathcal{D}_{\mathcal{P}}(E_k)$$

for every k. Then every density matrix ρ satisfies

$$\mathrm{Tr}(E_k \rho) = \mathrm{Tr}(E_k \mathcal{D}_{\mathcal{P}}(\rho)).$$

Proof. Since $\mathcal{D}_{\mathcal{P}}$ is self adjoint for the Hilbert–Schmidt inner product,

$$\mathrm{Tr}(E_k \rho) = \mathrm{Tr}(\mathcal{D}_{\mathcal{P}}(E_k)\rho) = \mathrm{Tr}(E_k \mathcal{D}_{\mathcal{P}}(\rho)).$$

□

II.7.1 Channel superblocks

Let $\Phi : \mathrm{End}(\mathcal{H}_X) \to \mathrm{End}(\mathcal{H}_Y)$ be linear. Choose packet systems (P_a) on $\mathcal{H}_X$ and (Q_c) on $\mathcal{H}_Y$. Define

$$\Phi_{cd,ab} = \mathcal{Q}_{cd} \Phi \mathcal{P}_{ab}.$$

Theorem II.7.6 (Exact channel block calculus)**.** *Every linear map has the exact reconstruction*

$$\Phi = \sum_{a,b,c,d} \Phi_{cd,ab}.$$

If $\Psi : \mathrm{End}(\mathcal{H}_Y) \to \mathrm{End}(\mathcal{H}_Z)$, then

$$(\Psi\Phi)_{ef,ab} = \sum_{c,d} \Psi_{ef,cd} \Phi_{cd,ab}.$$

Proof. Insert the complete operator packet resolutions before and after Φ. For composition, insert the middle resolution between Ψ and Φ and collect the output and input packets. □

Standard Fact II.7.7 (Finite Kraus and Choi criteria)**.** A linear map $\Phi : M_n(\mathbb{C}) \to M_m(\mathbb{C})$ is completely positive exactly when it has a Kraus representation

$$\Phi(X) = \sum_r K_r X K_r^*.$$

It is trace preserving exactly when

$$\sum_r K_r^* K_r = I.$$

Equivalently, its Choi matrix

$$J(\Phi) = \sum_{i,j} \Phi(|i\rangle\langle j|) \otimes |i\rangle\langle j|$$

is positive, and trace preservation is

$$\operatorname{Tr}_{\text{out}} J(\Phi) = I_{\text{in}}.$$

These finite criteria are classical [24, 5, 15, 27].

II.7.2 Covariance and coherence order

Let S be unitary and $N \geq 1$ an integer with $S^N = I$, and define the conjugation action

$$\operatorname{Ad}_S(X) = SXS^*.$$

Theorem II.7.8 (Coherence order projectors)**.** *For $q \in \mathbb{Z}/N\mathbb{Z}$, define*

$$\mathcal{L}_q(X) = \frac{1}{N} \sum_{r=0}^{N-1} \omega^{-qr} S^r X S^{-r}.$$

Then the $\mathcal{L}_q$ form a complete orthogonal packet system on Hilbert–Schmidt operator space. Their ranges are the operators satisfying

$$SXS^* = \omega^q X.$$

If P_j are the state charge projectors, then

$$\operatorname{Ran} \mathcal{L}_q = \bigoplus_j P_{j+q} \operatorname{End}(\mathcal{H}) P_j.$$

Proof. Apply the cyclic character projector formula to the unitary representation Ad_S on operator space. The last identity follows from theorem II.3.5 applied to each operator packet. □

Theorem II.7.9 (Covariant channels preserve coherence order)**.** *Suppose*

$$\Phi(SXS^*) = S\Phi(X)S^*$$

for every X. Then

$$\Phi\mathcal{L}_q = \mathcal{L}_q\Phi$$

for every q. Thus Φ cannot mix distinct coherence orders.

Proof. The covariance identity says that Φ commutes with every power of Ad_S. It therefore commutes with each finite character average $\mathcal{L}_q$. □

Theorem II.7.10 (Choi symmetry criterion)**.** *Let $U : G \to \mathcal{U}(\mathcal{H})$ be a finite group representation. A channel Φ is covariant,*

$$\Phi\big(U(g)XU(g)^*\big) = U(g)\Phi(X)U(g)^*,$$

if and only if

$$(U(g) \otimes \overline{U(g)})J(\Phi)(U(g)^* \otimes U(g)^{\mathsf{T}}) = J(\Phi)$$

for every $g \in G$.

Proof. Let

$$\Omega = \sum_i |i\rangle \otimes |i\rangle .$$

Then

$$J(\Phi) = (\Phi \otimes \mathrm{id})(|\Omega\rangle\langle\Omega|).$$

The vector Ω is invariant under $U \otimes \overline{U}$. Covariance therefore implies the displayed Choi invariance. Conversely, the displayed transformation is the Choi matrix of

$$\mathrm{Ad}_{U(g)} \circ \Phi \circ \mathrm{Ad}_{U(g)^*} .$$

The Choi correspondence is injective, so invariance implies that this map equals Φ, which is covariance. □

Corollary II.7.11 (Choi packet decomposition)**.** *The Choi matrix of a covariant channel is block diagonal with respect to the isotypic decomposition of $U \otimes \overline{U}$.*

Proof. Apply theorem II.3.1 to the representation $U \otimes \overline{U}$ and use theorem II.7.10. □

Example II.7.12 (Amplitude damping)**.** For $0 \le \gamma \le 1$, let

$$K_0 = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{1-\gamma} \end{pmatrix}, \qquad K_1 = \begin{pmatrix} 0 & \sqrt{\gamma} \\ 0 & 0 \end{pmatrix}.$$

The channel

$$\Phi_\gamma(\rho) = K_0\rho K_0^* + K_1\rho K_1^*$$

is trace preserving. It sends the off diagonal packet $|0\rangle\langle 1|$ to $\sqrt{1-\gamma}\,|0\rangle\langle 1|$, while the excited population transfers partly into the ground population.

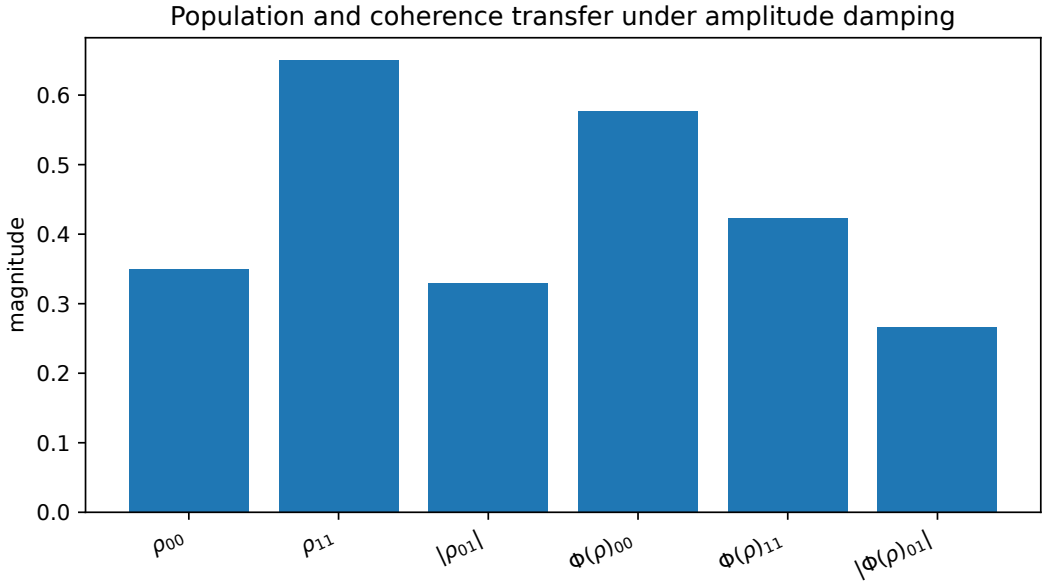

Figure 30. Amplitude damping transfers population and contracts the coherence packet.

II.7.3 Quantum dynamical semigroups

Standard Fact II.7.13 (Finite Lindblad generator)**.** A norm continuous semigroup of completely positive trace preserving maps on a finite matrix algebra, in the Schrödinger picture, has a generator of the form

$$\mathcal{G}(X) = -\mathrm{i}[H, X] + \sum_r \left(L_r X L_r^* - \frac{1}{2} L_r^* L_r X - \frac{1}{2} X L_r^* L_r \right),$$

where $H = H^*$. Conversely, every operator of this form generates a completely positive trace preserving semigroup [16].

Theorem II.7.14 (Charge preservation by a Lindblad generator)**.** *Let S be unitary and $N \geq 1$ an integer with $S^N = I$. Assume*

$$SHS^* = H$$

and, for every jump operator, there is a charge q_r such that

$$SL_rS^* = \omega^{q_r} L_r.$$

Then the Lindblad generator $\mathcal{G}$ preserves every coherence order:

$$\mathcal{G}\mathcal{L}_p = \mathcal{L}_p \mathcal{G}.$$

The quantum dynamical semigroup $\mathrm{e}^{t\mathcal{G}}$ has the same property.

Proof. Let X have coherence order p. The Hamiltonian commutator has order p because H has charge zero. The jump term $L_r X L_r^*$ has charge

$$q_r + p - q_r = p.$$

Also $L_r^* L_r$ has charge zero, so both anticommutator terms have charge p. Thus $\mathcal{G}$ preserves Ran $\mathcal{L}_p$. The exponential series then shows that $\mathrm{e}^{t\mathcal{G}}$ preserves the same packets. □

Corollary II.7.15 (Independent coherence evolution)**.** *Under the hypotheses of theorem II.7.14, each coherence component of an initial operator evolves within its own order. In particular, a density matrix in the zero order sector remains in that sector.*

Proof. Decompose the initial operator by theorem II.7.8 and apply the invariant packet statement to each component. □

Preservation of coherence order does not by itself give a closed classical Markov chain for the packet populations. Such scalar population equations require additional isotropy within each packet.

II.8 Quantum error correction as a compression obstruction

Let P be the orthogonal projector onto a code space

$$\mathcal{C} = P\mathcal{H}, \qquad k = \dim \mathcal{C} \geq 1.$$

The compression of $A \in \mathrm{End}(\mathcal{H})$ to the code is $PAP \in \mathrm{End}(\mathcal{C})$. The zero code has only the zero supported operator and no normalized code state. Part III treats that branch in the mathematical completion.

Definition II.8.1 (Code compression obstruction)**.** Let

$$q_P : \mathrm{End}(\mathcal{C}) \longrightarrow \mathrm{End}(\mathcal{C})/(\mathbb{C} I_{\mathcal{C}})$$

be the quotient map. Define

$$\mathrm{Ob}_P(A) = q_P(PAP).$$

Equivalently, one may use the traceless representative

$$\mathfrak{o}_P(A) = PAP - \frac{\mathrm{Tr}(PAP)}{k} P.$$

The class vanishes exactly when A acts as a scalar after compression to the code. Such an operator cannot distinguish normalized code vectors by expectation value.

Exact correction of an error span means that one completely positive trace preserving recovery $\mathcal{R}$ satisfies $\mathcal{R}(F\rho F^*) = q_F \rho$ for every F in that span and every code-supported matrix ρ, with a nonnegative scalar q_F depending on F but not on the logical input. For every normalized channel with Kraus operators in the same span, the same recovery restores the code input with total scalar one. Individual unnormalized errors are not required to have unit recovery weight.

Theorem II.8.2 (Knill–Laflamme as obstruction vanishing). *Let $E_1, \dots, E_r$ be an error family. The code $\mathcal{C}$ corrects their linear span exactly if and only if*

$$\mathrm{Ob}_P(E_a^* E_b) = 0$$

for all a, b. Equivalently, there is a matrix $c = (c_{ab})$ such that

$$P E_a^* E_b P = c_{ab} P$$

for all a, b.

Proof. The equivalence between the quotient statement and the scalar compression identity is immediate from the definition. The latter identity is the finite Knill–Laflamme criterion [14, 22]. □

The next result turns the scalar compression identities into a family of orthogonal syndrome packets. Those packets provide the coordinates used by the recovery map.

Theorem II.8.3 (Orthogonal syndrome construction). *Assume the Knill–Laflamme identities. Then the coefficient matrix c is positive semidefinite. Choose a unitary matrix W such that*

$$W c W^* = \mathrm{diag}(\lambda_1, \dots, \lambda_r), \qquad \lambda_j \geq 0,$$

and define

$$F_j = \sum_a \overline{W_{ja}} E_a.$$

For every j with $\lambda_j > 0$, the operator

$$V_j = \lambda_j^{-1/2} F_j P$$

is an isometry from the code into $\mathcal{H}$. Its range projector

$$Q_j = V_j V_j^*$$

is a syndrome packet, and the nonzero Q_j are pairwise orthogonal.

Proof. For $z \in \mathbb{C}^r$, let $F_z = \sum_a z_a E_a$. Then

$$P F_z^* F_z P = (z^* c z) P \geq 0,$$

so $c \geq 0$. The unitary change of error coordinates gives

$$P F_j^* F_\ell P = \lambda_j \delta_{j\ell} P.$$

Thus

$$V_j^* V_\ell = \delta_{j\ell} P.$$

Each V_j is an isometry on $P\mathcal{H}$, and distinct ranges are orthogonal. Their range projectors are therefore pairwise orthogonal. □

Theorem II.8.4 (Exact recovery on the error span)**.** *Under the hypotheses of theorem II.8.3, define on the syndrome support*

$$Q = \sum_{\lambda_j > 0} Q_j$$

the completely positive map

$$\mathcal{R}_0(X) = \sum_{\lambda_j > 0} V_j^* Q_j X Q_j V_j.$$

It extends to a quantum channel $\mathcal{R}$ on $\mathrm{End}(\mathcal{H})$*. If*

$$\Phi(X) = \sum_a E_a X E_a^*$$

is trace preserving on code states, then

$$\mathcal{R}\Phi(\rho) = \rho$$

for every density matrix $\rho = P\rho P$.

Proof. The map $\mathcal{R}_0$ is completely positive. It is trace preserving on operators supported in $Q\mathcal{H}$ because

$$\mathrm{Tr}(V_j^* Q_j X Q_j V_j) = \mathrm{Tr}(Q_j X Q_j).$$

Fix a code state ρ_0 and write $Q^\perp = I - Q$. Then

$$\mathcal{R}(X) = \mathcal{R}_0(QXQ) + \mathrm{Tr}(Q^\perp X)\rho_0$$

is completely positive and trace preserving. It extends $\mathcal{R}_0$ on operators supported in $Q\mathcal{H}$.

Unitary mixing of a Kraus family does not change the channel, so

$$\Phi(\rho) = \sum_j F_j \rho F_j^* = \sum_{\lambda_j > 0} \lambda_j V_j \rho V_j^*.$$

Recovery gives

$$\mathcal{R}\Phi(\rho) = \left(\sum_j \lambda_j \right) \rho.$$

Trace preservation on a code state implies $\sum_j \lambda_j = 1$. □

Corollary II.8.5 (Syndrome measurement preserves logical information)**.** *For a channel trace preserving on code states as in the preceding theorem, the completed projective measurement consisting of $(Q_j)_{\lambda_j>0}$ and $I - \sum_{\lambda_j>0} Q_j$ identifies the orthogonal error syndrome without resolving the encoded state inside the code. The complement outcome has probability zero on the corrupted code state.*

Proof. On syndrome j, the encoded state is carried by the isometry V_j. The outcome probability is λ_j, independent of the normalized code state, while the postmeasurement state is $V_j \rho V_j^*$. □

Definition II.8.6 (Approximate Knill–Laflamme defect)**.** For a finite error family, define the following defect. When the family is empty, assign the maximum the value zero.

$$\varepsilon_{\mathrm{KL}} = \max_{a,b} \inf_{c\in\mathbb{C}} \|PE_a^* E_b P - cP\| .$$

Proposition II.8.7 (Meaning of the approximate defect)**.** *For each pair (a, b), choose a minimizing scalar c_{ab}. For unit code vectors ψ, ϕ,*

$$|\langle E_a\psi, E_b\phi\rangle - c_{ab}\,\langle\psi,\phi\rangle| \le \varepsilon_{\mathrm{KL}}.$$

Thus $\varepsilon_{\mathrm{KL}}$ controls the deviation of error overlaps from their scalar code form.

Proof. The left side is

$$|\langle\psi, (PE_a^* E_b P - c_{ab}P)\phi\rangle| ,$$

which is bounded by the operator norm. □

No recovery fidelity estimate is inferred from this norm alone. Approximate error correction requires a separate continuity theorem and a declared channel metric.

Example II.8.8 (Three qubit repetition code)**.** Let

$$|0_L\rangle = |000\rangle , \qquad |1_L\rangle = |111\rangle ,$$

and take the errors

$$I, \quad X\otimes I\otimes I, \quad I\otimes X\otimes I, \quad I\otimes I\otimes X.$$

Their images of the code are four pairwise orthogonal two dimensional syndrome packets whose sum is the full eight dimensional Hilbert space.

Standard Fact II.8.9 (Correctable observable algebras)**.** Let Φ be a finite completely positive trace preserving channel with Kraus operators (E_a). A finite dimensional unital star subalgebra $\mathcal{M} \subseteq P\,\mathrm{End}(\mathcal{H})P$ is correctable when a completely positive trace preserving recovery $\mathcal{R}$ satisfies $P(\Phi^* \circ \mathcal{R}^*)(X)P = X$ for every $X \in \mathcal{M}$, where stars on maps denote Heisenberg adjoints. This holds exactly when every compressed product $PE_a^* E_b P$ belongs to the commutant $\mathcal{M}'$ on the code. The scalar code criterion is the special case $\mathcal{M} = P\,\mathrm{End}(\mathcal{H})P$ [1].

Figure 31. The syndrome packets of the three qubit repetition code. Each packet has dimension two and carries the full logical state.

II.9 Feshbach effective dynamics and hidden packet memory

Let P be an orthogonal projector, put $Q = I - P$, and write a self adjoint Hamiltonian as

$$H = \begin{pmatrix} A & B \\ B^{*} & D \end{pmatrix}$$

relative to $P\mathcal{H} \oplus Q\mathcal{H}$.

Definition II.9.1 (Feshbach map and self energy)**.** For $z \notin \operatorname{Spec} D$, define

$$\Sigma(z) = B(z - D)^{-1} B^{*}$$

and

$$F_{P}(z) = z - A - \Sigma(z).$$

Theorem II.9.2 (Exact projected resolvent)**.** *If $z \notin \operatorname{Spec} D$ and $F_{P}(z)$ is invertible, then*

$$P(z - H)^{-1} P = F_{P}(z)^{-1}$$

as an operator on $P\mathcal{H}$.

Proof. The lower right block of $z - H$ is $z - D$. Block Gaussian elimination gives

$$\begin{pmatrix} I & B(z-D)^{-1} \\ 0 & I \end{pmatrix} (z - H) \begin{pmatrix} I & 0 \\ (z-D)^{-1} B^{*} & I \end{pmatrix} = \begin{pmatrix} F_{P}(z) & 0 \\ 0 & z - D \end{pmatrix}.$$

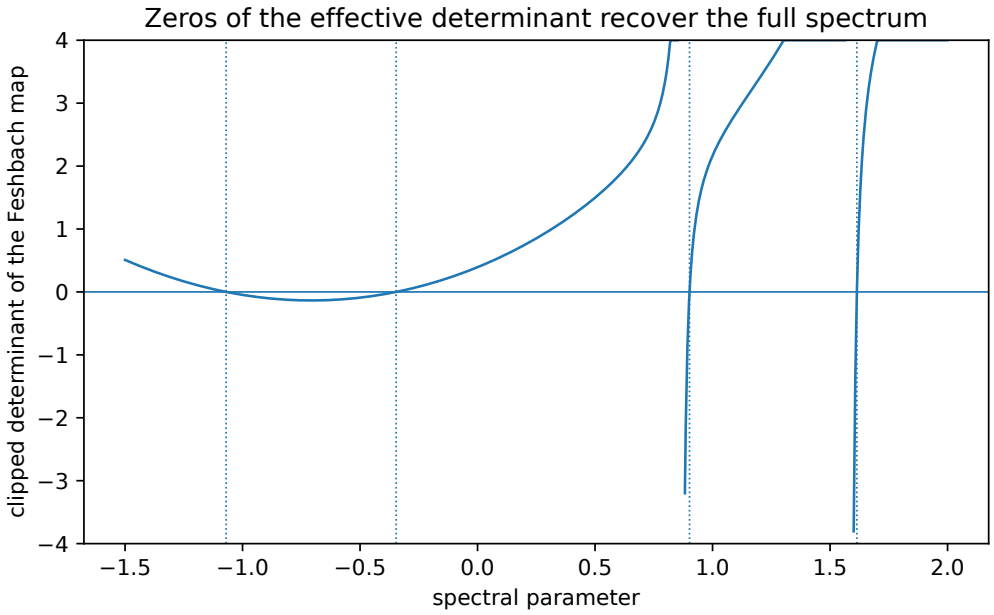

Figure 32. The zeros of the Feshbach determinant recover the eigenvalues of the full finite Hamiltonian away from the hidden spectrum.

Invert the factors. The retained resolvent is the block in the upper left corner of the resulting inverse. □

Theorem II.9.3 (Spectral equivalence). *Let* $z \notin \operatorname{Spec} D$. *Then*

$$z \in \operatorname{Spec} H \quad \Longleftrightarrow \quad 0 \in \operatorname{Spec} F_P(z).$$

The map

$$x \longmapsto \begin{pmatrix} x \\ (z-D)^{-1} B^* x \end{pmatrix}$$

is an isomorphism from $\operatorname{Ker} F_P(z)$ *onto* $\operatorname{Ker}(z-H)$.

Proof. The equation $(z-H)(x,y)^{\mathsf{T}} = 0$ is

$$(z-A)x - By = 0, \qquad -B^* x + (z-D)y = 0.$$

The second equation gives $y = (z-D)^{-1}B^*x$. Substitution into the first gives $F_P(z)x = 0$. The construction is reversible. □

Theorem II.9.4 (Upper half plane sign). *If* $\operatorname{Im} z > 0$, *then*

$$\operatorname{Im} \Sigma(z) = -(\operatorname{Im} z) B (z-D)^{-1} (\overline{z}-D)^{-1} B^* \leq 0.$$

Thus $-\Sigma$ *is an operator valued Herglotz function.*

Proof. For $R(z) = (z - D)^{-1}$, the resolvent identity gives

$$R(z) - R(z)^* = (\overline{z} - z)R(z)R(z)^*.$$

Divide by 2i, then multiply the result on the left by B and on the right by B^*. □

Proposition II.9.5 (Uniform self energy bounds)**.** *Let*

$$\delta = \operatorname{dist}(z, \operatorname{Spec} D) > 0, \qquad g = \|B\|.$$

Then

$$\|\Sigma(z)\| \leq \frac{g^2}{\delta}$$

and

$$\|\Sigma'(z)\| \leq \frac{g^2}{\delta^2}.$$

For real E, E' in an interval at distance at least δ from Spec D*,*

$$\|\Sigma(E) - \Sigma(E')\| \leq \frac{g^2}{\delta^2} |E - E'|.$$

Proof. The self adjoint resolvent satisfies

$$\left\|(z - D)^{-1}\right\| = \frac{1}{\operatorname{dist}(z, \operatorname{Spec} D)}.$$

Differentiate the resolvent to obtain

$$\Sigma'(z) = -B(z - D)^{-2}B^*.$$

Taking operator norms gives the first two estimates. Applying the derivative bound along the real interval gives the final mean value estimate. □

Proposition II.9.6 (Low energy expansion)**.** *Assume D is invertible and $|z| \left\|D^{-1}\right\| < 1$. Then*

$$\Sigma(z) = -\sum_{n=0}^{\infty} z^n B D^{-n-1} B^*$$

with norm convergence. In particular,

$$F_P(z) = z - A + BD^{-1}B^* + O(|z| \|B\|^2 \left\|D^{-1}\right\|^2).$$

Proof. Write

$$(z - D)^{-1} = -D^{-1}(I - zD^{-1})^{-1} = -\sum_{n=0}^{\infty} z^n D^{-n-1}$$

and multiply on the left by B and on the right by B^*. □

Proposition II.9.7 (Bare truncation error identity)**.** *If both $F_P(z)$ and $z - A$ are invertible, then*

$$P(z-H)^{-1}P - (z-A)^{-1} = F_P(z)^{-1}\Sigma(z)(z-A)^{-1}.$$

Proof. Use the inverse difference identity

$$X^{-1} - Y^{-1} = X^{-1}(Y-X)Y^{-1}$$

with $X = F_P(z)$ and $Y = z - A$. □

II.9.1 Time memory

Write a Schrödinger state as $\psi = x + y$, where $x = P\psi$ and $y = Q\psi$.

Theorem II.9.8 (Exact retained memory equation)**.** *The retained coordinate satisfies*

$$\begin{aligned} \mathrm{i}\dot{x}(t) &= Ax(t) + B\mathrm{e}^{-\mathrm{i}tD}y(0) \\ &\quad - \mathrm{i}\int_0^t K(t-s)x(s)\,\mathrm{d}s, \end{aligned}$$

where

$$K(t) = B\mathrm{e}^{-\mathrm{i}tD}B^*.$$

For $\operatorname{Re} s > 0$,

$$\int_0^\infty \mathrm{e}^{-st}K(t)\,\mathrm{d}t = B(s+\mathrm{i}D)^{-1}B^*.$$

Proof. The hidden equation is

$$\mathrm{i}\dot{y} = B^*x + Dy.$$

Variation of constants gives

$$y(t) = \mathrm{e}^{-\mathrm{i}tD}y(0) - \mathrm{i}\int_0^t \mathrm{e}^{-\mathrm{i}(t-s)D}B^*x(s)\,\mathrm{d}s.$$

Substitute into $\mathrm{i}\dot{x} = Ax + By$. The Laplace formula follows by diagonalizing D or integrating the norm convergent finite dimensional exponential. □

Theorem II.9.9 (Positive definite quantum memory)**.** *The kernel $K(t-s)$ is positive definite. For times $t_1, \dots, t_m$ and retained vectors $v_1, \dots, v_m$,*

$$\sum_{j,k=1}^m \left\langle v_j, K(t_j - t_k)v_k \right\rangle \geq 0.$$

Proof. Set

$$w = \sum_{k=1}^m \mathrm{e}^{\mathrm{i}t_kD}B^*v_k.$$

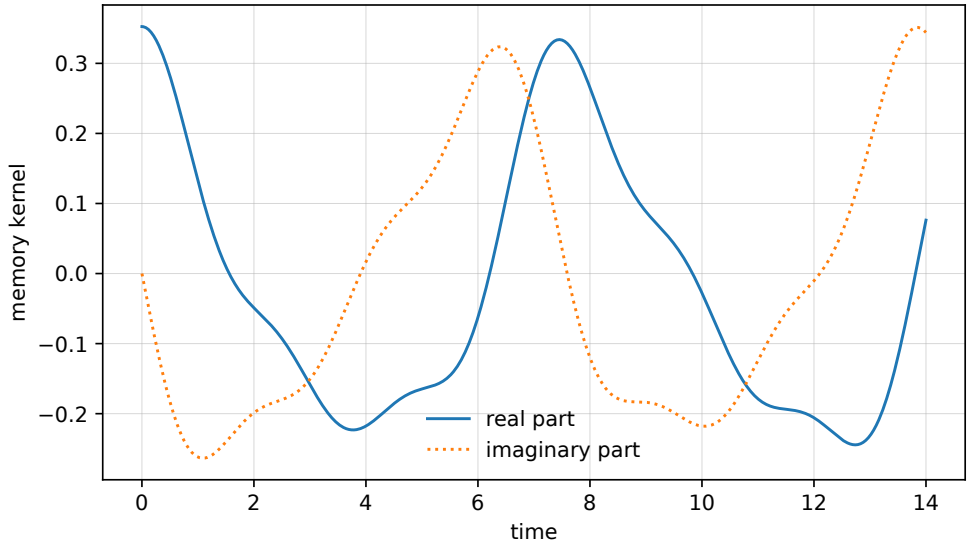

Figure 33. A finite hidden spectrum produces an oscillatory memory kernel. The retained dynamics therefore depend on the history of the retained state.

Then

$$\|w\|^2 = \sum_{j,k} \left\langle B^* v_j, \mathrm{e}^{-\mathrm{i}(t_j - t_k)D} B^* v_k \right\rangle = \sum_{j,k} \left\langle v_j, K(t_j - t_k) v_k \right\rangle .$$

□

Corollary II.9.10 (Finite oscillatory memory expansion)**.** *If*

$$D = \sum_r E_r Q_r$$

is the spectral decomposition of the hidden Hamiltonian, then

$$K(t) = \sum_r \mathrm{e}^{-\mathrm{i}tE_r} B Q_r B^* .$$

Every coefficient BQ_rB^* is positive semidefinite.

Proof. Inserting the spectral decomposition into the exponential gives the stated sum. The spectral projectors are positive semidefinite, so multiplication by the coupling and its adjoint preserves positivity of each coefficient. □

Theorem II.9.11 (Exact local closure criterion)**.** *Assume $y(0) = 0$. The retained equation is local and equal to*

$$\mathrm{i}\dot{x} = Ax$$

for every retained initial state exactly when $B = 0$. Equivalently, exact local closure holds exactly when the retained and hidden packets reduce H.

Proof. If $B = 0$, the retained and hidden equations decouple. Conversely, suppose that every solution with $y(0) = 0$ satisfies $x(t) = \mathrm{e}^{-\mathrm{i}tA}x(0)$. The full block equation gives

$$\ddot{x}(0) = -(A^2 + BB^*)x(0),$$

while the declared local equation gives

$$\ddot{x}(0) = -A^2x(0).$$

Since this holds for every retained initial vector, $BB^* = 0$. Hence $B = 0$. □

II.9.2 Stability across models

Theorem II.9.12 (Stability of the self energy)**.** *Let $D = D^*$ and $\widetilde{D} = \widetilde{D}^*$ act on one fixed hidden Hilbert space, and let $B, \widetilde{B}$ map that hidden space to one fixed retained Hilbert space. Define*

$$\Sigma(z) = B(z - D)^{-1}B^*, \qquad \widetilde{\Sigma}(z) = \widetilde{B}(z - \widetilde{D})^{-1}\widetilde{B}^*.$$

Assume

$$\|B\|, \left\|\widetilde{B}\right\| \leq g$$

and

$$\operatorname{dist}(z, \operatorname{Spec} D), \operatorname{dist}(z, \operatorname{Spec} \widetilde{D}) \geq \delta > 0.$$

Then

$$\left\|\Sigma(z) - \widetilde{\Sigma}(z)\right\| \leq \frac{2g}{\delta}\left\|B - \widetilde{B}\right\| + \frac{g^2}{\delta^2}\left\|D - \widetilde{D}\right\|.$$

Proof. Add and subtract $\widetilde{B}(z - D)^{-1}B^*$ and $\widetilde{B}(z - D)^{-1}\widetilde{B}^*$. The first two differences give the coupling term. For the last, use

$$(z - D)^{-1} - (z - \widetilde{D})^{-1} = (z - D)^{-1}(D - \widetilde{D})(z - \widetilde{D})^{-1}.$$

Apply the resolvent bounds. □

Corollary II.9.13 (Uniform Feshbach control)**.** *For a family represented on fixed retained and hidden Hilbert spaces, with self adjoint hidden Hamiltonians, a common hidden spectral separation δ, and a common coupling bound g, the self energies are uniformly bounded and uniformly Lipschitz on the declared spectral region. If the couplings and hidden Hamiltonians converge in norm, then the self energies converge uniformly there.*

Proof. The common gap and coupling bounds allow proposition II.9.5 and theorem II.9.12 to be applied uniformly across the family. □

This result identifies hypotheses that make Feshbach control uniform in the cutoff. Whether a chosen geometric refinement tower satisfies those hypotheses remains a separate question.

II.10 Euclidean transfer and finite reflection positivity

Let $H = H^*$ on a nonzero finite dimensional Hilbert space and let

$$E_0 = \min \operatorname{Spec} H.$$

For a lattice time step $a > 0$, define

$$T = \mathrm{e}^{-a(H - E_0 I)}.$$

Theorem II.10.1 (Finite Euclidean transfer). *The operator T is positive definite, self adjoint, and contractive. Its spectrum lies in $(0, 1]$, and*

$$T^n = \mathrm{e}^{-na(H - E_0 I)}$$

for every $n \in \mathbb{N}$.

Proof. Diagonalize H. Each eigenvalue of T is

$$\mathrm{e}^{-a(E_j - E_0)}$$

and therefore lies in $(0, 1]$. The power law follows from the functional calculus. □

Theorem II.10.2 (Hamiltonian reconstruction from transfer). *Let T be positive definite, self adjoint, and contractive. Then*

$$H_T = -a^{-1} \log T$$

is a nonnegative self adjoint operator and

$$T^n = \mathrm{e}^{-naH_T}.$$

It is the unique nonnegative self adjoint operator with $T = \mathrm{e}^{-aH_T}$.

Proof. Apply the real logarithm to the positive spectrum of T. The spectral calculus gives existence and the power identity. Injectivity of the scalar exponential on $[0, \infty)$ gives uniqueness. □

Theorem II.10.3 (Finite reflection positivity). *For vectors $v_1, \dots, v_m \in \mathcal{H}$ and nonnegative integers $n_1, \dots, n_m$, the matrix*

$$G_{jk} = \left\langle v_j, T^{n_j + n_k} v_k \right\rangle$$

is positive semidefinite. Equivalently,

$$\sum_{j,k} \overline{c_j} c_k \left\langle v_j, T^{n_j + n_k} v_k \right\rangle \geq 0$$

for every $c \in \mathbb{C}^m$.

Proof. Since T is positive and self adjoint,

$$\left\langle v_j, T^{n_j + n_k} v_k \right\rangle = \left\langle T^{n_j} v_j, T^{n_k} v_k \right\rangle.$$

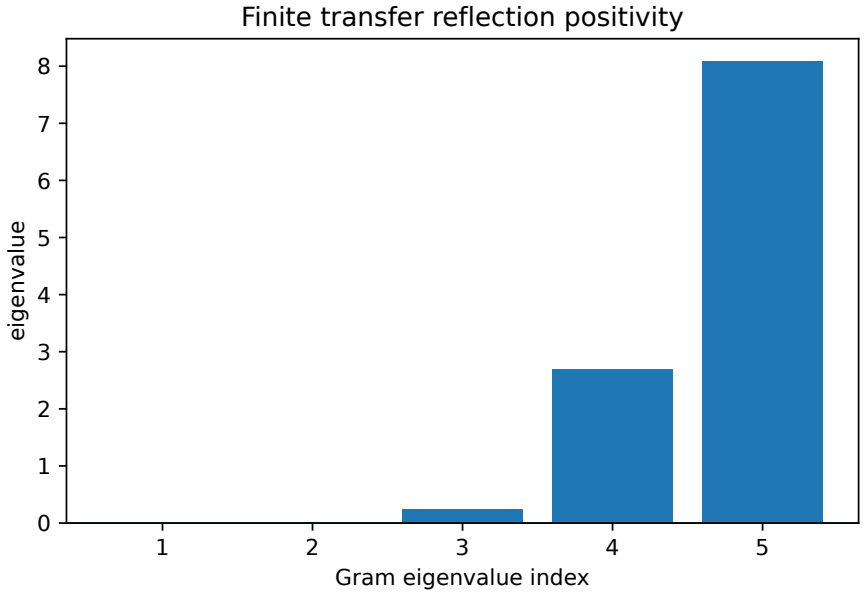

Figure 34. Eigenvalues of a finite reflection positive Gram matrix. Small numerical negative values would signal either roundoff or failure of the transfer assumptions.

The quadratic form is the squared norm of

$$\sum_k c_k T^{n_k} v_k.$$

□

Corollary II.10.4 (Reflection positive correlators)**.** *Fix a vector Ω and operators $A_1, \dots, A_m$. The matrix*

$$C_{jk} = \langle A_j \Omega, T^{n_j + n_k} A_k \Omega \rangle$$

is positive semidefinite.

Proof. Apply theorem II.10.3 with $v_j = A_j \Omega$. □

Proposition II.10.5 (Ground packet convergence)**.** *Let P_0 be the spectral projector of H at E_0, and let*

$$\Delta = \min\{E_j - E_0 : E_j > E_0\}.$$

If an excited eigenvalue exists, then

$$\|T^n - P_0\| = \mathrm{e}^{-na\Delta}.$$

Proof. In the spectral decomposition, $T^n - P_0$ has eigenvalues zero on the ground space and $\mathrm{e}^{-na(E_j - E_0)}$ on the excited eigenspaces. The largest is $\mathrm{e}^{-na\Delta}$. □

Proposition II.10.6 (Symmetry resolved transfer)**.** *If $[H, P_a] = 0$ for a complete packet family, then*

$$T = \sum_a P_a T P_a$$

and each reflection positive Gram matrix decomposes as the sum of its packet Gram matrices.

Proof. The functional calculus preserves commutation. Decompose every vector into packet components and use orthogonality. □

Finite reflection positivity is a necessary structural property of transfer data. It is not by itself the continuum Osterwalder–Schrader theorem, which also requires a suitable algebra of Euclidean fields, covariance, regularity, clustering, and a controlled continuum limit [19, 20, 10].

II.11 Finite spectral geometry and diffusion dimension

A finite spectral datum consists of a finite dimensional Hilbert space, a nonnegative self adjoint operator L, and any declared packet family. One may take $L = D^2$ for a finite Dirac type operator or a graph Laplacian. Related geometric viewpoints appear in [6, 26].

Definition II.11.1 (Heat trace and spectral dimension)**.** Let the eigenvalues of L be $\lambda_1, \dots, \lambda_N$, with at least one zero eigenvalue. Define

$$Z_L(t) = \mathrm{Tr}(\mathrm{e}^{-tL})$$

and

$$d_L(t) = -2\frac{\mathrm{d}\log Z_L(t)}{\mathrm{d}\log t} = 2t\frac{\mathrm{Tr}(L\mathrm{e}^{-tL})}{\mathrm{Tr}(\mathrm{e}^{-tL})}.$$

Proposition II.11.2 (Finite scale limits)**.** *For every finite nonnegative L with nontrivial kernel,*

$$\lim_{t\downarrow 0} d_L(t) = 0$$

and

$$\lim_{t\to\infty} d_L(t) = 0.$$

For every $t > 0$,

$$0 \le d_L(t) \le 2t\,\|L\|\,.$$

Proof. The formula in definition II.11.1 is twice t times a weighted average of the eigenvalues. This gives the bound and the limit at zero. At large time, the denominator converges to $\dim \mathrm{Ker}\, L$, while every positive eigenvalue contribution in the numerator decays exponentially. □

Thus a finite system cannot have a nonzero spectral dimension at the extreme ultraviolet or infrared ends. A geometric dimension can appear only in a refinement window.

Proposition II.11.3 (Heat packet decomposition). *If $[L, P_a] = 0$ for every packet, then*

$$Z_L(t) = \sum_a Z_{L,a}(t), \qquad Z_{L,a}(t) = \mathrm{Tr}(P_a \mathrm{e}^{-tL}).$$

The global spectral dimension is the average of the packet dimensions weighted by their heat traces:

$$d_L(t) = \sum_{a: Z_{L,a}(t)>0} \frac{Z_{L,a}(t)}{Z_L(t)} d_{L,a}(t),$$

where

$$d_{L,a}(t) = 2t \frac{\mathrm{Tr}(P_a L \mathrm{e}^{-tL})}{Z_{L,a}(t)}$$

for nonempty packet heat traces.

Proof. Commutation gives a block diagonal heat operator. Add the traces and the corresponding first spectral moments, then divide by the total heat trace. □

II.11.1 Periodic lattices

Let $N \geq 2$ and let $\Lambda_N = (\mathbb{Z}/N\mathbb{Z})^d$ be the unit flat torus grid with spacing $1/N$. The standard periodic difference Laplacian has eigenvalues

$$\lambda_N(k) = 4N^2 \sum_{j=1}^{d} \sin^2\left(\frac{\pi k_j}{N}\right),$$

where k runs through centered residue representatives. This is the standard periodic finite difference Laplacian [25].

Theorem II.11.4 (Low mode dispersion in dimension d). *For every centered mode k,*

$$0 \leq 4\pi^2 |k|^2 - \lambda_N(k) \leq \frac{4\pi^4}{3N^2} \sum_{j=1}^{d} k_j^4.$$

Proof. For $x \in [0, \pi/2]$,

$$\sin x \leq x$$

and

$$\sin x \geq x - \frac{x^3}{6}.$$

Thus

$$0 \leq x^2 - \sin^2 x \leq \frac{x^4}{3}.$$

Apply this with $x = \pi |k_j| / N$, multiply by $4N^2$, and sum over j. □

Theorem II.11.5 (Fixed time heat trace convergence)**.** *For every $t > 0$,*

$$\sum_{k \in \Lambda_N^*} \mathrm{e}^{-t\lambda_N(k)} \longrightarrow \sum_{k \in \mathbb{Z}^d} \mathrm{e}^{-4\pi^2 t|k|^2}$$

as $N \to \infty$. The first spectral moments also converge:

$$\sum_{k \in \Lambda_N^*} \lambda_N(k) \mathrm{e}^{-t\lambda_N(k)} \longrightarrow \sum_{k \in \mathbb{Z}^d} 4\pi^2 |k|^2 \mathrm{e}^{-4\pi^2 t|k|^2}.$$

Consequently, the discrete spectral dimensions converge to the continuum torus spectral dimension at every fixed positive time.

Proof. For a fixed integer mode, theorem II.11.4 gives

$$\lambda_N(k) \longrightarrow 4\pi^2 |k|^2 .$$

For centered modes, the inequality

$$\sin x \geq \frac{2x}{\pi}, \qquad 0 \leq x \leq \frac{\pi}{2},$$

gives

$$\lambda_N(k) \geq 16 |k|^2 .$$

Also $\lambda_N(k) \leq 4\pi^2 |k|^2$. Extend the discrete summands by zero outside the centered residue box. The heat trace terms are dominated by

$$\mathrm{e}^{-16t|k|^2},$$

and the moment terms by

$$4\pi^2 |k|^2 \mathrm{e}^{-16t|k|^2}.$$

Both dominating sequences are summable on $\mathbb{Z}^d$. Dominated convergence proves the two limits. Their quotient gives spectral dimension convergence. □

Standard Fact II.11.6 (Theta transformation)**.** The continuum flat torus heat trace satisfies

$$Z_d(t) = \sum_{k \in \mathbb{Z}^d} \mathrm{e}^{-4\pi^2 t|k|^2} = (4\pi t)^{-d/2} \sum_{n \in \mathbb{Z}^d} \mathrm{e}^{-|n|^2/(4t)}.$$

This is the Poisson summation formula for a Gaussian.

Theorem II.11.7 (Continuum torus small time dimension)**.** *Let*

$$d_{\text{torus}}(t) = -2 \frac{\mathrm{d} \log Z_d(t)}{\mathrm{d} \log t}.$$

Then

$$d_{\text{torus}}(t) = d + O\left(t^{-1} \mathrm{e}^{-1/(4t)}\right)$$

as $t \downarrow 0$.

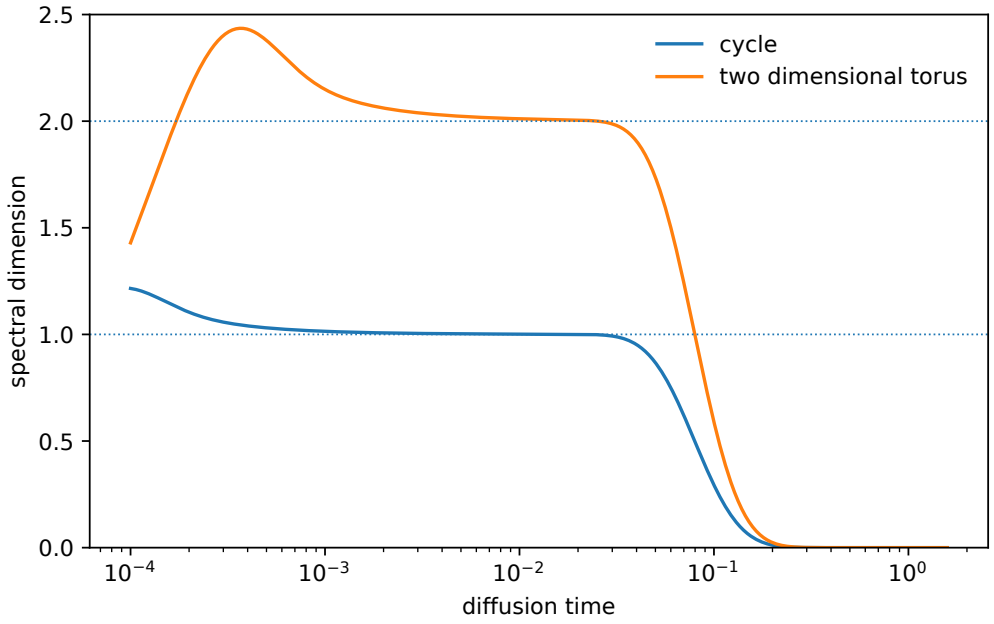

Figure 35. Finite periodic lattices show an intermediate dimension window. The ultraviolet and infrared limits return to zero because the state space is finite.

Proof. By standard fact II.11.6,

$$Z_d(t) = (4\pi t)^{-d/2}(1 + R(t)),$$

where

$$R(t) = \sum_{n \neq 0} \mathrm{e}^{-|n|^2/(4t)} = O(\mathrm{e}^{-1/(4t)}).$$

Differentiation gives

$$tR'(t) = O\left(t^{-1}\mathrm{e}^{-1/(4t)}\right).$$

Substituting this estimate into the logarithmic derivative gives the stated small time expansion. □

Corollary II.11.8 (Rigorous intermediate dimension window)**.** *For every $\varepsilon > 0$, there is a diffusion time $t_\varepsilon > 0$ and an integer N_ε such that*

$$\left|d_{L_N}(t_\varepsilon) - d\right| < \varepsilon$$

for every $N \geq N_\varepsilon$.

Proof. Choose t_ε so that theorem II.11.7 is within $\varepsilon/2$ of d. Then apply theorem II.11.5 to choose N_ε so that the discrete spectral dimension is within $\varepsilon/2$ of the continuum value. □

The order of limits matters. Taking $t \downarrow 0$ at fixed N gives zero. Taking $N \to \infty$ at fixed positive t, then taking $t \downarrow 0$, gives the continuum dimension.

II.12 Constraint closure and anomaly packets

Let $C_1, \dots, C_m$ be self adjoint constraint operators on a finite dimensional Hilbert space. The distinction between constraint action and constraint closure is standard in constrained Hamiltonian theory [7, 11]. Write

$$\mathfrak{c} = \operatorname{span}_{\mathbb{C}}\{C_1, \dots, C_m\} \subseteq \operatorname{End}(\mathcal{H}).$$

Definition II.12.1 (Universal closure obstruction)**.** Let

$$q_{\mathfrak{c}} : \operatorname{End}(\mathcal{H}) \longrightarrow \operatorname{End}(\mathcal{H})/\mathfrak{c}$$

be the quotient map. Define

$$\mathrm{Ob}^{\mathrm{cl}}_{ab} = q_{\mathfrak{c}}([C_a, C_b]).$$

Theorem II.12.2 (Finite constraint closure criterion)**.** *The constraint span $\mathfrak{c}$ is closed under commutators exactly when*

$$\mathrm{Ob}^{\mathrm{cl}}_{ab} = 0$$

for all a, b.

Proof. The quotient class vanishes exactly when $[C_a, C_b] \in \mathfrak{c}$. This holds for every pair exactly when $\mathfrak{c}$ is a Lie algebra under the commutator. □

If structure coefficients ${f_{ab}}^{c}$ are prescribed, define the fixed structure anomaly

$$\mathfrak{A}_{ab} = [C_a, C_b] - \mathrm{i}\sum_c {f_{ab}}^{c} C_c.$$

Exact realization of the prescribed algebra is the stronger condition $\mathfrak{A}_{ab} = 0$.

Proposition II.12.3 (Physical compression is not a closure test)**.** *Let*

$$\mathcal{H}_{\mathrm{phys}} = \bigcap_a \operatorname{Ker} C_a$$

and let P_{phys} be its orthogonal projector. Then

$$P_{\mathrm{phys}}[C_a, C_b]P_{\mathrm{phys}} = 0$$

for every pair a, b, whether or not the constraint span closes.

Proof. Self adjointness and $C_a P_{\mathrm{phys}} = 0$ give $P_{\mathrm{phys}} C_a = 0$. Both terms in the compressed commutator therefore vanish. □

The quotient in definition II.12.1 is needed because closure concerns the operator algebra. Compression to physical states tests only the action on the common kernel, where the constraints already vanish.

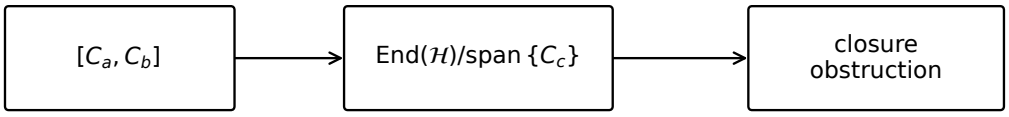

Figure 36. The closure obstruction lives in a quotient by the constraint span. Physical compression is automatic for self adjoint constraints and cannot replace this quotient.

Theorem II.12.4 (Invariance of the physical space)**.** *Let $H = H^*$. Suppose*

$$[H, C_a] = \sum_c b_a{}^c C_c$$

for every a. Then H preserves $\mathcal{H}_{\text{phys}}$, and so does $\mathrm{e}^{-\mathrm{i}tH}$ for every real t.

Proof. For $\psi \in \mathcal{H}_{\text{phys}}$,

$$C_a H\psi = HC_a\psi - [H, C_a]\psi = 0.$$

Thus $H\psi \in \mathcal{H}_{\text{phys}}$. The exponential preserves every invariant finite dimensional subspace. □

II.12.1 Constraint refinement

Let $(\mathcal{H}_\ell, C_{\ell,a})$ and $(\mathcal{H}_{\ell+1}, C_{\ell+1,a})$ be two levels, and let

$$R_\ell : \mathcal{H}_\ell \longrightarrow \mathcal{H}_{\ell+1}$$

be an isometry.

Theorem II.12.5 (Exact constraint transport). *Assume*

$$C_{\ell+1,a}R_\ell = R_\ell C_{\ell,a}$$

for every a. Then

$$[C_{\ell+1,a}, C_{\ell+1,b}]R_\ell = R_\ell[C_{\ell,a}, C_{\ell,b}].$$

If the same structure coefficients are used at both levels, then

$$\mathfrak{A}_{\ell+1,ab}R_\ell = R_\ell\mathfrak{A}_{\ell,ab}.$$

The isometry maps coarse physical states into fine physical states.

Proof. Apply the intertwining identity twice to each product in the commutator. The anomaly identity follows by subtracting the same linear combination of constraints. If $C_{\ell,a}\psi = 0$, then

$$C_{\ell+1,a}R_\ell\psi = R_\ell C_{\ell,a}\psi = 0.$$

□

Proposition II.12.6 (Approximate constraint transport). *Assume*

$$\|C_{\ell+1,a}R_\ell - R_\ell C_{\ell,a}\| \le \varepsilon_a$$

and

$$\|C_{\ell,a}\|, \|C_{\ell+1,a}\| \le M.$$

Then a coarse physical unit vector ψ satisfies

$$\|C_{\ell+1,a}R_\ell\psi\| \le \varepsilon_a.$$

Also,

$$\begin{aligned}\|[C_{\ell+1,a}, C_{\ell+1,b}]R_\ell - R_\ell[C_{\ell,a}, C_{\ell,b}]\| \\ \le 2M(\varepsilon_a + \varepsilon_b).\end{aligned}$$

Proof. The first claim follows by applying the intertwining defect to ψ. Write

$$E_a = C_{\ell+1,a}R_\ell - R_\ell C_{\ell,a}.$$

Expanding the two commutators gives four error terms:

$$E_a C_{\ell,b}, \quad C_{\ell+1,a}E_b, \quad -E_b C_{\ell,a}, \quad -C_{\ell+1,b}E_a.$$

The triangle inequality and the stated bounds on the constraints and defects give the claimed estimate. □

Approximate transport controls finite violations. It does not turn a nonzero anomaly into an exact continuum algebra without a limit theorem and a common operator domain.

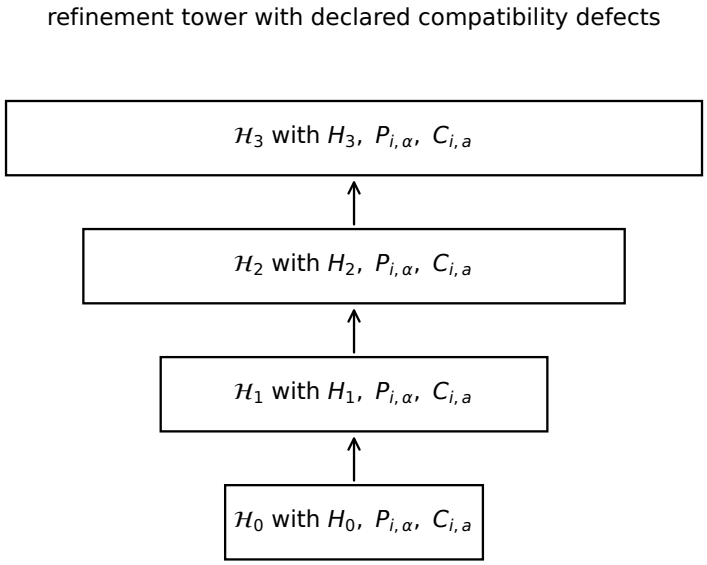

Figure 37. A refinement tower carries Hamiltonians, packets, constraints, and transfer data. Each family has its own compatibility defect.

II.13 Quantum refinement towers

Definition II.13.1 (Finite quantum refinement tower)**.** A finite quantum refinement tower consists of Hilbert spaces $\mathcal{H}_\ell$, isometries

$$R_\ell : \mathcal{H}_\ell \longrightarrow \mathcal{H}_{\ell+1},$$

self adjoint Hamiltonians H_ℓ, packet projectors $P_{\ell,\alpha}$, constraints $C_{\ell,r}$, and positive transfer operators T_ℓ. Exact compatibility means that every declared object intertwines with R_ℓ. Approximate compatibility is recorded by the corresponding operator norm defects.

II.13.1 Exact bounded direct limits

Let $\mathcal{H}_\infty$ be the Hilbert direct limit of the isometric system, and let

$$\iota_\ell : \mathcal{H}_\ell \longrightarrow \mathcal{H}_\infty$$

be the canonical isometries.

Theorem II.13.2 (Bounded Hamiltonian direct limit)**.** *Assume*

$$H_{\ell+1}R_\ell = R_\ell H_\ell$$

and

$$\sup_\ell \|H_\ell\| < \infty.$$

Then there is a unique bounded self adjoint operator H_∞ on $\mathcal{H}_\infty$ such that

$$H_\infty \iota_\ell = \iota_\ell H_\ell$$

for every ℓ. It satisfies

$$\mathrm{e}^{-\mathrm{i}tH_\infty}\iota_\ell = \iota_\ell \mathrm{e}^{-\mathrm{i}tH_\ell}$$

and

$$\mathrm{e}^{-tH_\infty}\iota_\ell = \iota_\ell \mathrm{e}^{-tH_\ell}$$

when the Hamiltonians are nonnegative.

Proof. Define H_∞ on the algebraic union of the embedded levels by

$$H_\infty \iota_\ell x = \iota_\ell H_\ell x.$$

Compatibility makes the definition independent of the chosen level. The uniform norm bound makes the operator bounded on the dense union, so it extends uniquely to the completion. It is symmetric because every H_ℓ is self adjoint. A bounded symmetric operator defined on the whole Hilbert space is self adjoint. The functional calculus intertwining follows first for polynomials and then for exponentials by uniform convergence. □

Theorem II.13.3 (Exact packet direct limit)**.** *Assume the packet families have one fixed finite address set at every level and each packet address a is compatible in the sense*

$$P_{\ell+1,a}R_\ell = R_\ell P_{\ell,a}.$$

Then there is an orthogonal projector $P_{\infty,a}$ on $\mathcal{H}_\infty$ satisfying

$$P_{\infty,a}\iota_\ell = \iota_\ell P_{\ell,a}.$$

Finite completeness and orthogonality pass to the direct limit.

Proof. Use the same construction as in theorem II.13.2. Every projector has norm at most one, so no additional boundedness assumption is needed. The projector identities hold on the dense algebraic union and hence on the completion. □

II.13.2 Norm summable approximation

The next theorem places all approximating Hamiltonians on a common Hilbert space. It applies to bounded effective Hamiltonians. An unbounded field Hamiltonian requires a different convergence argument.

Theorem II.13.4 (Norm summable Hamiltonian tower)**.** *Let (H_n) be bounded self adjoint operators on one Hilbert space and assume*

$$\sum_{n=0}^{\infty} \|H_{n+1} - H_n\| < \infty.$$

Then H_n converges in norm to a bounded self adjoint operator H. For every $T > 0$,

$$\sup_{|t|\le T} \left\|\mathrm{e}^{-\mathrm{i}tH_n} - \mathrm{e}^{-\mathrm{i}tH}\right\| \le T \left\|H_n - H\right\|.$$

If every $H_n \ge 0$, then

$$\sup_{0\le t\le T} \left\|\mathrm{e}^{-tH_n} - \mathrm{e}^{-tH}\right\| \le T \left\|H_n - H\right\|.$$

Proof. The summability condition makes (H_n) Cauchy in operator norm. The limit is self adjoint. Duhamel's identity gives

$$\mathrm{e}^{-\mathrm{i}tH_n} - \mathrm{e}^{-\mathrm{i}tH} = -\mathrm{i}\int_0^t \mathrm{e}^{-\mathrm{i}(t-s)H_n}(H_n - H)\mathrm{e}^{-\mathrm{i}sH}\,\mathrm{d}s.$$

Both unitary factors have norm one, which gives the first estimate. The same argument gives the Euclidean estimate because the semigroups generated by nonnegative Hamiltonians are contractions. □

Corollary II.13.5 (Limit of packet leakage)**.** *Let P_n be orthogonal projectors and H_n bounded self adjoint operators on one Hilbert space, with $P_n \to P$ and $H_n \to H$ in norm. Then for every bounded time interval,*

$$(I - P_n)\mathrm{e}^{-\mathrm{i}tH_n}P_n \longrightarrow (I - P)\mathrm{e}^{-\mathrm{i}tH}P$$

uniformly in time.

Proof. Add and subtract terms so that one factor changes at a time. The projector terms converge uniformly because $P_n \to P$ in norm. Duhamel's identity gives

$$\sup_{|t|\le T} \left\|\mathrm{e}^{-\mathrm{i}tH_n} - \mathrm{e}^{-\mathrm{i}tH}\right\| \le T \left\|H_n - H\right\|,$$

which proves uniform convergence of the middle factor. □

Theorem II.13.6 (Reflection positivity is closed under limits)**.** *Suppose $C_n(j,k)$ are reflection positive kernels on $\mathbb{N}$, meaning every finite matrix*

$$\left(C_n(j_r, j_s)\right)_{r,s}$$

is positive semidefinite. If

$$C_n(j,k) \longrightarrow C(j,k)$$

for every pair, then C is reflection positive.

Proof. For a fixed finite set of times and coefficients, the corresponding quadratic forms are nonnegative and converge to the quadratic form of C. The limit is nonnegative. □

Theorem II.13.7 (Constraint closure under norm convergence)**.** *Let $C_{n,a} \to C_a$ in norm for every a, and fix structure coefficients ${f_{ab}}^c$. If*

$$\left\| [C_{n,a}, C_{n,b}] - \mathrm{i} \sum_c {f_{ab}}^c C_{n,c} \right\| \longrightarrow 0,$$

then

$$[C_a, C_b] = \mathrm{i} \sum_c {f_{ab}}^c C_c.$$

Proof. Operator multiplication and the commutator are continuous in operator norm. Pass to the limit in the anomaly identity. □

Theorem II.13.8 (Heat trace convergence from trace norm)**.** *Let L_n, L be nonnegative self adjoint operators on one Hilbert space. For a fixed $t > 0$, assume their heat operators are trace class and that*

$$\mathrm{e}^{-tL_n} \longrightarrow \mathrm{e}^{-tL}$$

in trace norm. Then

$$\mathrm{Tr}(\mathrm{e}^{-tL_n}) \longrightarrow \mathrm{Tr}(\mathrm{e}^{-tL}).$$

If also the heat moment operators are trace class and

$$L_n \mathrm{e}^{-tL_n} \longrightarrow L\mathrm{e}^{-tL}$$

in trace norm and the limiting heat trace is nonzero, then the spectral dimensions defined by the heat moment ratio converge at that time.

Proof. The trace is continuous in trace norm. Apply this to the heat operators and to the first heat moments, then take the quotient in definition II.11.1. □

Remark II.13.9. The theorems above produce bounded continuum Hamiltonians. A physically useful continuum Hamiltonian is often unbounded. Its construction generally requires strong resolvent convergence, convergence of closed quadratic forms, or another method that controls operator domains [13, 21]. None of those conclusions follows from finite matrix convergence without additional hypotheses.

II.14 Continuum requirements and scope

The finite theorems establish exact identities and criteria for bounded limits. Passing from a finite transfer model to a continuum theory still requires several separate arguments. This section states those remaining mathematical tasks.

Definition II.14.1 (Anomaly free continuum constraint system)**.** A continuum constraint system consists of a Hilbert space, a common invariant dense domain $\mathcal{D}$, and operators C_a on $\mathcal{D}$. It is anomaly free for prescribed structure coefficients when

$$[C_a, C_b]\psi = \mathrm{i}\sum_c f_{ab}{}^c C_c \psi$$

for every $\psi \in \mathcal{D}$, and when the associated gauge evolution is defined on the physical quotient or physical subspace.

Norm closure of bounded finite constraints, as in theorem II.13.7, is one special case. It does not treat unbounded constraints, changing domains, structure functions, or renormalized operator products.

Definition II.14.2 (Reflection positive Euclidean limit)**.** A reflection positive Euclidean limit requires a limiting algebra of observables, Euclidean time translations, a reflection operation, and correlation functions whose reflected quadratic forms are nonnegative. A field theoretic reconstruction also requires the regularity and covariance assumptions needed to construct a Hilbert space, a vacuum, and a self adjoint time translation generator.

Theorem II.13.6 shows that positivity of each fixed finite Gram matrix survives pointwise convergence. It does not prove existence, locality, clustering, or the remaining Osterwalder–Schrader axioms.

Definition II.14.3 (Einstein infrared criterion)**.** A quantum geometric tower meets an Einstein infrared criterion only if an effective action is controlled at long wavelengths and has an expansion whose leading geometric terms take the form

$$\Gamma_{\text{eff}}[g] = \int \sqrt{|g|}\left(\Lambda + \frac{1}{16\pi G}R + \text{controlled higher order terms}\right)\mathrm{d}^d x.$$

Here the volume coefficient includes the sign and normalization written explicitly in the cosmological term in Part I. The expansion must respect the limiting gauge identities and must include an estimate for the omitted terms on the declared infrared regime.

A spectral dimension close to four does not imply this criterion. A heat trace records eigenvalue growth. It does not determine the tensor structure, gauge identities, sign, or interaction coefficients of an effective action.

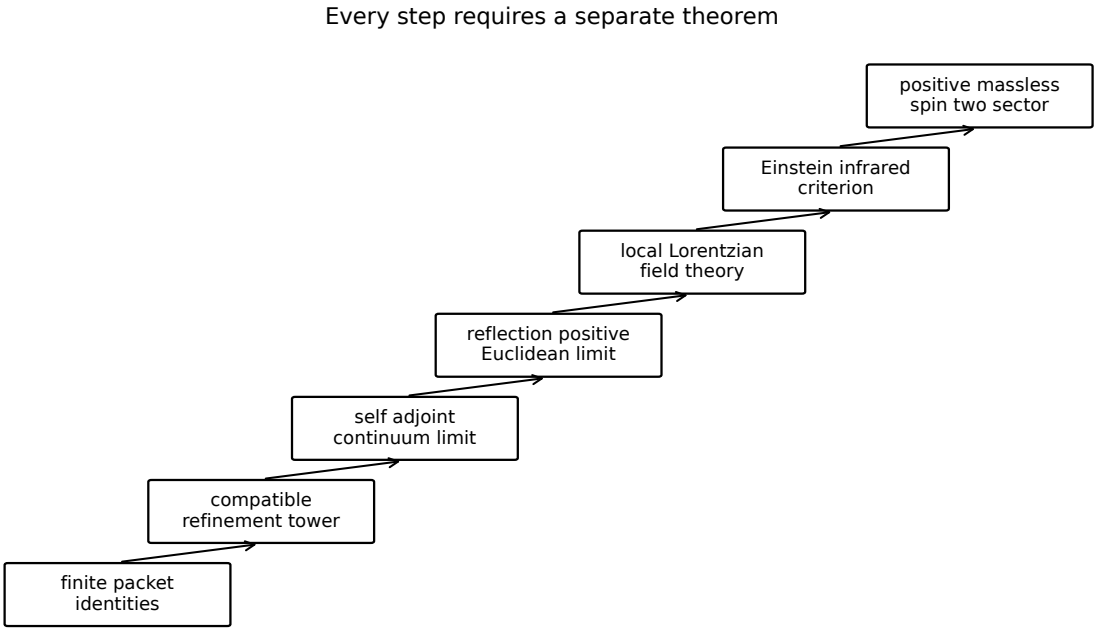

Figure 38. The finite identities occupy the first step. Every later step needs a separate convergence or reconstruction theorem.

Definition II.14.4 (Massless spin two criterion)**.** A positive massless spin two sector requires a physical two point function or resolvent with a massless pole in the transverse traceless sector, positive residue on physical states, absence of negative norm modes, and compatibility with the limiting gauge constraints. Interactions must preserve the constraint structure.

A low energy eigenvalue, a spectral dimension plateau, or a finite rank two tensor packet does not establish a massless spin two particle.

II.15 Conclusion

A complete packet family gives one coordinate language for finite quantum structure. Group characters produce symmetry packets. Charged operators obey exact selection rules. Circuits become coherent sums over packet paths. The canonical moving connection separates geometric transport from physical mixing. Density matrices and channels use two sided packets, while channel covariance becomes block preservation on operator space and symmetry of the Choi matrix.

Compression to a code gives a natural error correction obstruction. Its vanishing is the Knill–Laflamme condition. Diagonalizing the resulting coefficient matrix produces orthogonal syndrome packets and an exact recovery on the error span. Schur–Feshbach elimination gives an equally exact description of hidden Hamiltonian packets. Their frequency response is the self energy, and their time response is a positive definite memory kernel.

Positive Euclidean transfer gives finite reflection positivity. Periodic lattice heat traces converge to the continuum torus at every fixed positive diffusion time, and the continuum small time spectral dimension is recovered after the refinement limit. Constraint closure is measured by a quotient of operator space, not by compression to the physical kernel.

Continuum objective	Finite result available here	Missing continuum input
Symmetry and constraints	exact packets and quotient obstruction	common unbounded domain and renormalized closure
Effective dynamics	exact Feshbach map and uniform gap bounds	cutoff independent spectral separation and locality
Euclidean transfer	positive finite transfer and finite reflection positivity	convergent Euclidean fields and reconstruction axioms
Spectral dimension	lattice heat trace convergence	relation to a physical metric and interacting observables
Lorentzian theory	bounded unitary direct limits	unbounded generator, causality, locality, and field algebra
Einstein regime	a definition of the required expansion	derivation and error control for the effective action
Spin two sector	a precise spectral criterion	positive physical pole and interaction consistency

Table 3. What the finite results establish and what remains outside the article.

The theorems for bounded towers show how exact compatibility and summable differences in operator norm produce limiting quantum evolutions. Their hypotheses also mark the scope of the argument. Unbounded field Hamiltonians, continuum gauge constraints, reflection positive field measures, the Einstein infrared action, and a massless spin two sector each require additional theorems. The finite packet calculus gives a common framework in which those questions can be stated and studied, while leaving their physical resolution open.

Part III Bundle constructions and complementary derivations

A route through this section

The six supplements retain the substantive algebra and geometry of the formal completion. The final supplement constructs local range-bundle charts, their overlaps, and a fiber-valued connection. Three earlier derivations follow because they offer a distinct route through the same finite mathematics.

III.1 Exact packets and arbitrary circuit length

Let R be a unital ring, not necessarily commutative, and let I be a finite address set. An exact packet family consists of elements $P_a \in R$ satisfying

$$P_a P_b = \begin{cases} P_a, & a = b, \\ 0, & a \neq b, \end{cases} \qquad \sum_{a \in I} P_a = 1.$$

Adjoint conditions are added when needed. For an operator U, define the transfer corner

$$U_{ba} = P_b U P_a.$$

The target index comes first. Completeness and distributivity give

$$\sum_{b,a} U_{ba} = U, \qquad (UV)_{ba} = \sum_c U_{bc} V_{ca}.$$

The second identity uses $P_c^2 = P_c$ when adjacent transfer corners are multiplied.

III.1.1 Circuit paths: source Theorem 4.1

For $U = U_m \cdots U_1$, the checked result is

$$P_{a_m} U P_{a_0} = \sum_{a_1, \ldots, a_{m-1}} P_{a_m} U_m P_{a_{m-1}} \cdots P_{a_1} U_1 P_{a_0}.$$

The Lean implementation defines a recursive path sum and proves the identity by induction over an arbitrary finite gate list. It is not restricted to a fixed circuit depth. The empty list has circuit operator 1 and path value $P_b P_a$. Summing the source and target indices reconstructs the full circuit.

III.1.2 Adjoint conservation: source Theorem 4.2

Assume a star operation with $P_a^* = P_a$. Then

$$(U_{ba})^* = P_a U^* P_b.$$

The two checked conservation laws are

$$U^*U = 1 \quad \Longrightarrow \quad \sum_b (U_{ba})^* U_{bc} = \delta_{ac} P_a,$$
$$UU^* = 1 \quad \Longrightarrow \quad \sum_a U_{ba} (U_{da})^* = \delta_{bd} P_b.$$

For the first law, expand each corner, collapse P_b^2 and sum:

$$\sum_b P_a U^* P_b U P_c = P_a U^* \left(\sum_b P_b \right) U P_c = P_a P_c.$$

The second law follows by the analogous calculation and has its own formal proof. For complex matrices, the adjoint is the conjugate transpose. The order of the operator products is preserved throughout.

III.2 Symmetry and measurement

III.2.1 Exact symmetry: source Theorem 5.1

If $HP_a = P_a H$ for every packet, then

$$P_b H P_a = 0 \quad (b \neq a), \qquad H = \sum_a P_a H P_a.$$

In a complex Banach algebra, commutation also propagates to the actual exponential:

$$e^{zH} P_a = P_a e^{zH} \qquad (z \in \mathbb{C}).$$

Consequently,

$$e^{zH} = \sum_a P_a e^{zH} P_a, \qquad P_b e^{zH} P_a = 0 \quad (b \neq a).$$

Taking $z = -it$ gives evolution in real time. The Lean proof applies the exponential commutation theorem directly, so invariance of the packets is a proved consequence of commutation. Self-adjointness of H is not needed for the algebraic reducing property, so this result applies more broadly than the Hermitian specialization in the paper.

This result describes exact symmetry. The quantitative leakage estimate when symmetry is broken appears in Theorem 5.2 and requires the separate Duhamel and norm arguments developed later.

III.2.2 Measurements: source Theorem 7.1

For finite complex matrices, define packet dephasing by

$$\mathcal{D}_P(X) = \sum_a P_a X P_a.$$

The code proves idempotence and trace duality:

$$\mathcal{D}_P(\mathcal{D}_P(X)) = \mathcal{D}_P(X), \qquad \operatorname{tr}(\mathcal{D}_P(E)\rho) = \operatorname{tr}(E\mathcal{D}_P(\rho)).$$

Trace duality follows term by term from cyclicity:

$$\operatorname{tr}(P_a E P_a \rho) = \operatorname{tr}(E P_a \rho P_a).$$

Therefore an effect that is diagonal in the packets, $\mathcal{D}_P(E) = E$, satisfies

$$\boxed{\operatorname{tr}(E\rho) = \operatorname{tr}(E\mathcal{D}_P(\rho)).}$$

The proof holds for arbitrary finite complex matrices E and ρ. Density matrices and positive measurement effects are valid specializations rather than assumptions needed for this trace identity. Taking $E = 1$ also gives trace preservation of packet dephasing.

The full theorem for Kraus channels and the Knill–Laflamme recovery criterion require further arguments about positivity, auxiliary systems, and recovery maps. The trace identity above supplies only the measurement statement.

III.3 Corrected Feshbach resolvent

Write a finite complex matrix in retained and eliminated coordinates:

$$H = \begin{pmatrix} A & B \\ C & D \end{pmatrix}, \qquad zI - H = \begin{pmatrix} zI_P - A & -B \\ -C & zI_Q - D \end{pmatrix}.$$

Set

$$D_z = zI_Q - D, \qquad S_z = zI_P - A - BD_z^{-1}C.$$

The effective Hamiltonian is $H_{\text{eff}}(z) = A + BD_z^{-1}C$, so $S_z = zI_P - H_{\text{eff}}(z)$.

III.3.1 Correct statement: source Theorem 9.1

Assume both D_z and $zI - H$ are invertible. Then S_z is invertible and

$$\boxed{\left((zI - H)^{-1}\right)_{PP} = S_z^{-1}.}$$

The left side is the submatrix of the full inverse on the retained coordinates. This matches the paper's compressed operator when written in an orthonormal basis of the retained subspace. The proof is valid for arbitrary complex blocks of compatible sizes and does not require Hermiticity.

The checked invertibility criterion is

$$D_z \text{ invertible} \quad \Longrightarrow \quad (zI - H \text{ invertible} \iff S_z \text{ invertible}).$$

Thus one may equivalently assume invertibility of D_z and S_z.

Why the original assumption is insufficient. Take $z = 0$ and $H = \operatorname{diag}(0, -1)$, retaining the first coordinate. Then

$$D_z = 1, \qquad zI - H = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

The eliminated block is invertible, but the full matrix is singular. Hence the original hypothesis does not ensure the existence of its stated resolvent. The Lean counterexample proves invertibility of the scalar 1 and noninvertibility of this full 2×2 matrix.

III.3.2 Relation to memory and limits

The general block inverse uses the same finite identity as the Schur–Feshbach construction in Chapter VI. Its formal specialization and the counterexample above are included in the Chapter VII source. The identity is read with both stated invertibility assumptions.

The memory equation in the time domain in Section 9.2, resolvent control uniform in the cutoff, and continuum limits require arguments beyond this finite inverse identity. The source amendment makes the two invertibility assumptions explicit without changing the intended effective Hamiltonian.

III.4 Dispersion with an explicit spacing condition

The grid eigenvalue in source Theorem 11.1 is

$$\lambda_{k,h} = \frac{4}{h^2} \sin^2\left(\frac{kh}{2}\right).$$

The original low-mode condition is $0 \le kh/2 \le 1$. A nonzero spacing is also required for the quotient to have its intended meaning. For a physical grid, one normally takes $h > 0$.

III.4.1 Checked stronger statement

For every $k, h \in \mathbb{R}$ with $h \neq 0$,

$$\boxed{0 \le k^2 - \lambda_{k,h} \le \frac{k^4 h^2}{12}.}$$

The code proves this without the low-mode restriction. The bound may be loose away from the low-mode regime, but it remains valid.

The proof begins with an estimate valid for every real argument:

$$0 \le x^2 - \sin^2 x \le \frac{x^4}{3}.$$

The lower bound follows from $|\sin x| \le |x|$. For the upper bound, use

$$|x - \sin x| \le \frac{|x|^3}{6}, \qquad |x + \sin x| \le 2|x|.$$

Factoring the difference of squares gives

$$0 \le x^2 - \sin^2 x = |x - \sin x|\,|x + \sin x| \le \frac{x^4}{3}.$$

With $x = kh/2$ and $h \neq 0$,

$$k^2 - \lambda_{k,h} = \frac{4}{h^2}\left(x^2 - \sin^2 x\right),$$
$$\frac{4}{h^2}\frac{x^4}{3} = \frac{k^4 h^2}{12}.$$

Every algebraic transformation and inequality in the active source was accepted by Lean.

III.4.2 What this does not establish

This is an exact deterministic error bound for the displayed dispersion relation. The numerical convergence experiment and spectral dimension measurements provide finite computational evidence. The bound alone does not select a physical spacetime geometry.

III.5 A constraint diagnostic that vanishes automatically

Section 12 defines the physical projector using the exact common kernel of the constraints. In finite dimensions this gives $C_a P = 0$ for every a. Absorb the factor i and any structure coefficient into f_c, and write

$$\mathcal{A}_{ab} = C_a C_b - C_b C_a - \sum_c f_c C_c.$$

Proposition III.5.1 (Exact common-kernel compression)**.** *If $C_c P = 0$ for every c, then*

$$\mathcal{A}_{ab} P = 0, \qquad P \mathcal{A}_{ab} P = 0.$$

No idempotence or adjoint property of P is needed for this implication.

Proof. Associativity gives

$$\mathcal{A}_{ab} P = C_a(C_b P) - C_b(C_a P) - \sum_c f_c (C_c P) = 0.$$

Left multiplication by P gives the second identity. □

III.5.1 Compressed vanishing without operator closure

Over the rationals, take

$$P = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad X = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad Z = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

These displayed matrices are symmetric. The code checks that $P^2 = P$, $P \neq 0$ and $XP = ZP = 0$, but

$$[X, Z] = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -2 \\ 0 & 2 & 0 \end{pmatrix} \neq 0, \qquad P[X, Z]P = 0.$$

The commutator therefore violates the closure relation with zero structure coefficients outside the physical range, even though its physical compression vanishes exactly.

III.5.2 Interpretation for the paper

Vanishing of the compressed anomaly is automatic for the exact finite common kernel. It therefore cannot by itself certify full operator closure. A nonzero computed compression would instead contradict those exact assumptions or expose an approximation or implementation defect.

Existence of a nontrivial compatible refinement tower and the broader continuum program remain separate questions. A stronger closure claim must test more than this compression, and unbounded constraints need their operator domains specified. This audit is additional to the six checked source items and is not counted as a seventh original theorem.

III.6 One seed for the computational basis

Manuscript item 2.4. `ComputationalSeed.lean` 14 declarations

For $n \geq 0$, let

$$A_n = (\mathbb{Z}/2\mathbb{Z})^{\{0,\dots,n-1\}}, \qquad V_n = \{v : A_n \to \mathbb{C}\}.$$

For an address $a \in A_n$, define the standard coordinate vector

$$|a\rangle\,(x) = \begin{cases} 1 & x = a, \\ 0 & x \neq a. \end{cases}$$

The seed is $\psi_0 = |0\rangle$. Define a translation operator by

$$(T_a v)(x) = v(x - a).$$

At position j, the local Pauli X is $X_j = T_{e_j}$, where e_j has a single nonzero binary coordinate. The formal circuit uses the identity when $a_j = 0$ and X_j when $a_j = 1$.

Supplementary statement. For every binary address a,

$$W_a = \prod_{j=0}^{n-1} X_j^{a_j} = T_a, \qquad W_a\psi_0 = |a\rangle\,.$$

The family $(W_a\psi_0)_{a\in A_n}$ is linearly independent, spans V_n, and has exactly 2^n elements. It is the standard computational basis.

Proof. Composition gives $T_aT_b = T_{a+b}$, and direct evaluation gives $T_a\,|b\rangle = |a+b\rangle$. Every binary address satisfies $a + a = 0$, so each translation is an involution. In particular, the local operator changes precisely the addressed bit:

$$X_j\,|a\rangle = \big|a \text{ with coordinate } j \text{ replaced by } a_j + 1\big\rangle\,.$$

The selected factor at j equals translation by the address supported at j with value a_j. Induction on a list proves that the product of translations is translation by their sum. Each of these addresses contributes one coordinate, and their sum is a. Thus $W_a = T_a$ and $W_a\psi_0 = |a\rangle$.

Lean identifies the resulting family with `Pi.basisFun` over $\mathbb{C}$. Its standard basis theorems supply linear independence and full span. The finite function-space cardinality gives $|A_n| = 2^n$. □

Formal scope. The proof constructs the sequence of gates that produces each addressed state and then identifies the resulting family with the standard coordinate basis. It includes the empty circuit for $n = 0$. Orthogonality belongs to the usual computational basis interpretation. The formal endpoint records the basis identification, together with separate explicit theorems for span and linear independence.

III.7 Tensor and polyphase refinement

Manuscript item 3.2. `TensorRefinement.lean` 11 declarations

Let F be an arbitrary finite set of factors and let D_i be a finite coordinate index for factor i. For matrix families A_i, define the coordinate tensor product on the product index space by

$$\mathsf{T}(A)(x,y) = \prod_{i\in F} A_i(x_i, y_i).$$

The proof first establishes the laws for multiplication, identity, adjoints, and finite sums. These laws apply to any finite number of factors with the stated finite coordinate sets.

Suppose $N > 0$ and each factor has a complete orthogonal self-adjoint projector family $(P_j^{(i)})_{j\in\mathbb{Z}/N\mathbb{Z}}$. For a fine address $a : F \to \mathbb{Z}/N\mathbb{Z}$, set

$$Q_a = \mathsf{T}(i \mapsto P_{a_i}^{(i)}), \qquad C_r = \sum_{\sum_i a_i = r} Q_a.$$

Supplementary statement. The fine and coarse families are complete orthogonal self-adjoint projector systems. In particular,

$$C_r C_s = \delta_{rs} C_r, \qquad \sum_r C_r = I, \qquad C_r^* = C_r.$$

Each coarse projector is exactly the displayed sum of its fine descendants.

Proof. Expanding the finite product of sums gives

$$\mathsf{T}(A)\mathsf{T}(B) = \mathsf{T}(i \mapsto A_i B_i).$$

Consequently, if two fine addresses differ in any coordinate, the corresponding product contains a zero factor. If the addresses agree, the product is the same fine projector. The adjoint passes through the finite coordinate product, so $Q_a^* = Q_a$. Summing over all address functions and using the same expansion yields

$$\sum_a Q_a = \mathsf{T}\left(i \mapsto \sum_j P_j^{(i)}\right) = I.$$

A separate algebraic regrouping theorem applies to any finite orthogonal family and any address map into a finite set. In the double sum for $C_r C_s$, orthogonality removes all terms with different fine addresses. A surviving address can lie in both classes only when $r = s$. Completeness follows by summing each fine projector exactly once. Adjoint preservation follows term by term. Specializing the address map to total residue proves the claim. □

Formal scope. Residue grouping is proved for every positive modulus and arbitrary finite factor dimensions. It assumes the supplied local projector laws. Constructing those local projectors from cyclic characters, as in item 3.1, requires the separate proof in the next supplement.

III.8 Differentiated moving coordinates

Manuscript item 6.1. `MovingFrames.lean` 9 declarations

Fix a real time t and a finite complex coordinate space. Let $U(s)$ be a unitary matrix curve, differentiable entrywise at t, and let $\psi(s)$ be differentiable componentwise at t. Write $\dot{U}$ and $\dot{\psi}$ for those derivatives. Suppose

$$i\dot{\psi} = H\psi(t).$$

Only the value of the Hamiltonian at the chosen time is needed. No derivative of H is assumed.

Supplementary statement. The explicitly defined coordinate curve

$$y(s) = U(s)^* \psi(s)$$

is differentiable at t, with

$$\dot{y} = \dot{U}^* \psi(t) + U(t)^* \dot{\psi}.$$

It satisfies

$$\boxed{i\dot{y} = H_{\text{eff}} y(t), \qquad H_{\text{eff}} = U(t)^* H U(t) - iU(t)^* \dot{U}.}$$

The connection term $-iU(t)^*\dot{U}$ is Hermitian. If $H^* = H$, then $H_{\text{eff}}^* = H_{\text{eff}}$.

Proof. Applying the product rule entry by entry proves the differentiation formulas for matrix products and for matrices acting on vectors. Since the parameter is real, conjugation commutes with differentiation, giving the stated derivative of U^* and hence of y.

Differentiate $U^*U = I$ using those rules and uniqueness of derivatives:

$$\dot{U}^*U + U^*\dot{U} = 0.$$

Thus $(U^*\dot{U})^* = -U^*\dot{U}$, so multiplication by $-i$ produces a Hermitian matrix.

The identity $UU^* = I$ gives $\psi = Uy$ for the constructed coordinate curve. Differentiating and inserting the original equation yields

$$i\dot{U}y + iU\dot{y} = HUy.$$

Multiplying by U^* and using $U^*U = I$ gives the transformed equation, with the negative sign on the connection term. Finally, conjugation by U preserves Hermiticity of H, and the sum of the two Hermitian terms is Hermitian. □

Formal scope. The main certificate constructs y and its derivative rather than assuming a separate derivative witness for the desired answer. Both unitary identities are explicit. The proofs are pointwise and apply at any time where the stated hypotheses hold. They do not assert existence of a global solution to an evolution equation.

III.9 The canonical packet connection

Manuscript item 6.3. `CanonicalConnection.lean` 9 declarations

Let $P_a(s)$ be a finite family in a normed real algebra with a continuous compatible adjoint. Assume actual derivatives $D_a = \dot{P}_a(t)$ exist and, for all parameter values under consideration,

$$P_aP_b = \delta_{ab}P_a, \qquad \sum_a P_a = I, \qquad P_a^* = P_a.$$

In the supplied Lean theorem, the curves are defined on $\mathbb{R}$ and the projector laws hold at every real parameter. The algebraic formulation applies to matrices and bounded operators whenever they satisfy the stated typeclass hypotheses.

Supplementary statement. Define $C = \sum_a D_aP_a(t)$. Then

$$\boxed{C = \frac{1}{2}\sum_a [D_a, P_a(t)], \qquad C^* = -C,}$$

and, for every b,

$$\boxed{[C, P_b(t)] = D_b.}$$

Proof. The derivative product rule and uniqueness of derivatives give

$$D_aP_b + P_aD_b = \delta_{ab}D_a.$$

Differentiating completeness and adjoint invariance gives

$$\sum_a D_a = 0, \qquad D_a^* = D_a.$$

These are proved derivative consequences, not additional axioms supplied in place of differentiation.

On the diagonal, $D_a P_a + P_a D_a = D_a$. Summing shows

$$\sum_a P_a D_a = -\sum_a D_a P_a = -C.$$

This proves the formula involving half the sum of commutators, together with $C^* = -C$.

Orthogonality directly yields $C P_b = D_b P_b$. For the left product, multiply the differentiated identity for (b, a) on the right by P_a and sum over a. Completeness reduces the result to

$$D_b + P_b C = D_b P_b.$$

Subtracting this equation from the identity for multiplication on the right gives $C P_b - P_b C = D_b$. □

Formal scope. The proof derives the differentiated identities before using their algebraic consequences, so the role of the derivative hypotheses remains explicit. It establishes the canonical connection identity for one parameter. The range bundle over a parameter manifold, the exterior differential calculus, and the curvature theorem of item 6.4 are developed in the later supplements.

III.10 Finite Kraus channels and full amplification

Manuscript item 7.2. `KrausChannels.lean` 7 declarations

For a finite family of complex matrices K_a, define

$$\Phi(\rho) = \sum_a K_a \rho K_a^*.$$

The formalization constructs this as a complex-linear map and proves the following properties directly in the finite matrix representation.

Supplementary statement. The map Φ is completely positive. If

$$\sum_a K_a^* K_a = I,$$

then $\operatorname{tr} \Phi(\rho) = \operatorname{tr} \rho$ for every matrix ρ. In particular, positive semidefinite matrices of trace one are mapped to positive semidefinite matrices of trace one.

Proof. Matrix multiplication distributes across addition and scalar multiplication, which gives complex linearity. If $\rho \succeq 0$, each term $K_a \rho K_a^*$ is positive semidefinite, hence so is their finite sum.

To prove complete positivity rather than positivity alone, let J be an arbitrary finite auxiliary index set. For a matrix X indexed by $J \times n$, define its blockwise amplification by

$$[\Phi^{(J)}(X)]_{(i,u),(j,v)} = \Phi\big(X_{(i,\cdot),(j,\cdot)}\big)_{u,v}.$$

The explicit index calculation proves the identity

$$\boxed{\Phi^{(J)}(X) = \sum_a (I_J \otimes K_a) X (I_J \otimes K_a)^*.}$$

The displayed identity identifies the defined amplification with tensoring by the identity, which is the operation needed for complete positivity. Every summand on the right is positive when X is positive, and this holds for every finite J.

Finally, cyclicity and linearity of the trace give

$$\begin{aligned} \operatorname{tr} \Phi(\rho) &= \sum_a \operatorname{tr}(K_a \rho K_a^*) \\ &= \operatorname{tr}\left(\left(\sum_a K_a^* K_a \right) \rho \right) = \operatorname{tr} \rho. \end{aligned}$$

Positivity together with trace preservation gives the stated conclusion for density matrices. □

Formal scope. Complete positivity is proved for every finite auxiliary dimension. Normalization is required only for trace preservation and the conclusion about density matrices. The converse representation theorem for arbitrary completely positive maps lies outside this argument.

III.11 Actual orbits and sharp seed counts

Let $C \in M_{d\times m}(\mathbb{C})$ be the coefficient matrix of one seed. Define its orbit by actual matrix multiplication:

$$\mathcal{O}(C) = \{AC : A \in M_d(\mathbb{C})\}.$$

This set is already a linear subspace. The source proves that it equals the linear span of the orbit before computing its dimension.

A matrix X belongs to $\mathcal{O}(C)$ exactly when each of its rows belongs to $\operatorname{Row}(C)$. One direction follows by expanding AC. For the converse, choose the coefficients producing each row separately and place them in the corresponding row of A. An explicit linear equivalence therefore gives

$$\mathcal{O}(C) \simeq \operatorname{Row}(C)^d, \qquad \boxed{\dim_{\mathbb{C}} \mathcal{O}(C) = d \operatorname{rank} C.}$$

If $d > 0$, equality with the full $d \times m$ coefficient space is equivalent to $\operatorname{rank} C = m$. Consequently a cyclic seed requires $m \le d$. The assumption that there is at least one row is essential for canceling the factor d.

III.11.1 Several seeds: both necessity and construction

Continue under the assumption above that the number of rows is positive. For seeds $C_1, \dots, C_k$, generation means the concrete statement

$$\forall X \in M_{d\times m}(\mathbb{C}), \quad \exists A_1, \dots, A_k \in M_d(\mathbb{C}) : \quad X = \sum_{a=1}^{k} A_a C_a.$$

Stack the C_a vertically into a $kd \times m$ matrix D. The source identifies the action on the stacked matrix and proves the equivalence

$$\text{the seeds generate} \quad \Longleftrightarrow \quad \operatorname{rank} D = m.$$

Thus $m \le kd$ is necessary. It is sufficient as well: embed the m coordinate columns into kd coordinate positions to obtain a matrix D of full column rank, then split its rows back into k seeds. This construction proves that generating matrices with the required dimensions exist.

III.11.2 Simultaneous generation in a direct sum

For the stipulated block representation

$$\mathcal{A} = \bigoplus_i (M_{d_i}(\mathbb{C}) \otimes I_{m_i}), \qquad d_i > 0,$$

the proof establishes that k seeds generate all blocks simultaneously exactly when $m_i \le kd_i$ for every i. It follows that

$$\boxed{\operatorname{srank}_{\mathcal{A}}(\mathcal{H}) = \max_i \left\lceil \frac{m_i}{d_i} \right\rceil .}$$

The final Lean proposition is an `IsLeast` statement over the set of feasible seed counts. It proves both attainment and minimality. For an empty block family the finite supremum is defined as 0, matching the zero module.

III.12 Schmidt rank and the reduced state

Use coordinates ψ_{ij} in the standard product basis and let $C_{ij} = \psi_{ij}$. An explicit linear equivalence identifies the state vector on the product index set with its coefficient matrix. The implementation checks the actual Kronecker action:

$$\operatorname{coeff}((A \otimes I_B)\psi) = AC.$$

It also proves that the transported matrix orbit equals the span of the state vectors obtained by this Kronecker action. The dimension formula therefore applies to the physical local action on the state space.

III.12.1 An independent definition of Schmidt rank

The source defines Schmidt rank as the least number of summands that are product vectors. A decomposition of length s is the concrete equality

$$C_{ij} = \sum_{a=1}^{s} u_a(i) v_a(j).$$

It factors $C = UV$ through an s-dimensional intermediate space, so $\operatorname{rank} C \le s$. Conversely, choose a basis of the row space of C. Expanding each row in this basis constructs a decomposition with exactly $\operatorname{rank} C$ product terms. Thus

$$\boxed{r(\psi) = \operatorname{rank} C.}$$

The definition uses a least natural number, and the equality with matrix rank is a theorem. This argument establishes the minimum number of product terms. It does not construct an orthonormal Schmidt decomposition or prove a new theorem on singular value decomposition.

The matrix-orbit dimension and the coefficient equivalence now yield

$$\boxed{\dim_{\mathbb{C}} \operatorname{span}\{(A \otimes I_B)\psi : A \in M_{d_A}(\mathbb{C})\} = d_A r(\psi).}$$

III.12.2 The actual partial trace and its support

The reduced matrix is defined by tracing the addressed index of the density matrix of the pure state:

$$(\rho_B)_{j\ell} = \sum_i \psi_{ij} \overline{\psi_{i\ell}}.$$

For the coefficient convention used here, the exact Gram identity is

$$\rho_B = C^{\mathsf{T}} (C^{\mathsf{T}})^*, \qquad \operatorname{rank} \rho_B = \operatorname{rank} C = r(\psi).$$

The transpose is important. With this convention, writing C^*C instead would conjugate the reduced matrix. The Lean source checks the entrywise identity and positivity of the resulting matrix.

Full support is expressed as surjectivity of the reduced matrix's linear map. Assuming $d_A > 0$, the checked equivalence is

$$\boxed{\mathcal{O}_A(\psi) = \mathcal{H}_A \otimes \mathcal{H}_B \quad \Longleftrightarrow \quad \operatorname{Ran} \rho_B = \mathcal{H}_B.}$$

Normalization of ψ is unnecessary for these dimension and support statements. The zero state has rank 0 because its decomposition needs no product terms.

III.13 Constructed cyclic character projectors

Let $N > 0$ and let S be a unitary complex matrix with $S^N = I$. The implementation uses the standard additive character of $\mathbb{Z}/N\mathbb{Z}$ and proves its expression through a root of unity:

$$\omega = \exp(2\pi i/N), \qquad \chi(r) = \omega^{\mathrm{val}(r)}.$$

Here $\mathrm{val}(r)$ is the canonical representative in $\{0, \dots, N-1\}$. The representation is constructed as

$$\rho(r) = S^{\mathrm{val}(r)}.$$

Reduction of exponents modulo N is proved from $S^N = I$, giving $\rho(r+s) = \rho(r)\rho(s)$ and $\rho(0) = I$. The final matrix theorem derives the representation law and character orthogonality from the stated inputs.

III.13.1 Exact coefficient formula

The packet definition is a finite sum over residue classes:

$$P_j = \frac{1}{N} \sum_{r \in \mathbb{Z}/N\mathbb{Z}} \chi(-rj)\rho(r).$$

The source proves

$$\chi(-rj) = \left(\omega^{\mathrm{val}(r)\,\mathrm{val}(j)}\right)^{-1},$$

so this is precisely the manuscript's N-term Fourier projector formula, with canonical representatives.

III.13.2 Algebraic identities

Primitivity of the standard character yields the checked finite sum

$$\sum_r \chi(tr) = \begin{cases} N, & t = 0, \\ 0, & t \neq 0. \end{cases}$$

Reindexing finite sums then gives

$$\boxed{P_j P_k = \delta_{jk} P_j, \qquad \sum_j P_j = I, \qquad S P_j = \omega^j P_j.}$$

Multiplicativity and completeness are first proved for a general representation in a complex algebra, then instantiated with the actual powers of S. This organization makes the algebra of finite sums reusable while preserving the final hypotheses.

III.13.3 Orthogonality of the projectors

Unitarity supplies $\rho(r)^* = \rho(-r)$, while the character obeys $\overline{\chi(r)} = \chi(-r)$. Reindexing $r \mapsto -r$ proves $P_j^* = P_j$. The final concrete matrix theorem includes Hermiticity together with multiplication, completeness, and eigenaction. Together these identities establish orthogonal spectral packets.

The proof includes the degenerate modulus $N = 1$: finite order then forces $S = I$ and the sole projector is I. It does not need an artificial assumption $N > 1$.

III.14 The actual Euclidean transfer exponential

Let H be a Hermitian matrix on a nonzero complex state space of finite dimension. The source defines

$$T_e(t) = \exp(-t(H - eI))$$

using Lean's exponential defined by a power series. The proof then relates this defined operator to its spectral expansion.

III.14.1 Connecting power series and spectral calculus

The shifted generator is proved Hermitian. The implementation then identifies the actual matrix exponential with continuous functional calculus:

$$\boxed{T_e(t) = f_t(H), \qquad f_t(x) = e^{-t(x-e)}.}$$

The formal proof uses composition, scalar multiplication, subtraction, and the established agreement between the exponential in functional calculus and the exponential defined by a power series. Spectral mapping is consequently available for the operator that was actually defined:

$$\mathrm{Spec}_{\mathbb{R}}\, T_e(t) = \{e^{-t(x-e)} : x \in \mathrm{Spec}_{\mathbb{R}}\, H\}.$$

Hermiticity also identifies the full complex spectrum with the image of these real eigenvalues. A separate checked theorem states the interval containing the complex spectrum explicitly.

III.14.2 The minimum eigenvalue

The ground energy is the minimum of the finite, nonempty eigenvalue set. The proof establishes both

$$E_0 \in \mathrm{Spec}_{\mathbb{R}}\, H, \qquad E_0 \le x \quad (x \in \mathrm{Spec}_{\mathbb{R}}\, H).$$

The assumption that the state space is nonzero is recorded in the theorem because the minimum of an empty spectrum is not defined by the manuscript's formula.

III.14.3 Positivity, semigroup composition, and the interval

Every eigenvalue of $T_e(t)$ is strictly positive, for arbitrary real e, t, since the real exponential is positive. For $e = E_0$ and $t \geq 0$ it is also at most one. Therefore

$$\boxed{T_{E_0}(t) > 0, \qquad \operatorname{Spec} T_{E_0}(t) \subseteq (0, 1].}$$

The two scalar multiples of $H - eI$ commute, so the exponential defined by the power series obeys

$$\boxed{T_e(t+s) = T_e(t)T_e(s), \qquad T_e(0) = I.}$$

The semigroup identity is proved for all real t, s. Nonnegative time is needed for the upper spectral bound, not for the composition identity or strict positivity.

These results concern operators on a finite dimensional space. Continuum transfer limits, gravitational path integrals and physical spacetime models require further structure. The numerical figures provide separate computational illustrations.

III.15 Quantitative leakage from the actual exponential

Let A be a unital complex C-star algebra, let $H = H^*$, and let $P = P^* = P^2$. Put $Q = 1 - P$. The checked statement is

$$\boxed{\|Q \exp(-itH)P\| \leq |t| \, \|HP - PH\| \qquad (t \in \mathbb{R}).}$$

The matrix specialization uses the operator norm on the Hilbert space, implemented by `Matrix.Norms.L2Operator`. It is not an entrywise norm or the row-sum operator norm. The theorem includes the zero projector and empty matrix index type. The theorem also applies at time zero.

III.15.1 Deriving the estimate by differentiation

For a skew-adjoint generator G, define the actual conjugation path

$$T_P(t) = \exp(tG)P\exp(-tG).$$

The formalization derives its derivative from the exponential power series and the product rule:

$$T_P'(t) = \exp(tG)(GP - PG)\exp(-tG).$$

Both exponential factors are proved unitary. Left and right multiplication by a unitary preserve the C-star norm. Therefore

$$\|T_P'(t)\| = \|GP - PG\|, \qquad \|T_P(t) - T_P(s)\| \leq |t - s| \, \|GP - PG\|.$$

The second inequality follows from the mean value inequality in normed spaces and covers either ordering of s and t. It is not a finite-difference estimate or a numerical time discretization.

Multiplication by $\exp(tG)$ gives

$$(T_P(t) - P)\exp(tG) = \exp(tG)P - P\exp(tG).$$

For every orthogonal projector, $\|P\| \le 1$ and $\|1 - P\| \le 1$. The exact corner identity

$$(1 - P)UP = (1 - P)(UP - PU)P$$

then bounds leakage by the exponential commutator. Taking $G = -iH$ gives the stated theorem because $\|[G, P]\| = \|[H, P]\|$.

III.15.2 Checked consequences

Unitarity also gives the capped estimate

$$\|Q \exp(-itH)P\| \le \min\{1,\ |t|\, \|[H, P]\|\}.$$

If $H = H_0 + V$, both summands are self-adjoint, and $[H_0, P] = 0$, then

$$\|Q \exp(-it(H_0 + V))P\| \le 2|t|\, \|V\|.$$

The latter uses $\|[V, P]\| \le 2\|V\|$. Its constant is not claimed to be optimal. Exact commutation gives zero leakage. The work does not include unbounded generators or time-dependent Hamiltonians.

III.16 Actual projected differentiation and curvature

Let E, F be real normed spaces. Let $P : E \to \mathcal{L}(F, F)$ be differentiable with $P(x)^2 = P(x)$ for every x. Let $s : E \to F$ be C^2 with $P(x)s(x) = s(x)$, and let $X, Y : E \to E$ be differentiable vector fields. The checked connection is the actual expression

$$\nabla_X s(x) = P(x)\, Ds(x)[X(x)].$$

It is proved to preserve the range condition. It is linear in the vector field direction and obeys the scalar Leibniz rule

$$\nabla_X(cs) = Dc[X]\, s + c\nabla_X s$$

for differentiable real scalar functions c. No differentiated projector identities are inserted as hypotheses in the main curvature theorem.

III.16.1 Differentiated projector and section identities

Differentiating $P^2 = P$ and $Ps = s$ produces

$$\begin{aligned} DP[v]P + PDP[v] &= DP[v], \\ PDP[v]P &= 0, \\ Ds[v] &= DP[v]s + PDs[v]. \end{aligned}$$

The zero sandwich follows algebraically from the first identity. All products preserve their noncommutative order.

III.16.2 Retaining the bracket of vector fields

Define the actual curvature action by

$$R_P(X,Y)s = \nabla_X \nabla_Y s - \nabla_Y \nabla_X s - \nabla_{[X,Y]} s.$$

The source uses the Lie bracket defined through Fréchet derivatives. Symmetry of second derivatives is supplied by the C^2 hypothesis, not postulated separately. Expanding the connection gives

$$R_P(X,Y)s = P(DP[X]Ds[Y] - DP[Y]Ds[X]).$$

Substituting the section identity and removing the zero sandwich terms proves

$$\boxed{R_P(X,Y)s = P(DP[X]DP[Y] - DP[Y]DP[X])Ps.}$$

Thus the coefficient is precisely $P(\,\mathrm{d}P \wedge \mathrm{d}P)P$ with the convention $(\,\mathrm{d}P \wedge \mathrm{d}P)(v,w) = DP[v]DP[w] - DP[w]DP[v]$.

III.16.3 Tensor properties and the remaining global boundary

The coefficient is proved bilinear, alternating, and supported on the range on both sides. The chain rule proves the pullback identity

$$F_{P\circ f}(x)(v,w) = F_P(f(x))(Df(x)v, Df(x)w).$$

The main theorem has global regularity hypotheses on normed parameter spaces. The pullback identity alone does not supply localization, smooth local trivializations, or gluing. The final supplement constructs the global range bundle and proves that the local connections glue.

III.17 A constructive and total syndrome recovery

Let P be an orthogonal code projector. The input certificate consists of a finite family V_a satisfying

$$V_a P = V_a, \qquad V_a^* V_b = \delta_{ab} P.$$

These hypotheses state that the operators are partial isometries with orthogonal syndromes. The next supplement derives such a family from arbitrary Knill–Laflamme Gram data.

III.17.1 Constructing the recovery on the whole ambient space

Define the syndrome projectors and their complement by

$$S_a = V_a V_a^*, \qquad S = \sum_a S_a, \qquad Q = 1 - S.$$

The source proves self-adjointness, $S_a S_b = \delta_{ab} S_a$, $S^2 = S$, and $Q^2 = Q = Q^*$. It also proves $QV_a = 0$ and $V_a^* Q = 0$.

The recovery is not left undefined outside the syndrome subspaces. Its explicit Kraus operators are $R_a = V_a^*$ together with $R_{\text{extra}} = Q$, giving

$$\mathcal{R}(\rho) = \sum_a V_a^* \rho V_a + Q\rho Q.$$

They satisfy exact completeness:

$$\sum_a R_a^* R_a + R_{\text{extra}}^* R_{\text{extra}} = \sum_a V_a V_a^* + Q = S + Q = I.$$

For finite complex matrices, trace preservation and complete positivity at every finite auxiliary dimension are proved for this actual map. The amplified map is identified with the Kraus family $I_J \otimes R_a$, including the complement term. Positivity is not merely checked on a single matrix size.

III.17.2 Exact correction, including coherent errors

For every operator supported on the code, $P\rho P = \rho$, the central identity is

$$\boxed{\mathcal{R}(V_a \rho V_b^*) = \delta_{ab}\rho.}$$

Consequently normalized mixtures satisfy

$$\mathcal{R}\left(\sum_a p_a V_a \rho V_a^*\right) = \rho \quad \text{when} \quad \sum_a p_a = 1.$$

The identity is algebraic and is proved for complex weights. Physical mixtures use the nonnegative real case. For a coherent error $E_z = \sum_a z_a V_a$, the calculation of the cross terms yields

$$\mathcal{R}(E_z \rho E_z^*) = \left(\sum_a z_a \overline{z_a}\right) \rho.$$

Thus the same map also corrects normalized coherent superpositions. This construction supplies the recovery stage used in the full Knill–Laflamme proof that follows.

III.18 The precise finite channel statement

Let $\mathcal{H} = \mathbb{C}^n$ be a finite coordinate space and let $P = P^* = P^2$. A matrix is code supported when $P\rho P = \rho$. For a finite family of square matrices E_a, put

$$\mathcal{N}_E(\rho) = \sum_a E_a \rho E_a^*.$$

The input channel normalization is the actual matrix identity

$$\sum_a E_a^* E_a = I.$$

A finite Kraus recovery has the form $\mathcal{R}(\sigma) = \sum_r R_r \sigma R_r^*$, with $\sum_r R_r^* R_r = I$. This representation, together with the checked amplification results, provides complete positivity and trace preservation on the entire ambient matrix space.

III.18.1 Necessary and sufficient conditions

Under the stated normalization, the following equivalence is proved:

$$\boxed{\begin{array}{c}\exists\, \mathcal{R} \text{ of the above finite Kraus form,} \\ \mathcal{R}\mathcal{N}_E(\rho) = \rho \quad \text{for every } \rho \succeq 0,\ \operatorname{Tr}\rho = 1,\ P\rho P = \rho\end{array}} \iff \boxed{\begin{array}{c}\exists C \succeq 0, \\ PE_a^* E_b P = C_{ab} P \quad \text{for all } a, b.\end{array}}$$

The statement applies throughout the code space. The formalization separately proves equivalence with correction of *every* complex matrix supported on the code. It also proves preservation with arbitrary finite reference systems, as detailed in the discussion of density matrices and reference systems below.

III.18.2 Including degenerate cases

The matrix C need not be positive definite. The proof includes zero eigenvalues, redundant error operators, an empty set of positive eigenvalues, and the zero projector. If $P = 0$, the only supported matrix is zero and no trace-one code density matrix exists. The proofs handle that case separately rather than dividing by the code rank or by $\operatorname{Tr} P$.

For an unnormalized error family, the correct statement is generally

$$\mathcal{R}\mathcal{N}_E(\rho) = \operatorname{Tr}(C)\rho,$$

not unconditional equality to ρ. Normalization forces $\operatorname{Tr} C = 1$ on a nonzero code. The discussion of coherent errors below treats unrestricted error families and shows when the same decoder works throughout their span.

III.19 From Gram data to an actual total recovery

Assume $C \succeq 0$ and $PE_a^* E_b P = C_{ab} P$. First restrict the error operators to the code, $F_a = E_a P$. The finite Hermitian spectral theorem supplies a unitary U such that

$$U^* C U = \operatorname{diag}(\lambda_r), \qquad \lambda_r \geq 0.$$

Define the transformed errors by an actual finite sum,

$$B_r = \sum_a U_{ar} F_a.$$

The formal module proves the identities

$$B_r P = B_r, \qquad B_r^* B_s = \delta_{rs} \lambda_r P, \qquad \sum_r B_r \rho B_r^* = \sum_a F_a \rho F_a^*.$$

For ρ supported on the code, the restricted and unrestricted error sums are equal. Thus the unitary change of error coordinates preserves the actual channel on the code.

III.19.1 Null directions are removed by proof

If $\lambda_r = 0$, then $B_r^* B_r = 0$. Positivity of the ordinary complex matrix inner product gives $B_r = 0$. This is the checked declaration `DiagonalErrors.zero_weight_error`. The normalized syndrome operators are defined only on

$$A_+ = \{r : \lambda_r > 0\}, \qquad V_r = \lambda_r^{-1/2} B_r.$$

Consequently no inverse square root at a null eigenvalue is needed. Lean proves

$$V_r P = V_r, \qquad V_r^* V_s = \delta_{rs} P.$$

The recovery from the previous block is instantiated from these derived syndromes, rather than from an assumed orthogonal error family.

III.19.2 A channel on the whole ambient space

Put $Q = I - \sum_{r \in A_+} V_r V_r^*$. The recovery is

$$\boxed{\mathcal{R}(\sigma) = \sum_{r \in A_+} V_r^* \sigma V_r + Q \sigma Q.}$$

The complement is an orthogonal projector and

$$\sum_{r \in A_+} V_r V_r^* + Q^* Q = I.$$

Hence the recovery is trace preserving. Its finite Kraus form also proves positivity after amplification by the identity on every finite auxiliary space. The complement term matters: the map is defined as a channel even outside the syndrome ranges.

Finally the checked calculation gives $\mathcal{R}\mathcal{N}_E(\rho) = \sum_r \lambda_r \rho = \mathrm{Tr}(C)\rho$. Under normalization of the input channel and $P \neq 0$, summing the diagonal Gram identities gives $\mathrm{Tr}(C)P = P$, hence $\mathrm{Tr}\, C = 1$. The proof for the zero code does not use this cancellation.

III.20 Deriving the Gram matrix from recovery

Suppose a finite recovery that preserves trace corrects every operator supported on the code. To derive the Knill–Laflamme condition without assuming a syndrome decomposition, the proof expands the composite channel into the finite Kraus family

$$A_{ra} = R_r E_a P.$$

For every ambient matrix ρ, correction on the code implies

$$\sum_{r,a} A_{ra} \rho A_{ra}^* = P \rho P.$$

This equality on all matrices follows by applying correction to the sandwich supported on the code, $P\rho P$, using the projector identities.

III.20.1 Rank-one rigidity of the corrected channel

The module tests the map equality on actual matrix units and flattens each A_{ra} into a row. If X is the matrix of those rows and p is the vector of entries of P, the resulting Gram identity is

$$X^*X = \overline{p}\,p^{\mathsf{T}}.$$

The checked rank-one Gram lemma proves that every row of X is proportional to p. For nonzero p, a nonzero coordinate is selected and a test vector supported on two coordinates is placed in the null space of the Gram matrix. The implication $X^*Xv = 0 \Rightarrow Xv = 0$ then gives the required proportionality. When $p = 0$, the Gram identity forces $X = 0$ directly.

Applied to the corrected Kraus family, this yields scalars z_{ra} with

$$R_r E_a P = z_{ra} P.$$

The essential declarations are `rank_one_gram_rigidity`, `kraus_rank_one_rigidity` and `corrected_kraus_family`. No rank-one Choi characterization is inserted as an axiom or as the desired conclusion in hypothesis form.

III.20.2 Trace-preserving recovery supplies the original Gram data

Let $Z_{ra} = z_{ra}$. The recovery normalization gives

$$\begin{aligned} PE_a^* E_b P &= PE_a^* \Big(\sum_r R_r^* R_r\Big) E_b P \\ &= \sum_r (R_r E_a P)^* (R_r E_b P) \\ &= \Big(\sum_r \overline{z_{ra}} z_{rb}\Big) P = (Z^*Z)_{ab} P. \end{aligned}$$

Thus $C = Z^*Z$ is positive semidefinite and satisfies the required compressed identities. The theorem `gram_of_recovery` implements this calculation with the original error and recovery matrices.

A second rigidity argument handles a nonnegative scalar multiple of the identity code map. It uses $\sqrt{t}\,P$ as the rank-one map generator and includes $t = 0$. That argument proves necessity for unnormalized error families, which need not define channels.

III.21 Density matrices, all operators and finite references

The necessity argument is stated for all operators, so it must be connected to correction of physical density matrices. The proof establishes this connection explicitly for complex linear maps on finite matrices.

III.21.1 Normalization is not an extra assumption

A nonzero positive semidefinite matrix has strictly positive real trace. If a complex-linear map fixes every normalized code density matrix, apply that hypothesis to

$$\frac{\rho}{\operatorname{Tr}\rho}$$

for each nonzero positive code-supported ρ. Linearity then gives equality on ρ itself. The zero matrix is handled separately. The source proves that the trace is real and nonzero, then justifies cancellation of the scalar. These steps establish that normalization is valid.

III.21.2 Complex polarization reaches the whole operator space

Write $q(x) = xx^*$. The module proves the exact identity

$$4xy^* = q(x+y) - q(x-y) + i(q(x+iy) - q(x-iy)).$$

Agreement on all positive pure outer products therefore implies agreement on every outer product. Actual matrix units then span the full matrix space. Applying this argument to the sandwich by P proves equality on every code-supported operator, including non-Hermitian ones.

The result `density_corrects_iff_operators` establishes the equivalence for the actual composite Kraus maps. It does not replace the set of density matrices by an assumed basis of logical states.

III.21.3 An arbitrary finite reference system

For any finite reference index set A, the amplified channel is defined using the actual Kronecker Kraus operators,

$$\widetilde{\mathcal{N}}_E(\rho) = \sum_a (I_A \otimes E_a)\rho(I_A \otimes E_a)^*.$$

Its reference blocks are proved equal to the original channel applied blockwise. If

$$(I_A \otimes P)\rho(I_A \otimes P) = \rho,$$

then every reference block is code supported. Applying the checked correction theorem for operators to those blocks gives

$$\boxed{\widetilde{\mathcal{R}}\,\widetilde{\mathcal{N}}_E(\rho) = \rho.}$$

This includes entangled density matrices supported on the combined reference and code space. In fact, the identity holds for every jointly supported matrix and every finite reference dimension.

The declaration `recovery_with_reference` proves the equality. The finite Kraus amplification separately establishes complete positivity of the recovery, which is needed to preserve states in the presence of a reference system.

III.22 Coherent combinations and normalization

A correction proof for only one selected Kraus presentation is weaker than a proof that one decoder works throughout the error span. The formal module connects the constructed spectral recovery back to the original error operators.

III.22.1 Cross terms for the original errors

For arbitrary positive Gram data, the same recovery satisfies

$$\boxed{\mathcal{R}(E_a \rho E_b^*) = C_{ba}\rho \qquad (P\rho P = \rho).}$$

The index order ba is intentional: the defining Gram relation is $PE_a^*E_bP = C_{ab}P$. The proof first derives scalar corrected Kraus composites for the constructed recovery and then uses its trace-preserving completeness to identify the original Gram entries.

For $E(c) = \sum_a c_a E_a$, finite-sum expansion gives

$$\mathcal{R}(E(c)\rho E(c)^*) = \left(\sum_{a,b} c_a \overline{c_b} C_{ba}\right)\rho = (c^* C c)\rho.$$

The formula with a double sum is the literal checked conclusion. The final notation as a quadratic form follows by renaming finite indices. It is not restricted to orthogonal errors or real coefficients.

III.22.2 Every normalized channel in the same span

Suppose $F_j = \sum_a c_{ja} E_a$ and $\sum_j F_j^* F_j = I$. The decoder is *not* reconstructed for the F_j. Summing the coherent identities gives a scalar multiple $q\rho$. Trace preservation of both the F channel and the recovery forces $q = 1$ on a nonzero code. The proof uses positivity of P to justify cancellation of its trace and handles $P = 0$ separately. Therefore

$$\boxed{\mathcal{R}\Big(\sum_j F_j \rho F_j^*\Big) = \rho.}$$

This is `Data.recovery_span_channel`, a quantified statement over arbitrary finite F families and their complex coefficients.

III.22.3 The equivalence for unnormalized error families

For arbitrary finite E, define exact family recovery to mean that a finite trace-preserving Kraus recovery and a single $t \geq 0$ exist such that

$$\mathcal{R}\mathcal{N}_E(\rho) = t\rho \quad \text{for every code-supported } \rho.$$

Then `error_family_correctable_iff_gram` proves that this condition is equivalent to the existence of $C \succeq 0$ satisfying the Gram identities. Sufficiency chooses $t = \operatorname{Tr} C$. Necessity constructs C from the scaled rank-one rigidity argument.

The scale is essential. Zero errors can give $t = 0$ and cannot be inverted to a nonzero normalized state. An input with a larger total trace is not silently declared a channel. For normalized input channels, the separate channel theorem removes the scale exactly as described in the sufficiency argument above.

III.23 Exact examples, trust audit and remaining work

III.23.1 Singular, nonorthogonal errors are accepted

On a qubit with full code $P = I$, take

$$E_0 = \frac{3}{5} I, \qquad E_1 = \frac{4}{5} I, \qquad C = \begin{pmatrix} 9/25 & 12/25 \\ 12/25 & 16/25 \end{pmatrix}.$$

Lean checks the channel normalization, the Gram identities, positivity of C, $\det C = 0$, and the nonzero off-diagonal entry. It then applies the criterion for density matrices to prove correctability. The calculation is exact and uses rational complex entries.

III.23.2 A genuine channel can still be uncorrectable

For full qubit dephasing, $E_0 = \operatorname{diag}(1, 0)$ and $E_1 = \operatorname{diag}(0, 1)$, the Kraus normalization is checked. But $E_0^* E_0$ cannot be a scalar multiple of I, as its two diagonal entries differ. Necessity therefore proves that no finite recovery channel corrects the full code space. The case of the zero code is also checked independently.

III.24 The global projected connection

Let M be a smooth real manifold without boundary, F a complete normed real vector space and $P : M \to \operatorname{End}(F)$ a smooth family of bounded idempotents. For smooth range sections s, define

$$\nabla_X s = P \, \mathrm{d}s[X].$$

The proof begins by constructing the range bundle from P. Its local connection formulas glue, and the actual covariant commutator satisfies

$$\boxed{(\nabla_X \nabla_Y - \nabla_Y \nabla_X - \nabla_{[X,Y]}) s = P(\, \mathrm{d}P[X] \, \mathrm{d}P[Y] - \, \mathrm{d}P[Y] \, \mathrm{d}P[X]) P \, s.}$$

The derivative and Lie bracket are Mathlib's actual manifold operators. No global coordinate chart is assumed. The result requires idempotence, not an additional orthogonality hypothesis.

III.25 Local products constructed from the projector

The fiber over x is the actual fixed subspace

$$\mathcal{E}_x = \{v \in F : P(x)v = v\} = \operatorname{Ran} P(x).$$

The total space is the subset $\mathcal{E} = \{(x, v) : P(x)v = v\} \subseteq M \times F$, with the induced topology. The construction provides local homeomorphisms of this total space as well as the transition functions between them.

III.25.1 An invertible intertwiner near each anchor

For idempotents p, q, set

$$T(p, q) = pq + (I - p)(I - q).$$

Lean proves $T(p, p) = I$ and $pT(p, q) = T(p, q)q$. For an anchor $a \in M$, define

$$U_a = \{x : T(P(x), P(a)) \text{ is invertible}\}.$$

The invertible elements form an open subset of the algebra of bounded operators. Consequently U_a is open and contains a. The family (U_a) covers the whole base. Invertibility is *derived locally*, not assumed at every pair of points.

III.25.2 The mutually inverse local maps

Write $T_a(x) = T(P(x), P(a))$. For $x \in U_a$,

$$B_a(x) : \mathcal{E}_a \longrightarrow \mathcal{E}_x, \quad v \longmapsto T_a(x)v,$$

$$A_a(x) : \mathcal{E}_x \longrightarrow \mathcal{E}_a, \quad w \longmapsto P(a)T_a(x)^{-1}w.$$

The intertwining identity and its inverse counterpart show that the displayed targets are correct. Lean proves both inverse laws, continuity, linearity in the fiber and smooth dependence on the base. Thus

$$\mathcal{E}|_{U_a} \cong U_a \times \mathcal{E}_a$$

is a local product homeomorphism that preserves the base point.

III.25.3 Smooth overlap maps and rank

The coordinate transition is $g_{ab}(x) = A_b(x)B_a(x)$. It is smooth on $U_a \cap U_b$, agrees with the actual change between local homeomorphisms, and satisfies

$$g_{aa} = I, \qquad g_{bc}g_{ab} = g_{ac}.$$

A continuous linear equivalence between $\mathcal{E}_a$ and $\mathcal{E}_x$ also gives local constancy of fiber dimension. No single constant rank across disconnected components is assumed.

III.26 A connection on the constructed bundle

The global formula is defined using the actual manifold derivative:

$$\nabla_X s(x) = P(x)\, D_M s(x)[X(x)].$$

Here D_M is represented by `mvfderiv`. A second definition, `GlobalConnection.covariant`, has values in the actual fiber:

$$\nabla s(x) : T_x M \longrightarrow \mathcal{E}_x.$$

It is not only an ambient expression asserted to land in the range.

III.26.1 Connection axioms and smoothness

The formal proofs establish range preservation, additivity in the section, linearity over functions in the vector field argument, and the scalar Leibniz identity

$$\nabla_X(fs) = \mathrm{d}f[X]\, s + f \nabla_X s.$$

Smooth P, smooth sections and smooth vector fields give smooth covariant derivatives. Equality of section germs gives equality of covariant derivatives at the point, so the operation is local.

III.26.2 Smoothness of sections in bundle coordinates

Let $x \in U_a$. If $P(y)s(y) = s(y)$ in a neighborhood of x, then

$$s \text{ is smooth at } x \quad \Longleftrightarrow \quad (y \mapsto A_a(y)s(y)) \text{ is smooth at } x.$$

The range condition is only local. The proof uses the actual inverse local maps and equality of germs. It follows that smoothness in bundle coordinates does not depend on the chosen chart.

III.26.3 The local connection and its change of coordinates

For a coordinate function u valued in $\mathcal{E}_a$, define

$$\nabla^{(a)}_X u = A_a(P\, D_M(B_a u)[X]).$$

For every overlap point, Lean proves the operator identity

$$\boxed{\nabla^{(b)}_X(g_{ab}u) = g_{ab}\nabla^{(a)}_X u.}$$

This is proved for arbitrary local coordinate functions. It does not assume that u was obtained from a globally smooth section or that a smooth extension has been supplied. Together with the local smoothness criterion, this closes the gluing step left open in the fifth block.

III.27 From differentiated projectors to the two-form

The curvature is defined by the covariant commutator, including the *actual manifold Lie bracket*. It is not defined to equal the desired projector expression.

III.27.1 The flat ambient identity is proved in charts

For a smooth vector-valued function s, the proof identifies directional derivatives with the pullback into each extended chart. It then proves

$$D_M s([X,Y]) = D_M(D_M s[Y])[X] - D_M(D_M s[X])[Y].$$

This uses the chart pullback of the actual vector fields and the ordinary differential identity, then transfers the result back to the manifold. The auxiliary module works locally at a point, so the argument applies within arbitrary open chart domains.

III.27.2 Projector and section identities are derived

Differentiating $P^2 = P$ in a tangent direction v yields

$$(\,\mathrm{d}P[v])P + P\,\mathrm{d}P[v] = \,\mathrm{d}P[v], \qquad P\,\mathrm{d}P[v]P = 0.$$

Differentiating $Ps = s$ gives

$$\mathrm{d}s[v] = \,\mathrm{d}P[v]s + P\,\mathrm{d}s[v].$$

Both statements are consequences of actual derivative rules. They are not additional assumptions.

III.27.3 Cancellation of the second derivatives

The product rule and the identity for the ambient Lie bracket reduce curvature to

$$R^{\nabla}(X,Y)s = P\,\mathrm{d}P[X]\,\mathrm{d}s[Y] - P\,\mathrm{d}P[Y]\,\mathrm{d}s[X].$$

Substitute the identity obtained by differentiating the range condition for the section. The terms containing $P\,\mathrm{d}P[v]P$ vanish, leaving

$$R^{\nabla}(X,Y)s = P(\,\mathrm{d}P[X]\,\mathrm{d}P[Y] - \,\mathrm{d}P[Y]\,\mathrm{d}P[X])Ps.$$

Lean also proves that this depends only on $X(x)$, $Y(x)$ and $s(x)$, not on their extensions. The operator-valued form is alternating, additive and homogeneous, and lands in the actual fiber. Constant projector bundles have zero curvature form.

III.27.4 Geometry and scalar conventions

The main global curvature theorem uses a smooth real manifold without boundary, modeled on a complete normed real space, and bounded real-linear endomorphisms of a complete normed real space. Finite-dimensional parameter and quantum spaces fall within the corresponding real differential calculus. Complex quantum spaces can be viewed through their underlying real normed spaces. This block does not introduce a separate typeclass wrapper for complex bundles.

The atlas and global connection constructions also support the more general infrastructure for models with corners wherever their hypotheses apply. The *curvature completion claim* concerns the stated theorem for manifolds without boundary. Extending that curvature result to boundaries or corners requires further work.

III.27.5 An explicit smooth atlas

The implementation exposes the actual total space, local product homeomorphisms, linear transitions, smoothness proofs and cocycle laws. It does not register these as a `ContMDiffVectorBundle` instance. This is an interface choice. The range bundle atlas, local trivializations, overlap identities, and curvature formula are all constructed or proved from the stated inputs.

The equivalence for smooth sections and the gauge law make the atlas usable intrinsically. The connection is also defined with values in `fiber(Px)`. Six constructed objects that contain proof fields, including both local equivalences and the derivative with values in the fiber, have separate axiom audits.

III.28 Earlier compact derivations retained as alternatives

The following derivations retain valid mathematical arguments from the original manuscript. Their hypotheses and notation agree with the corrected finite core. The earlier abbreviated argument for error correction is replaced by the complete normalized and scaled recovery proofs above, and its substantive conclusions are included there.

III.28.1 Duhamel proof of leakage from a fixed packet

Let $H = H^*$ on a finite-dimensional complex Hilbert space, $P = P^* = P^2$, $Q = I - P$, and $t \in \mathbb{R}$.

Alternative proof of the commutator leakage bound. Because $QP = 0$,

$$Qe^{-itH}P = Q[e^{-itH}, P]P.$$

The Duhamel identity gives

$$[e^{-itH}, P] = -i \int_0^t e^{-i(t-s)H}[H, P]e^{-isH}\, ds.$$

Both unitary factors have norm one, so taking norms and using the integration interval's length $|t|$ yields $\|Qe^{-itH}P\| \le |t|\, \|[H, P]\|$. □

III.28.2 Proof of projected curvature with exterior forms

Let P be a smooth idempotent field and extend the projected connection to differential forms with values in the range bundle by $\nabla\omega = P\,d\omega$. Thus ∇^2 denotes the exterior covariant square, including the Lie bracket term in the exterior derivative when evaluated on vector fields.

Alternative proof of the curvature formula. For a section s with $Ps = s$,

$$\nabla^2 s = P\,d(P\,ds) = P(dP) \wedge ds.$$

Since $ds = d(Ps) = (dP)s + Pds$ and $P(dP)P = 0$, the surviving term is

$$P(dP \wedge dP)Ps.$$

□

III.28.3 Restricted low-mode proof

Let $h \neq 0$, $x = kh/2$, and $0 \leq x \leq 1$.

Alternative proof in the original low-mode regime. Since $0 \leq \sin x \leq x$, the error is nonnegative. On $[0, 1]$,

$$\sin x \geq x - \frac{x^3}{6} \geq 0.$$

Therefore

$$\sin^2 x \geq \left(x - \frac{x^3}{6}\right)^2 \geq x^2 - \frac{x^4}{3}.$$

Hence $x^2 - \sin^2 x \leq x^4/3$. Multiplication by $4/h^2$ gives

$$0 \leq k^2 - \frac{4}{h^2}\sin^2(kh/2) \leq \frac{k^4 h^2}{12}.$$

□

How to use this volume

Follow each small model through its matrices and formulas, then read the cited general argument in the traditional volume. The Lean companion records the formal statements and their precise hypotheses.

Routes through the guide

Plates VII.1 through VII.40 identify worked pages independently of PDF pagination. The source line below each title points into the strengthened quantum development in Traditional Part II. The traditional volume also retains the corrected finite core and the completion supplements as distinct branches.

Route	Mathematical question	Plates
Seeds and symmetry	Which algebra and multiplicities determine the generated span?	1–7, 29
Coherent circuits	Which amplitudes interfere before an outcome is measured?	8–11, 27
Moving subspaces	How do transport, local charts, and curvature enter?	12–15, 30
Channels and recovery	What survives dephasing and which errors can be corrected?	16–20, 31–33
Hidden dynamics	What self-energy and memory return after elimination?	21–23, 34–36
Limits and constraints	Which additional hypotheses support continuum passage?	24–26, 37–40
Evidence	What is checked, proved, or still open?	28, 40

Keep the operation visible

A complete packet decomposition retains the vector. Measurement and dephasing can remove coherence. Eliminating hidden states produces an exact memory equation, while deleting their coupling usually produces a different model.

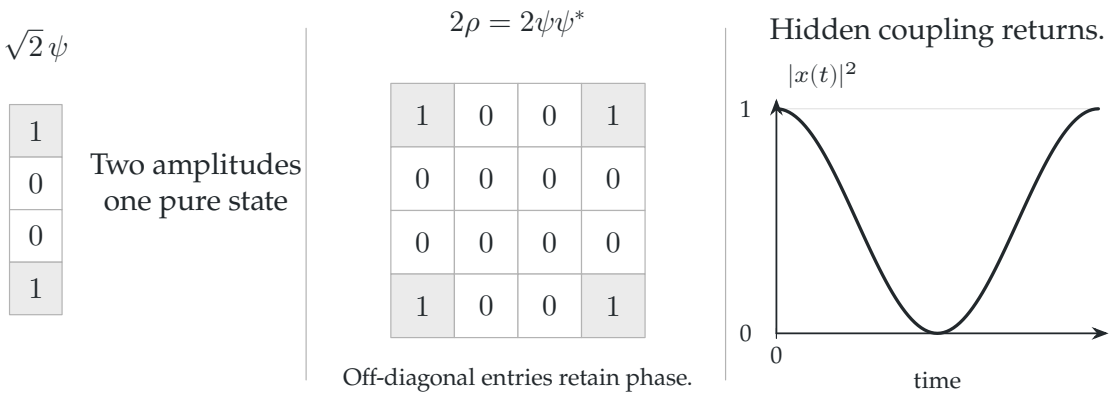
A finite example checks its specified matrices or formulas. A written theorem gives an argument under quantified assumptions. A compiled Lean theorem certifies its formal statement in the recorded environment. The reading links help compare these accounts while keeping their hypotheses and evidence scopes distinct.

Preservation and evidence

The first 28 worked pages retain the mathematical content of the original appendix. Twelve further pages explain the strengthened results. All 38 editable TikZ plates and their Python generators remain available. The retained execution records describe the example suites, their tested inputs, and their rejected controls. The formal companion distinguishes these finite checks from the theorem correspondence.

The finite formal correspondence covers nineteen scoped results. The broader quantum development retains its written hypotheses, and the five continuum research targets remain open. The examples explain how the finite results work and where further arguments are needed.

Read this as: Choose a question, calculate its small model, and then check the hypotheses of the traditional result and the declared formal statement.



Part IV Worked visual atlas

Plate VII.1 / HOW TO READ THIS APPENDIX

Three objects, three questions

Chapter VII: Section II.1, Section II.7, Section II.9.

A quantum calculation becomes easier to follow when its objects remain visible. This appendix follows a state vector, a density matrix, and a retained part of a dynamical system. They may describe the same experiment, but they do not answer the same question.

Amplitudes retain relative phase

For the Bell vector $\psi = (|00\rangle + |11\rangle)/\sqrt{2}$, the two nonzero entries are amplitudes. The density matrix $\rho = \psi\psi^*$ also records coherence in its off-diagonal entries. Measurements that compare the two addresses can detect this coherence. Deleting those entries applies a physical channel and changes the state.

How hidden dynamics returns

When a Hamiltonian couples a retained state to a hidden state, the retained amplitude can leave and later return. Its exact equation then remembers the hidden coupling. A smaller matrix obtained by deleting rows and columns does not generally reproduce that equation.

A route through the paper

Plate VII.3–Plate VII.10 develop seeds, symmetry, and coherent circuit paths. Plate VII.11–Plate VII.15 track leakage and moving subspaces. Plate VII.16–Plate VII.20 distinguish measurement, channels, and recovery. Plate VII.21–Plate VII.27 follow hidden dynamics and finite geometric diagnostics.

Read these examples alongside the mathematical text. The first twenty-eight plates develop the finite constructions and their geometric interpretation. Plate VII.29–Plate VII.40 develop the further results on bounded limits and constraints. The example checks and the inherited Lean certificates have separately recorded scopes.

> **Read this as:** A packet coordinate change preserves information. A measurement, dephasing operation, or truncation may not. Always identify which operation is actually being performed.

Plate VII.2 / AN ATLAS OF TYPES AND CONVENTIONS

The objects on the page

Chapter VII: Definition II.2.1, Definition II.7.1.

The same letter can stand for different kinds of data in different calculations. Keep the following types fixed while reading a formula. In this appendix, vectors are columns, operators compose from right to left, and A^* denotes the conjugate transpose.

Symbol	Object	What it records
$\mathcal{H}, \psi$	Hilbert space and state vector	They specify the space of addresses and its coherent amplitudes.
$\mathcal{A}$	Declared operator algebra	It specifies the available linear operations.
P_a	Orthogonal packet projector	It selects an entire subspace.
ρ	Positive matrix of trace one	It records populations and coherences.
E_k	Positive measurement effect	It gives the outcome probability $\mathrm{Tr}(E_k\rho)$.
K_a	Kraus operator	It describes one channel branch and need not be a projector.
H	Self-adjoint Hamiltonian	It generates evolution in real time through $e^{-\mathrm{i}tH}$.
C, ∇	Packet transport generator and connection	They describe moving subspaces and differentiation within their ranges.
P, Q	Retained and hidden projectors	They define a decomposition with $Q = I - P$.
$\Sigma(z)$	Self-energy	It records the spectral influence of the hidden sector.
$L, T(\tau)$	Nonnegative operator and Euclidean transfer	They determine decay factors and finite heat trace diagnostics.

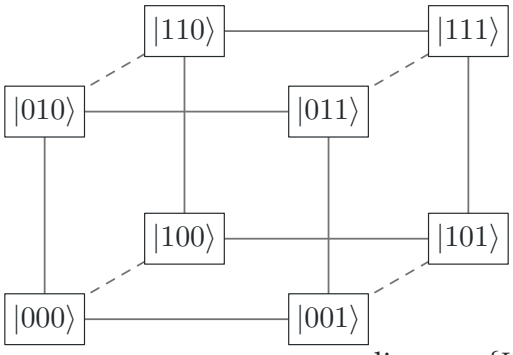
Normalization and indexing

The tensor factors are ordered from left to right, so $X_1 = X \otimes I \otimes I$. A normalized pure state gives $\rho = \psi\psi^*$. A coefficient matrix used to count a seed orbit need not be normalized. Scaling a nonzero seed does not change its generated linear span.

A Hamiltonian and a Hadamard gate are both traditionally denoted H. Where both appear, the gate is H_{Had} and the Hamiltonian keeps the letter H. Numerical labels on a drawing are coordinates or exact example values, not observations of a physical device.

> **Read this as:** Check the type before interpreting the picture. An idempotent projector, a density matrix, and a channel matrix have different defining equations.

Plate VII.3 / CYCLICITY DEPENDS ON THE GRAMMAR



One seed, eight addresses

Chapter VII: Proposition II.2.5.

Start with $\psi_0 = |000\rangle$ and allow the three bit flip operators X_1, X_2, X_3. For a binary address $a = (a_1, a_2, a_3)$, put

$$W_a = X_1^{a_1} X_2^{a_2} X_3^{a_3}. \qquad W_a \psi_0 = |a_1 a_2 a_3\rangle .$$

The drawing shows the actual eight states reached by these words. Dashed edges connect the two squares by changing the first bit. The other edges change one of the remaining bits.

Three actual words

$$W_{101} = X_1 X_3$$

$$W_{011} = X_2 X_3$$

$$W_{110} = X_1 X_2$$

$$\dim \operatorname{span}\{W_a |000\rangle\} = 8$$

Two different meanings of “reach”

The eight vectors are orthonormal, so their *linear span* is all of $\mathbb{C}^8$. This proves cyclicity for the algebra generated by the flips. Preparing every normalized vector requires more than products of these flips alone.

For example, no such word sends $|000\rangle$ to $(|000\rangle + |001\rangle)/\sqrt{2}$. A Hadamard gate, a suitable linear combination in the observable algebra, or a larger preparation grammar is required for that operation. Counting linearly independent addressed vectors and synthesizing a physical gate sequence are separate tasks.

The exact check constructs each 8×8 word matrix, applies it to the seed, and verifies that the matrix of all eight outputs is the identity. It also tests the displayed superposition against every word output. No search over an unspecified gate set is involved.

> **Read this as:** A cyclic seed generates a vector space under an algebra. That conclusion does not automatically provide a unitary preparation procedure for every vector in it.

Plate VII.4 / SCHMIDT RANK AS ACCESSIBLE MULTIPLICITY

Entanglement changes the local span

Chapter VII: Theorem II.2.2, Corollary II.2.4.

Write a bipartite vector as a coefficient matrix C, with the first subsystem indexing rows. Acting only on that subsystem transforms C to AC. Every resulting row remains in the row space of C, and every independent choice of such rows can be obtained in this way.

$$\dim \operatorname{span}\{(A \otimes I)\psi : A \in M_d(\mathbb{C})\} = d \operatorname{rank} C.$$

Product seed matrix

1	0
0	0

row rank 1
orbit dimension 2

Bell seed matrix $\sqrt{2}C$

1	0
0	1

row rank 2
orbit dimension 4

A acts on the left. It cannot invent a new direction in the row space.

The product vector $|00\rangle$ has matrix $C = \operatorname{diag}(1, 0)$. Its local orbit span allows arbitrary vectors in the first subsystem but only the second subsystem direction $|0\rangle$, so its dimension is two. The Bell vector has $C = I/\sqrt{2}$, rank two, and a four-dimensional local orbit span.

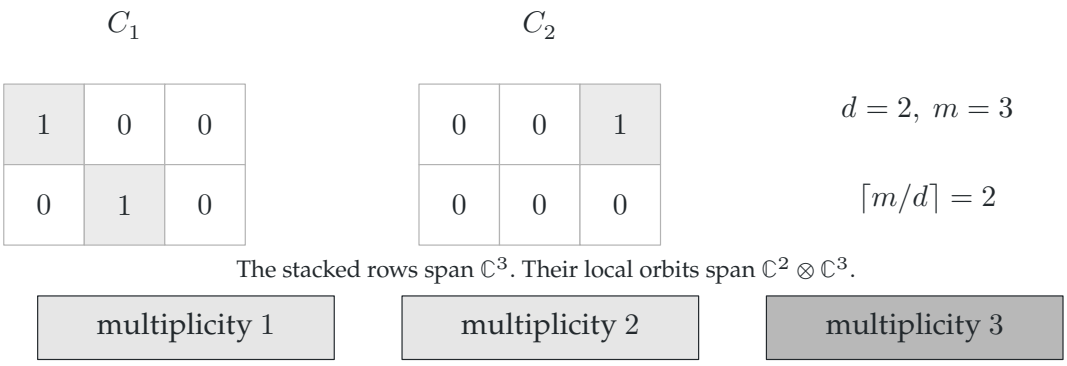
What the formula does not say

The action here allows arbitrary matrices and then takes a linear span. It is not the orbit under local unitary gates alone. Local unitary operations preserve Schmidt coefficients. They therefore cannot turn the Bell vector into an arbitrary product vector by a deterministic transformation between pure states.

For the exact calculation, apply the four matrix units E_{ab} to each seed matrix, flatten the outputs, and compute their column rank. The observed dimensions are two and four, respectively. The calculation directly exhibits the independent rows counted by the theorem.

> **Read this as:** Schmidt rank measures the remote multiplicity directions accessible to the local operator span. It is not permission for unrestricted deterministic local state preparation.

Plate VII.5 / AN EXACT MULTIPLICITY LOWER BOUND



Why one seed is not always enough

Chapter VII: Theorem II.2.3.

Consider $M_2(\mathbb{C}) \otimes I_3$ acting on $\mathbb{C}^2 \otimes \mathbb{C}^3$. A seed is a 2×3 coefficient matrix. Its two rows span at most two directions in the three-dimensional multiplicity factor. Therefore no single seed is cyclic for this algebra.

$$C_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \qquad C_2 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

These two matrices provide a complete set of row directions. Their individual orbit dimensions are four and two, and together those spans fill the six-dimensional state space.

From the example to the finite formula

For a block $M_d(\mathbb{C}) \otimes I_m$, k seed matrices contribute at most kd independent multiplicity directions. Hence $k \geq \lceil m/d \rceil$. Partitioning a multiplicity basis into groups of size at most d attains this bound. For a direct sum of such blocks, the worst block determines the required count:

$$\operatorname{srank}_{\mathcal{A}}(\mathcal{H}) = \max_i \lceil m_i/d_i \rceil.$$

This is an invariant of the declared representation of the algebra, and depends on more than the dimension of the Hilbert space alone. If the available algebra were enlarged to the full matrix algebra on $\mathbb{C}^6$, every nonzero seed would instead be cyclic.

The example checks both the ranks of the separate coefficient matrices and the rank three of their stacked row matrix. The argument explains why the construction meets the lower bound and therefore proves minimality.

> **Read this as:** Missing multiplicity directions cannot be created by reusing the same left action. Adding seeds and enlarging the operator algebra provide different ways to supply those directions.

Plate VII.6 / CHARACTER PROJECTORS YOU CAN MULTIPLY

Four phases resolve a cyclic shift

Chapter VII: Corollary II.3.3.

On four sites, let $S\,|k\rangle = |k+1 \bmod 4\rangle$ and let $\omega = \mathrm{i}$. The character projectors are the exact matrices

$$P_j = \frac{1}{4}\sum_{r=0}^{3} \mathrm{i}^{-jr} S^r, \qquad v_j(k) = \frac{1}{2}\mathrm{i}^{-jk}, \qquad P_j = v_j v_j^*.$$

All entries belong to the Gaussian rationals. Thus no approximation to a root of unity is needed in this model.

$2V$, with $V^*V = I$

	$j=0$	$j=1$	$j=2$	$j=3$
site 0	1	1	1	1
site 1	1	$-i$	-1	i
site 2	1	-1	1	-1
site 3	1	i	-1	$-i$

$$Sv_0 = 1v_0 \qquad P_0 = v_0 v_0^*$$

$$Sv_1 = iv_1 \qquad P_1 = v_1 v_1^*$$

$$Sv_2 = -1v_2 \qquad P_2 = v_2 v_2^*$$

$$Sv_3 = -iv_3 \qquad P_3 = v_3 v_3^*$$

Each column has four entries of magnitude $1/2$.

Reading the columns

Each column v_j is a normalized wave around the four sites. Advancing the address multiplies it by i^j. The entries show phase differences rather than four different probability distributions: every column has uniform site probability $1/4$.

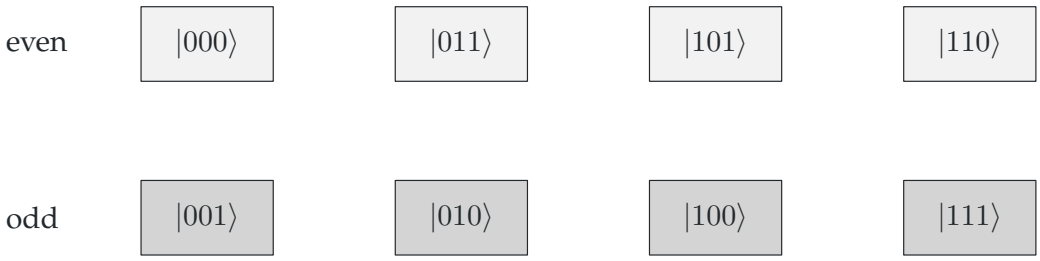
Multiplying the actual projectors gives $P_jP_k = 0$ for $j \neq k$, $P_j^2 = P_j$, and $\sum_j P_j = I$. In particular, the complete packet tuple $(P_j\psi)_j$ retains the original vector exactly. Recording only the four packet norms is a different operation and can discard phase information between packets.

The same shift on four sites returns on Plate VII.27, where it diagonalizes the Hamiltonian $L = 2I - S - S^*$, and its four character phases explain perfect transfer between opposite sites. The same fixed projectors serve as coordinates, symmetry sectors, and a complete interference ledger.

> **Read this as:** A character projector retains a complex subspace component. Its norm summarizes the size of that component while leaving its phase and direction unspecified.

Plate VII.7 / TENSOR REFINEMENT BY TOTAL PARITY

A coarse packet can still contain coherence



Chapter VII: Theorem II.3.7, Corollary II.3.8.

For three qubits, the eight fine projectors are $P_a = |a\rangle\langle a|$. Grouping addresses according to the parity of their Hamming weight gives

$$P_{\text{even}} = P_{000} + P_{011} + P_{101} + P_{110} = \frac{I + Z \otimes Z \otimes Z}{2}, \qquad P_{\text{odd}} = I - P_{\text{even}}.$$

This is a sum of subspaces, not an averaging of their coordinates. The rank-four even packet retains all complex amplitudes on its four children.

Each coarse projector has rank four. All eight fine projectors have rank one.

Refinement is not measurement

The fine packet description and the coarse packet description each reconstruct the full vector when every component is retained. Replacing a state by the mixture $\sum_a P_a \rho P_a$ is instead a dephasing channel. That operation removes coherence between the fine packets and can differ from dephasing only between the even and odd sectors.

For instance, a superposition of $|000\rangle$ and $|011\rangle$ lies entirely in the even packet. Its internal relative phase survives a parity measurement but is lost by a complete measurement in the computational basis if outcomes are forgotten. The two measurements use projectors from the same refinement hierarchy but expose different information.

The exact check verifies all eight addresses, their parity grouping, the rank of both coarse projectors, and equality with the tensor expression above. The general residue version replaces parity by total label modulo N and groups the tensor descendants by their summed residue.

> **Read this as:** A coarse packet is a whole subspace. Internal coherence survives a change of address description. It is lost only when an operation discards it.

Plate VII.8 / INTERMEDIATE PACKETS ARE NOT FINAL PACKETS

Track the Bell state through the circuit

Chapter VII: Theorem II.4.1, Example II.4.6.

The input is $|00\rangle$. First apply a Hadamard to the first qubit, then a controlled flip:

$$|00\rangle \xrightarrow{H_{\text{Had}}\otimes I} \frac{|00\rangle + |10\rangle}{\sqrt{2}} \xrightarrow{\text{CNOT}} \frac{|00\rangle + |11\rangle}{\sqrt{2}}.$$

The displayed columns keep amplitudes, including their normalization, at every step. The middle vector occupies both parity packets. The final vector occupies only the even packet.

	seed		after $H \otimes I$		after CNOT
00	1	00	$\frac{\sqrt{2}}{2}$	00	$\frac{\sqrt{2}}{2}$
01	0	01	0	01	0
10	0	10	$\frac{\sqrt{2}}{2}$	10	0
11	0	11	0	11	$\frac{\sqrt{2}}{2}$
	even only		both parity packets		even only, with coherence

How the exact path expansion works

Insert $P_{\text{even}} + P_{\text{odd}} = I$ between the two gates. Each summand records a particular intermediate packet, while the boundary projectors select its input and output packets. Summing all terms recovers the original 4×4 circuit matrix:

$$\sum_{a,b,c} P_b \,\text{CNOT}\, P_a (H_{\text{Had}} \otimes I) P_c = \text{CNOT}(H_{\text{Had}} \otimes I).$$

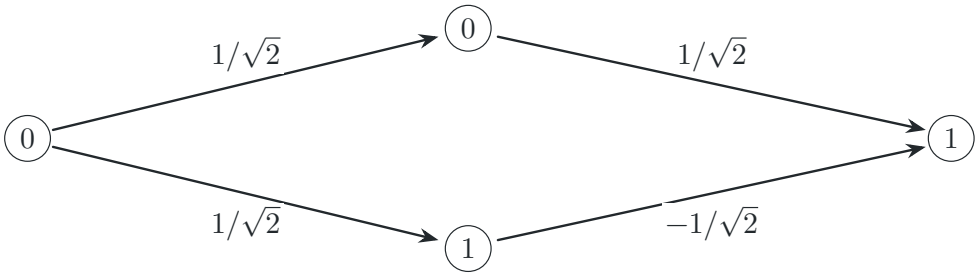
This expansion is an identity even though the intermediate parity is not measured. Physically inserting a measurement would alter the problem by removing interference between its alternatives. The derivation resolves intermediate coordinates without physically measuring them.

In the finite check, all eight matrix terms indexed by parity are constructed and summed. The matrix equality is checked before specializing to the input vector. It therefore verifies the decomposition for every input of this example, not merely agreement on the Bell seed.

> **Read this as:** A final invariant packet does not imply that each preceding gate preserved it. Follow the amplitudes through the actual intermediate resolutions.

Plate VII.9 / HOW TWO PATH AMPLITUDES CANCEL

Why path probabilities do not add



Chapter VII: Theorem II.4.2, Theorem II.4.4.

Two consecutive Hadamard gates multiply to the identity. Starting from $|0\rangle$, there are two resolved paths to output $|1\rangle$. Their signed products are

$$\langle 1|\, H_{\mathrm{Had}}\, |0\rangle\, \langle 0|\, H_{\mathrm{Had}}\, |0\rangle = \frac{1}{2}, \qquad \langle 1|\, H_{\mathrm{Had}}\, |1\rangle\, \langle 1|\, H_{\mathrm{Had}}\, |0\rangle = -\frac{1}{2}.$$

Their sum is zero. Squaring each separately gives a different answer.

Two actual Hadamard paths, not classical alternatives

$$\text{amplitude} = 1/2 - 1/2 = 0 \quad \neq \quad \text{sum of path probabilities} = 1/2$$

Where the missing term goes

For path amplitudes a, b, the outcome probability is $|a+b|^2 = |a|^2 + |b|^2 + 2\Re(a\bar{b})$. Here the last term is $-1/2$, canceling the first two terms. The path picture retains this information only if its edges carry complex amplitudes rather than unsigned reachability or probabilities.

The packetwise unitarity identity is likewise an operator identity, including the off-diagonal cancellations:

$$\sum_b U_{ba}^* U_{bc} = \delta_{ac} P_a, \qquad U_{ba} = P_b U P_a.$$

It cannot be replaced by the assertion that every path individually has unit norm. The exact checks verify all four choices of a, c for the two rank-one packets, as well as the two path products leading to the opposite output.

A measurement at the intermediate stage would remove the cross term. In that modified experiment the two alternatives really would contribute total probability $1/2$ to output one. Adding the two path probabilities would therefore describe the experiment with an intermediate measurement.

> **Read this as:** Insert projectors algebraically to resolve paths, then add amplitudes. Add probabilities only when the physical setup has actually made the alternatives incoherent.

Plate VII.10 / ONE HAMILTONIAN IN TWO ORDERS

A symmetry reveals blocks, not approximations

Chapter VII: Theorem II.5.1.

Take the exact rational Hamiltonian

$$H = X \otimes X + \frac{3}{8}(Z \otimes I + I \otimes Z).$$

It commutes with total parity $Z \otimes Z$. Reordering the computational basis into even addresses $(00, 11)$ and odd addresses $(01, 10)$ displays the invariant subspaces explicitly.

Computational order

	00	01	10	11
00	$\frac{3}{4}$	0	0	1
01	0	0	1	0
10	0	1	0	0
11	1	0	0	$-\frac{3}{4}$

same operator
different order

Parity order

	00	11	01	10
00	$\frac{3}{4}$	1	0	0
11	1	$-\frac{3}{4}$	0	0
01	0	0	0	1
10	0	0	1	0

Even eigenvalues: $\pm 5/4$. Odd eigenvalues: ± 1.

$$H_{\text{even}} = \begin{pmatrix} 3/4 & 1 \\ 1 & -3/4 \end{pmatrix}, \qquad H_{\text{odd}} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

The even block squares to $(25/16)I$, so its eigenvalues are $\pm 5/4$. The odd block squares to I, so its eigenvalues are ± 1. Exponentiating either block gives the corresponding part of the exact evolution. Transfer between the packets remains zero for every real time.

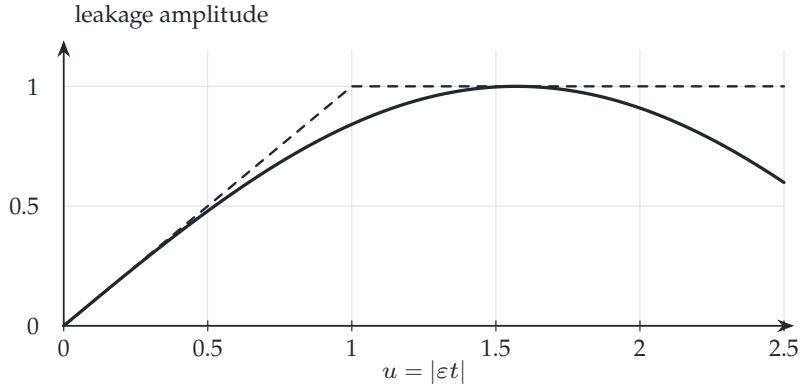
What has changed?

Only the order of basis vectors has changed. No matrix entries, amplitudes, or energy levels were discarded. This is why the decomposition is exact. Keeping just the even block would be a separate restriction of the state space, justified for initial data known to be even and for dynamics that preserve it.

The next page breaks a symmetry in a smaller model. There the entries coupling the packets no longer vanish, so their effect needs an explicit bound. The exact tests here multiply the commutator, verify the displayed permutation, and compute all four eigenvalues symbolically.

> **Read this as:** Block diagonalization uses an invariant decomposition already present in the operator. It is not evidence that an arbitrary chosen packet is invariant.

Plate VII.11 / COMMUTATORS AND PROBABILITY BOUNDS



Quantify the amplitude that escapes

Chapter VII: Theorem II.5.3, Corollary II.5.4.

For a two-level system, choose $H = \varepsilon X$, $P = |0\rangle\langle 0|$, and $Q = I - P$. Direct exponentiation gives

$$e^{-\mathrm{i}tH} = \cos(\varepsilon t) I - \mathrm{i}\sin(\varepsilon t) X, \quad \left\| Q e^{-\mathrm{i}tH} P \right\| = |\sin(\varepsilon t)|, \quad \|[H, P]\| = |\varepsilon|.$$

The general commutator estimate becomes the elementary bound $|\sin u| \le |u|$. Unitarity also bounds the amplitude by one.

$H = \varepsilon X$

solid: $|\sin u|$
dashed: $\min(1, u)$

Probability is $\sin^2 u$,
not $|\sin u|$.

From a norm to a probability

For this initial state, the escape probability is $\sin^2(\varepsilon t)$, not $|\sin(\varepsilon t)|$. Consequently

$$\Pr(\text{hidden packet at } t) \le \min\{1, \varepsilon^2 t^2\}.$$

At $\varepsilon t = \pi/6$, the amplitude is $1/2$ and the probability is $1/4$. Near zero, amplitudes are first order while escape probabilities are second order. Mixing those two quantities produces an incorrect interpretation of a leakage plot.

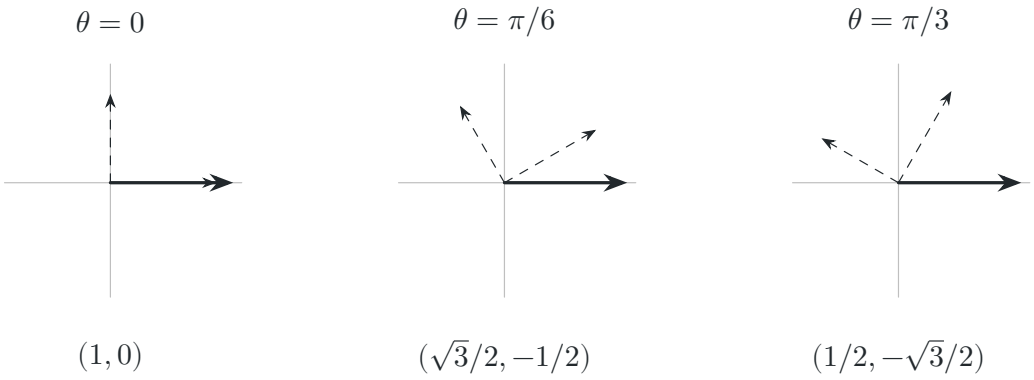
The figure displays samples of the explicit functions above. The supporting check verifies the exact exponential identity, its unitarity, the squared leakage matrix, and the special-time value. The paper's theorem supplies the bound for all times within its stated scope.

At larger times amplitude can return from the hidden packet. The commutator bound therefore limits the largest possible leakage without predicting that it must rise monotonically.

Read this as: The norm estimate controls amplitude. For a normalized state, square it to obtain a probability bound, and retain the distinction between a bound and the actual oscillatory dynamics.

Plate VII.12 / NOT ALL MOTION IS PHYSICAL EVOLUTION

A moving frame creates a connection term



Chapter VII: Theorem II.6.3.

Set the laboratory Hamiltonian to zero and keep $\psi(t) = |0\rangle$ fixed. Describe it in rotating coordinates,

$$U(t) = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}, \qquad y(t) = U(t)^* \psi(t) = \begin{pmatrix} \cos t \\ -\sin t \end{pmatrix}.$$

The vector has not moved in the laboratory, but its coordinate entries have changed.

Solid vector: fixed in the laboratory. Dashed axes: rotating frame.

The missing term can be computed exactly

Let $J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$. Since $U^*\dot{U} = J$, the coordinate Hamiltonian is

$$H_{\text{frame}} = -\mathrm{i}J = \begin{pmatrix} 0 & \mathrm{i} \\ -\mathrm{i} & 0 \end{pmatrix}, \qquad \mathrm{i}\dot{y} = H_{\text{frame}} y.$$

This matrix is Hermitian. Omitting it would predict a constant y, contradicting the displayed coordinates. In this example the norm of the omitted time derivative is exactly one, so the failure is not a small numerical residual.

For a nonzero laboratory Hamiltonian, the same product rule adds the transformed physical term U^*HU. Thus $U^*HU - \mathrm{i}U^*\dot{U}$ separates the physical generator from the coordinate correction. Both pieces belong to the same equation but have different origins.

The drawing shows actual rotated axes at three angles, not three different laboratory trajectories. The check differentiates the exact matrices and verifies the coordinate Schrödinger equation symbolically. The explicit derivatives make a numerical difference approximation unnecessary.

> **Read this as:** When coordinates move, even a stationary physical vector acquires changing components. The connection term accounts for that change without adding a force to the laboratory system.

Plate VII.13 / THE CANONICAL PACKET CONNECTION

Differentiate the subspace itself

Chapter VII: Theorem II.6.1, Theorem II.6.2.

Continue with $P(t) = U(t)\,\mathrm{diag}(1,0)U(t)^*$ and $Q(t) = I - P(t)$. Differentiating $P^2 = P$ gives

$$\dot{P}P + P\dot{P} = \dot{P}, \qquad P\dot{P}P = 0.$$

The second identity says that the derivative has no component entirely inside the current packet. It moves the subspace relative to its complement.

$P(0)$

1	0
0	0

$\dot{P}(0)$

0	1
1	0

C

0	-1
1	0

$$P\dot{P}P = 0, \qquad C^* = -C, \qquad [C, P] = \dot{P}.$$

For this complete pair of packets, define

$$C = \dot{P}P + \dot{Q}Q.$$

Exact calculation yields the constant matrix $C = J$, with $C^* = -C$ and $[C, P] = \dot{P}$. At $t = 0$, the displayed small matrices allow these identities to be checked by direct multiplication.

From two packets to a complete family

For differentiable orthogonal projectors P_a summing to the identity, the paper constructs

$$C = \sum_a \dot{P}_a P_a = \frac{1}{2}\sum_a [\dot{P}_a, P_a].$$

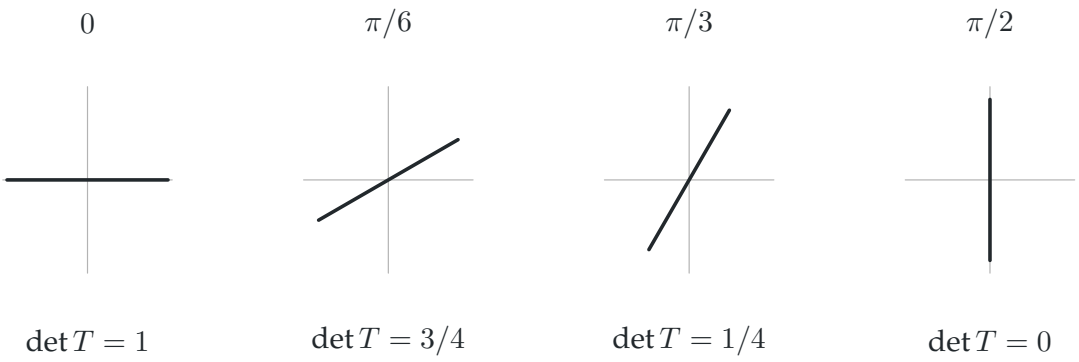
This single connection reproduces the motion of every packet in the family. No basis within a packet is needed for this formula. A basis choice would add internal coordinate data without changing which subspaces are selected.

The completeness of the family matters in deriving skew-Hermiticity and the simultaneous transport identities. Using only one summand of an incomplete list is not automatically the same connection. The example retains both P and Q throughout, even when the picture emphasizes only the first line.

> **Read this as:** The projector derivative describes motion between subspaces. The canonical connection reconstructs that motion from the complete family without choosing internal packet bases.

Plate VII.14 / THE RANGE BUNDLE IS CONSTRUCTED LOCALLY

A chart failure is not a singular fiber



Chapter VII: Theorem II.6.7. Details of the range atlas: Chapter VII, Part III, Sections III.24–III.26 (range-bundle construction).

The fiber of a projector field is the actual fixed subspace $E_x = \{v : P(x)v = v\}$. To compare it with a nearby anchor fiber E_a, the completion proof constructs

$$T_a(x) = P(x)P(a) + (I - P(x))(I - P(a)).$$

It equals the identity at the anchor and intertwines the two projectors. Where it is invertible, its restriction provides local fiber coordinates.

The ranges of $P(\theta)$ are shown with a horizontal anchor.

At the last position, use a new anchor. The fiber still has dimension one.

An exact example of the domain restriction

For the rotating line and anchor $P(0)$,

$$T_0(t) = \cos t\, U(t), \qquad \det T_0(t) = \cos^2 t.$$

The chart fails at $t = \pi/2$, but $P(\pi/2) = \mathrm{diag}(0, 1)$ is a perfectly regular rank-one projector. Choosing a vertical anchor supplies a new chart there. What failed was the comparison with one reference fiber, not the fiber itself.

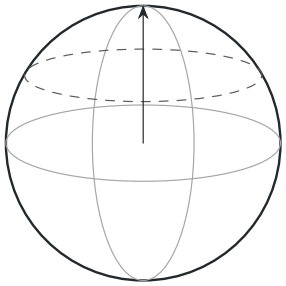
In general, the open sets where $T_a(x)$ is invertible cover the base. The inverse chart maps and smooth overlap maps are constructed from the actual matrices. Their cocycle identities express consistent coordinate changes, rather than assuming a global basis exists.

The range-bundle construction in Part III proves the intrinsic connection and its curvature using actual manifold derivatives. Its scope includes bounded idempotents, not only orthogonal ones. The illustration uses a finite-dimensional orthogonal projector to make the construction visible. Those simplifying choices do not restrict the recorded theorem.

> **Read this as:** A smooth bundle is built from compatible local charts. The singularity of one chart determinant can be harmless, provided another anchor covers the same smooth fiber.

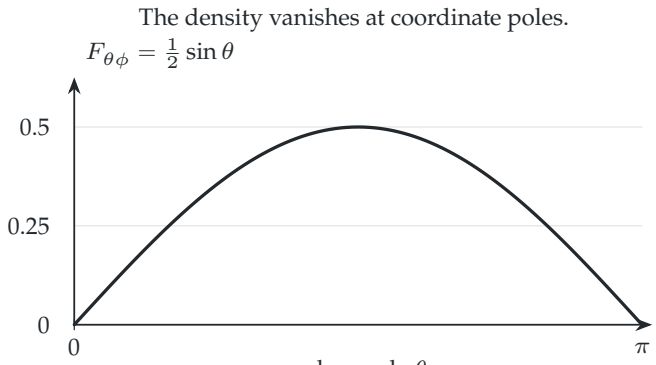
Plate VII.15 / AN EXACT BLOCH PROJECTOR CALCULATION

Curvature measures a local area response



Chapter VII: Theorem II.6.7, Corollary II.6.8.

On the unit sphere, set $n = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$ and



$$P(\theta,\phi) = \frac{1}{2}(I + n\cdot\sigma).$$

This is a smooth rank-one orthogonal projector. The intrinsic curvature is the endomorphism-valued two-form $P(\,\mathrm{d}P \wedge \mathrm{d}P)P$. With the paper's scalar convention, its component is

$$F_{\theta\phi} = -\mathrm{i}\,\mathrm{Tr}\big(P[\partial_\theta P, \partial_\phi P]\big) = \frac{1}{2}\sin\theta.$$

Cap flux at $\theta = \pi/3$ is $\pi/2$.

A local frame gives the same answer

Away from the south pole, use $u_N = (\cos(\theta/2), e^{\mathrm{i}\phi}\sin(\theta/2))^T$. Then $P = u_N u_N^*$ and the scalar one-form is

$$A_N = -\mathrm{i}u_N^*\,\mathrm{d}u_N = \frac{1-\cos\theta}{2}\,\mathrm{d}\phi, \qquad \mathrm{d}A_N = \frac{1}{2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi.$$

Thus the curvature flux through the cap $0 \le \theta \le \theta_0$ is $\pi(1-\cos\theta_0)$. At $\theta_0 = \pi/3$, it is exactly $\pi/2$. The latitude drawn in the plate illustrates this cap. The exact flux comes from the formula above.

The vanishing of the coordinate density at a pole does not mean the geometric curvature disappears there. The spherical area form also carries the factor $\sin\theta$. Assigning a phase to parallel transport also requires an orientation and a sign convention for the connection. These choices determine how flux relates to phase.

> **Read this as:** The projector formula and a local frame calculation agree. Curvature is intrinsic even when no single smooth frame covers the whole sphere.

Plate VII.16 / THE ANSWER DEPENDS ON ITS EFFECTS

Which coherence can a measurement see?

Chapter VII: Theorem II.7.2, Theorem II.7.4, Corollary II.7.5.

For the Bell density matrix $\rho = |\Phi^+\rangle\langle\Phi^+|$, parity dephasing does nothing: both nonzero amplitudes already lie in the even subspace. Dephasing in the computational basis removes the entries between addresses 00 and 11.

2ρ, also $2D_{\text{parity}}(\rho)$

	00	01	10	11
00	1	0	0	1
01	0	0	0	0
10	0	0	0	0
11	1	0	0	1

same diagonal
different coherence

$2D_{\text{computational}}(\rho)$

	00	01	10	11
00	1	0	0	0
01	0	0	0	0
10	0	0	0	0
11	0	0	0	1

Bell-projector outcome: 1 on the left, $1/2$ on the right.

Every effect in the computational basis $E_a = |a\rangle\langle a|$ has the same expectation on both matrices, namely $1/2$ at 00 and 11 and zero elsewhere. These measurements read only the diagonal. They cannot distinguish the pure Bell state from this incoherent mixture.

A measurement that resolves the difference

Use the valid two-outcome measurement with effects $E = \rho$ and $I - E$. Then

$$\operatorname{Tr}(E\rho) = 1, \qquad \operatorname{Tr}\Big(E D_{\text{computational}}(\rho)\Big) = \frac{1}{2}.$$

The effect itself is not diagonal in the fine computational packets. It compares their coherent combination, so it falls outside the paper's invariance result for block-diagonal effects.

This example contains three operations that should not be conflated: representing a state by all of its packet matrix blocks, applying a dephasing channel, and reading one specified measurement. Only the second discards the off-diagonal blocks. The third may or may not notice that loss, depending on its effects.

The exact checks construct all four fine projectors, both parity projectors, both dephased states, and the outcome traces. They reject the stronger statement that *every* measurement is invariant under dephasing.

> **Read this as:** A measurement's inability to see a coherence does not make that coherence absent. It states a restriction on the observable, not an equality of the underlying states.

Plate VII.17 / POPULATIONS AND COHERENCES TRANSFORM DIFFERENTLY

A channel acts on four matrix entries

Chapter VII: Theorem II.7.6, Example II.7.12.

Choose amplitude damping with $\gamma = 9/25$:

$$K_0 = \begin{pmatrix} 1 & 0 \\ 0 & 4/5 \end{pmatrix}, \qquad K_1 = \begin{pmatrix} 0 & 3/5 \\ 0 & 0 \end{pmatrix}, \qquad K_0^* K_0 + K_1^* K_1 = I.$$

The channel $\Phi(\rho) = \sum_a K_a \rho K_a^*$ is trace preserving and completely positive. The special parameter keeps every displayed coefficient rational.

Superoperator on matrix entries

	00	01	10	11
00	1	0	0	$\frac{9}{25}$
01	0	$\frac{4}{5}$	0	0
10	0	0	$\frac{4}{5}$	0
11	0	0	0	$\frac{16}{25}$

$\gamma = 9/25$

coherence factor $4/5$

Output from $|+\rangle$

$\frac{17}{25}$	$\frac{2}{5}$
$\frac{2}{5}$	$\frac{8}{25}$

$$\operatorname{Tr}\rho = 1, \quad \det\rho = 36/625 > 0$$

The superoperator uses the entry order $(\rho_{00}, \rho_{01}, \rho_{10}, \rho_{11})$. Population leaves the excited state with factor $9/25$, while coherences contract by $4/5$. These are not the same rate or the same coordinate.

For $\rho_+ = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$, the exact output is

$$\Phi(\rho_+) = \begin{pmatrix} 17/25 & 2/5 \\ 2/5 & 8/25 \end{pmatrix}.$$

Its trace is one and determinant is $36/625 > 0$, so it is a mixed positive state. Arrows that show population transfer alone would leave its off-diagonal entries unspecified.

How complete positivity is certified

The Choi matrix is an explicit sum of two outer products of vectorized Kraus operators. Its eigenvalues are $41/25, 9/25, 0, 0$, all nonnegative. This gives an independent finite certificate in addition to Kraus normalization. The Choi matrix has trace two under the convention used by the check, which leaves the maximally entangled vector unnormalized.

> **Read this as:** A packet channel acts on pairs of packet addresses, because density matrices have two indices. Population transfer alone does not reconstruct a quantum channel.

Plate VII.18 / WHY COMPLETE POSITIVITY IS THE RELEVANT CONDITION

An ancilla tests more than positivity

Chapter VII: Classical input II.7.7.

Ordinary transpose T sends a positive matrix on one system to another positive matrix and preserves its trace. Those properties are insufficient for a quantum channel on a subsystem of an entangled state. The test must include $\mathrm{id} \otimes \mathsf{T}$ on the larger system.

$$2(\mathrm{id} \otimes \mathsf{T})(\rho_{\mathrm{Bell}})$$

00	1	0	0	0
01	0	0	1	0
10	0	1	0	0
11	0	0	0	1

$$w = (|01\rangle - |10\rangle)/\sqrt{2}$$

$$w^*(\mathrm{id} \otimes \mathsf{T})(\rho)w = -1/2$$

Transpose is positive on one system.
It is not completely positive.

Apply this extended map to the Bell density matrix. The result is

$$(\mathrm{id} \otimes \mathsf{T})(\rho_{\mathrm{Bell}}) = \frac{1}{2}\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Its middle block has one negative eigenvalue. More concretely, the normalized vector $w = (|01\rangle - |10\rangle)/\sqrt{2}$ satisfies

$$w^*(\mathrm{id} \otimes \mathsf{T})(\rho_{\mathrm{Bell}})w = -\frac{1}{2}.$$

This exact negative value of the quadratic form certifies failure of positivity on the composite system. No numerical eigenvalue tolerance is needed.

Why the Kraus form avoids this problem

For every auxiliary dimension and positive X, each term $(I \otimes K_a)X(I \otimes K_a)^*$ is positive. Their sum is positive as well. This argument explains the word *completely*. The conclusion holds for every auxiliary dimension, which a test of one input density matrix on the original system cannot establish.

The transpose counterexample is an explanatory finite calculation, not a new addition to the formal theorem count. It makes visible the hypothesis that the manuscript's Kraus result already supplies. The exact check constructs the partial transpose with the stated tensor indexing and evaluates its negative witness directly.

> **Read this as:** A map can look harmless on an isolated system and fail on an entangled extension. Complete positivity retains compatibility with every auxiliary system.

Plate VII.19 / FOUR EXACT SYNDROME PACKETS

Find the error without reading the logical state

Chapter VII: Theorem II.8.2, Theorem II.8.4, Example II.8.8.

Encode a qubit by $|0_L\rangle = |000\rangle$ and $|1_L\rangle = |111\rangle$. Let P project onto this code and take errors $E_a \in \{I, X_1, X_2, X_3\}$. Their images are four orthogonal rank-two packets $Q_a = E_a P E_a^*$ that sum to the full identity.

Channel probabilities: $1/10,\ 2/10,\ 3/10,\ 4/10$.

no error	X_1	X_2	X_3
$\|000\rangle$	$\|100\rangle$	$\|010\rangle$	$\|001\rangle$
$\|111\rangle$	$\|011\rangle$	$\|101\rangle$	$\|110\rangle$
ratio $3:4$	ratio $3:4$	ratio $3:4$	ratio $3:4$

Use the logical state $\psi = (3\,|0_L\rangle + 4\,|1_L\rangle)/5$ and channel probabilities $w = (1, 2, 3, 4)/10$. The noisy state is $\sum_a w_a E_a \psi\psi^* E_a^*$. A syndrome measurement returns label a with probability w_a, independent of the logical amplitudes.

The recovery is an actual channel

The operators $R_a = E_a^* Q_a$ satisfy $\sum_a R_a^* R_a = I$. Applying the recovery $\mathcal{R}(X) = \sum_a R_a X R_a^*$ to the noisy state gives exactly $\psi\psi^*$. The off-diagonal logical coherence $12/25$ is recovered as well as the populations $9/25$ and $16/25$.

The Knill–Laflamme compressions are $P E_a^* E_b P = \delta_{ab} P$. Their scalar form says that the error labels do not resolve the encoded vector. The exact checks evaluate all sixteen compressions, all sixteen syndrome products, the four probabilities, the recovery normalization, and the full recovered matrix.

This code corrects the specified flips of individual bits. That result does not cover arbitrary errors on three qubits or arbitrary errors on a single qubit. The next example exhibits an error outside its protected family.

> **Read this as:** A syndrome identifies an error subspace while leaving a two-dimensional logical subspace intact. Measuring the two logical basis states separately would destroy the information the recovery must preserve.

Plate VII.20 / THE SCALAR COMPRESSION TEST MATTERS

An unchanged syndrome can hide a logical error

Chapter VII: Theorem II.8.2, Proposition II.8.7.

Apply $Z_1 = Z \otimes I \otimes I$ to the same repetition code. It sends $|000\rangle$ to itself and $|111\rangle$ to its negative. Both states remain inside the original code, so the previous syndrome partition reports no bit flip.

$$\frac{3\,|000\rangle + 4\,|111\rangle}{5} \longmapsto \frac{3\,|000\rangle - 4\,|111\rangle}{5}.$$

The populations are unchanged, but the relative phase is not.

$V^* Z_1 V$

1	0
0	-1

before: $(3, 4)/5$

after: $(3, -4)/5$

same code support
different relative phase

Required scalar form cI

c	0
0	c

A trace of zero does not make $\mathrm{diag}(1, -1)$ the zero operator.

Let V be the code isometry with columns $|000\rangle, |111\rangle$. For the proposed error family $\{I, Z_1\}$, its off-diagonal error compression is

$$V^* I^* Z_1 V = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

This matrix is not cI for any scalar c. Thus the Knill–Laflamme condition fails for that family. Its trace is zero even though its action on the code is nonzero. A trace test alone would miss the obstruction.

Known correction versus family recovery

If it is known with certainty that Z_1 occurred, applying Z_1 again reverses it. The failed criterion concerns a *single recovery valid for every unknown error in the declared family*, not invertibility of each error considered separately. This distinction prevents a misleading conclusion that no phase error can ever be undone.

The finite calculation checks the actual compressed matrix and rejects its equality to zero. The scalar obstruction is then transparent from the two unequal diagonal entries.

> **Read this as:** Correction must preserve all logical superpositions for the declared error family. Staying in the code and preserving basis probabilities are not sufficient.

Plate VII.21 / TWO INVERTIBILITY CONDITIONS, NOT ONE

Hidden states return as spectral dependence

Chapter VII: Theorem II.9.2, Theorem II.9.3.

Take $H = \begin{pmatrix} 0 & 1 \\ 1 & 2 \end{pmatrix}$ and retain its first coordinate. The eliminated block is $H_{QQ} = 2$. Whenever $z - 2$ and the full $zI - H$ are invertible,

$$H_{\text{eff}}(z) = \frac{1}{z-2}, \qquad \left[(zI - H)^{-1}\right]_{00} = \frac{1}{z - 1/(z-2)} = \frac{z-2}{z^2 - 2z - 1}.$$

These are the hypotheses used in the formal companion.

Filled: full resolvent poles. Open at 2: only the eliminated inverse fails.

At $z = 3$: exact retained resolvent $1/2$, bare truncation $1/3$.

At $z = 3$, the exact retained resolvent is $1/2$. Bare truncation uses only $H_{PP} = 0$ and gives $1/3$, an error of $1/6$. The omitted coupling has changed the response even though the retained diagonal entry did not change.

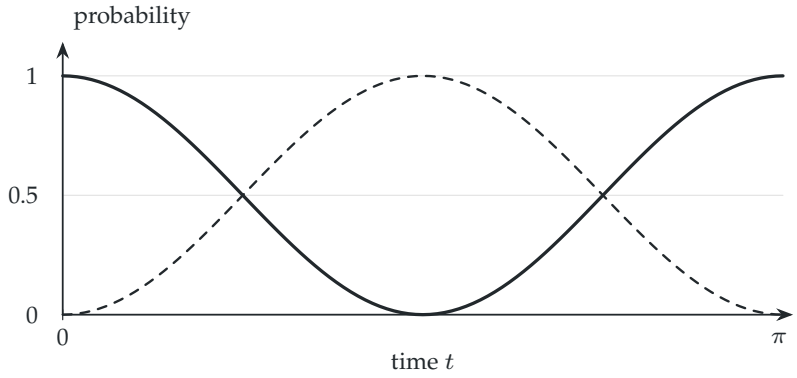
A pole can belong to the elimination chart

At $z = 2$, the eliminated inverse does not exist, so the displayed Schur formula cannot be applied there as written. Nevertheless, the full resolvent exists and its retained entry is zero. The rational expression has a continuation to this value. By contrast, $1 \pm \sqrt{2}$ are poles of the full resolvent.

Invertibility of the full matrix is an independent requirement. At $z = 0$, $H = \operatorname{diag}(0, -1)$ has an invertible eliminated block in $zI - H$, but the full matrix is singular. The original prose omitted this condition. The preserved amendments restore it. This appendix uses the corrected form throughout.

Read this as: An exact elimination formula has a spectral domain. Check both inverses before evaluating it, and distinguish poles of an intermediate inverse from poles of the full physical resolvent.

Plate VII.22 / AN EXACT QUANTUM MEMORY EQUATION



The smaller system remembers the discarded one

Chapter VII: Theorem II.9.8, Theorem II.9.11.

Choose $H = X$, initial state $(1,0)^T$, and retain the first coordinate. The coupled equations and their solution are

$$\mathrm{i}\dot{x} = y, \qquad \mathrm{i}\dot{y} = x, \qquad x(t) = \cos t, \quad y(t) = -\mathrm{i}\sin t.$$

The hidden probability returns periodically. Deleting the hidden row and column would instead leave the zero Hamiltonian and predict $x(t) = 1$.

solid: retained
dashed: hidden

$$K(t) = 1$$

The two probabilities sum to one.

Eliminate exactly, not approximately

Integrating the second equation with $y(0) = 0$ gives $y(t) = -\mathrm{i}\int_0^t x(s)\,ds$. Substitution produces

$$\dot{x}(t) = -\int_0^t x(s)\,ds.$$

The memory kernel is the constant function one. Differentiating once more recovers $\ddot{x} = -x$ with $x(0) = 1$ and $\dot{x}(0) = 0$, explaining the cosine solution. A nonzero hidden initial state would add a forcing term that must also be retained.

The full propagator is a unitary group, but its retained scalar entry is not a semigroup. At $t = s = \pi/4$,

$$x(t+s) - x(t)x(s) = 0 - \frac{1}{2} = -\frac{1}{2}.$$

There is no contradiction: compression of a product need not equal the product of the compressed factors when the hidden subspace carries intermediate amplitude.

The check verifies the differential and integral equations symbolically and the displayed nonzero semigroup defect exactly. The curves visualize the explicit solution and its periodic return of amplitude.

Read this as: Exact elimination replaces a hidden coordinate with memory and forcing from the initial data. Replacing that memory by a constant generator is an additional approximation, not part of the exact theorem.

Plate VII.23 / SPECTRAL POSITIVITY IS BASIS INDEPENDENT

Positive transfer is not a stochastic matrix

Chapter VII: Theorem II.10.1, Theorem II.10.3.

For $H = I - X$, the two eigenvalues are zero and two. Its Euclidean transfer is

$$T(\tau) = e^{-\tau H} = \frac{1}{2}\begin{pmatrix} 1+q & 1-q \\ 1-q & 1+q \end{pmatrix}, \qquad q = e^{-2\tau}.$$

For $\tau \geq 0$, the eigenvalues $1, q$ lie in $(0, 1]$, and multiplying two such matrices replaces q, r by qr. This is the semigroup law in spectral coordinates.

T at $e^{-2\tau} = 1/2$

$\frac{3}{4}$	$\frac{1}{4}$
$\frac{1}{4}$	$\frac{3}{4}$

Both have spectrum $\{1, 1/2\}$.

ZTZ in another basis

$\frac{3}{4}$	$-\frac{1}{4}$
$-\frac{1}{4}$	$\frac{3}{4}$

Positive-definite operator: $v^* T v > 0$ for $v \neq 0$. Not an entrywise test.

At $q = 1/2$, the displayed T happens also to have nonnegative entries and column sums one. Conjugate by the unitary Z. The spectrum and positivity of the quadratic form are preserved, but both off-diagonal entries become $-1/4$. Thus positivity as an operator is not entrywise positivity and does not by itself give a Markov interpretation.

A useful finite positive kernel

For this nonnegative H, vectors u_a and times $t_a \geq 0$ satisfy

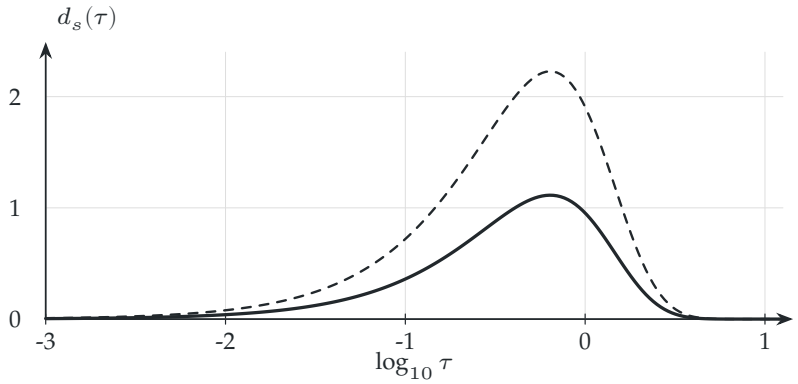
$$\sum_{a,b} \langle u_a, e^{-(t_a+t_b)H} u_b \rangle = \left\| \sum_a e^{-t_a H} u_a \right\|^2 \geq 0.$$

The factorization makes positivity transparent. It remains a finite operator identity. A continuum reconstruction theorem requires a compatible field structure, limits, positivity hypotheses, and the other assumptions of the chosen reconstruction framework. Each of these assumptions requires its own justification beyond the two positive eigenvalues.

The exact check verifies the matrix semigroup law as a polynomial identity in q, r and verifies the unchanged spectrum after conjugation. It rejects entrywise nonnegativity for the conjugated matrix.

> **Read this as:** Euclidean positivity refers to quadratic forms and spectral values. A stochastic interpretation or a continuum physical reconstruction needs additional structure.

Plate VII.24 / THE EXACT HEAT TRACE ON FOUR SITES



A dimension curve is a scale diagnostic

Chapter VII: Definition II.11.1, Proposition II.11.2.

For the Laplacian on a cycle with four sites $L = 2I - S - S^*$, the eigenvalues are $0, 2, 2, 4$. The normalized heat trace and its diagnostic of spectral dimension are therefore

$$K(\tau) = \frac{1 + 2e^{-2\tau} + e^{-4\tau}}{4} = \frac{(1 + e^{-2\tau})^2}{4}, \qquad d_s(\tau) = -2\tau \frac{K'(\tau)}{K(\tau)} = \frac{8\tau}{e^{2\tau} + 1}.$$

No numerical differentiation is needed for this finite example.

solid: four-cycle
dashed: product of two

No broad plateau is promised at four sites.

Finite diagnostic, not a dimension proof.

Both ends reflect the finite size of the system

As $\tau \to 0$, every eigenmode contributes approximately one and the dimension diagnostic tends to zero. As $\tau \to \infty$, the zero mode dominates, so it again tends to zero. A finite spectrum cannot sustain a nonzero plateau at all scales.

For the Cartesian product of two identical cycles with four sites, the Laplacian eigenvalues add and the heat traces multiply: $K_2 = K^2$. Consequently $d_{s,2} = 2d_s$ exactly. The product identity determines the second curve exactly from the first.

At $\tau = \log 2/2$, the first curve equals $4 \log 2/3$. This noninteger value is a spectral quantity that depends on scale, not a claim that the graph has a fractional topological dimension. Four sites are too few to promise a broad geometric plateau. Experiments on larger grids remain finite diagnostics. Convergence requires the analytic hypotheses developed on Plate VII.37.

> **Read this as:** A convincing continuum dimension needs a stable scale window that persists under controlled refinement. One appealing finite curve is not that theorem.

Plate VII.25 / AN EXACT ERROR ENCLOSURE, NOT A FITTED SLOPE

Refine the grid while holding the mode fixed

Chapter VII: Theorem II.11.4.

For the circle symbol, the continuum value is k^2 and the grid value is

$$\lambda_{k,h} = \frac{4}{h^2}\sin^2\left(\frac{kh}{2}\right), \qquad h \neq 0.$$

For a fixed low mode, the paper bounds the error by $0 \leq k^2 - \lambda_{k,h} \leq k^4 h^2/12$. The spacing condition matters because the displayed expression divides by h^2.

$h = \frac{1}{4}$	$h = \frac{1}{8}$	$h = \frac{1}{16}$
error (approx.)	error (approx.)	error (approx.)
$\simeq 0.005197495$	$\simeq 0.001301405$	$\simeq 0.000325478$
bound $h^2/12$	bound $h^2/12$	bound $h^2/12$
$\frac{1}{192}$	$\frac{1}{768}$	$\frac{1}{3072}$

Successive error ratios lie strictly between 3.99 and 4.

What is certified in the displayed table?

Take $k = 1$ and $h = 1/4, 1/8, 1/16$. For $x = h/2 \in [0, 1]$, alternating Taylor sums give rational lower and upper bounds for $\sin x$. Squaring these positive endpoints and multiplying by $4/h^2$ yields exact rational enclosures for each error. The displayed decimals only locate those much narrower rational intervals.

Each interval lies strictly inside $(0, h^2/12)$. Dividing successive interval endpoints proves that both error ratios are between 3.99 and 4. The check verifies these inequalities by rational arithmetic, without relying on approximate sine values or a fitted logarithmic slope.

Why the mode regime matters

If instead $k = \pi/h$ moves with the grid, the ratio $\lambda_{k,h}/k^2 = 4/\pi^2$ stays constant, not one. The bound's factor k^4 warns that it is not uniform in arbitrary moving high modes. The displayed rational test evaluates the analytic symbol. It does not assert that every chosen spacing defines an integer periodic grid.

Read this as: Second-order convergence is a quantified statement with a specified mode regime. Keep that regime fixed when reading an error curve or comparing refinements.

Plate VII.26 / TEST THE CONSTRAINTS BEFORE THE PROJECTION

A zero compressed anomaly can be automatic

Chapter VII: Theorem II.12.2, Proposition II.12.3.

Take the self-adjoint matrices

$$C_1 = \operatorname{diag}(0, 1, -1), \qquad C_2 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \qquad P = \operatorname{diag}(1, 0, 0).$$

Both constraints annihilate $P\mathbb{C}^3$, and their common kernel is exactly that one-dimensional space. Nevertheless, their full commutator is nonzero.

$[C_1, C_2]$

0	0	0
0	0	2
0	−2	0

$P = \operatorname{diag}(1, 0, 0)$

$C_1 P = C_2 P = 0$

$P[C_1, C_2]P$

0	0	0
0	0	0
0	0	0

The right matrix is zero by the common-kernel choice, not by operator closure.

Why the compressed test cannot decide closure

Since $C_1 P = C_2 P = 0$, each product $C_1 C_2 P$ and $C_2 C_1 P$ vanishes. Therefore $P[C_1, C_2]P = 0$ without any requirement that the unprojected commutator close in the chosen constraint span. In this example the skew off-diagonal commutator is not a linear combination of the two displayed symmetric constraints.

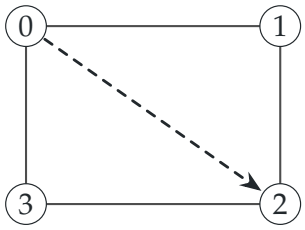
More generally, an anomaly expression made from their commutators and linear combinations of constraints also kills an exact projector onto the common kernel on the right. The formal companion makes this limit of the diagnostic explicit. A nonzero compressed residual can reveal inconsistent proposed data, but an automatic zero does not construct an anomaly-free constraint algebra.

A substantive closure analysis must inspect the operator relations, their domains, the actual physical subspace, and compatibility under refinement. For infinite systems, these questions also involve domain and limit control that finite matrix arithmetic cannot replace.

The exact example computes both constraint products, the full commutator, and its compression. It deliberately rejects the inference from compressed zero to unprojected zero.

> **Read this as:** Before interpreting a vanishing residual, check whether the definition of its projector already forces it to vanish. A tautological diagnostic cannot supply the missing existence or closure theorem.

Plate VII.27 / SEEDS, CHARACTERS, INTERFERENCE, AND DEPHASING



One calculation of transfer to the opposite site

Chapter VII: Corollary II.3.3, Theorem II.4.4, Theorem II.7.4.

Return to the shift on four sites S and Laplacian $L = 2I - S - S^*$. The same character projectors have energies $(0, 2, 4, 2)$. At time $t = \pi/2$, their evolution phases are $(1, -1, 1, -1)$, exactly the character eigenvalues of S^2. Hence

$$e^{-\mathrm{i}\pi L/2} = S^2, \qquad |0\rangle \longmapsto |2\rangle\,.$$

$e^{-\mathrm{i}\pi L/2} = S^2$

start	time $\pi/2$
1	0
0	0
0	1
0	0

Target probability after partial momentum dephasing: $1 - 3\eta/4$.

At halfway time $\pi/4$, the actual amplitude vector is $(-\mathrm{i}, 1, \mathrm{i}, 1)^T/2$, giving uniform site probabilities. The subsequent phases recombine those four amplitudes into a single output at the opposite site. Uniform intermediate probabilities do not imply an incoherent intermediate state.

A channel changes the conclusion predictably

Before evolving, mix the seed density matrix with its complete momentum dephasing:

$$\rho_\eta = (1-\eta)\,|0\rangle\langle 0| + \eta \sum_j P_j\,|0\rangle\langle 0|\,P_j = (1-\eta)\,|0\rangle\langle 0| + \eta I/4, \quad 0 \le \eta \le 1.$$

At transfer time, the probability at the opposite site is exactly $1 - 3\eta/4$. Complete momentum dephasing reduces it to $1/4$. This calculation isolates how discarded coherence changes the interference result.

Finally, the shift grammar generates four independent vectors from $|0\rangle$, while the Hamiltonian powers generate only three: its repeated energy links two momentum directions. The same seed can therefore be cyclic for the shift algebra and noncyclic for the Hamiltonian algebra, even though perfect transfer occurs at one time.

> **Read this as:** Perfect transfer is an exact finite interference statement. It neither implies cyclicity for every operator grammar nor survives an unaccounted dephasing operation.

Plate VII.28 / AN EVIDENCE GUIDE FOR THE READER

What these pictures establish

Chapter VII: Section II.14. Formal scope: the nineteen-result correspondence in the Lean companion.

The appendix uses small objects to make the paper's constructions inspectable. Every matrix and finite example is supplied in editable source, with a separate check record. The plates make those calculations visible. Their appearance helps explain the result, while the equations and check records supply its evidence.

Evidence	What it supports	What it does not supply
Exact matrices	The displayed finite identities, witnesses, and counterexamples.	A classification of arbitrary systems.
Symbolic derivatives	The explicit rotating and Bloch examples.	A proof inferred from numerical differentiation.
Rational enclosures	The three displayed dispersion intervals and ratio inequalities.	A continuum theorem from three sample points.
Formal companion	Its 19 registered finite items under their recorded hypotheses.	A fresh kernel run for this appendix.
Numerical record	The original finite software examples in the tested environment.	Physical experiments or unrestricted convergence.

Which source is authoritative?

The formal companion records 323 supporting theorem declarations in 25 modules for nineteen scoped finite items. The range-bundle construction and the finite examples have the distinct hypotheses stated in their respective treatments. Source and verification records identify the evidence for each claim.

The five research boundaries remain separate: an anomaly-free coherent refinement, uniform control of effective operators, Lorentzian reconstruction, an Einstein infrared limit, and a positive physical massless spin-two sector. A finite projector bundle, positive transfer matrix, or spectral diagnostic does not settle them.

A practical way to use the appendix

Choose one page, reproduce its matrix calculation, and then read the cited theorem with its hypotheses. The retained execution records give the exact assertions, tested ranges, and rejected controls for the finite and symbolic suites. The additional examples and their recorded bounds are described on Plate VII.40. In particular, retain the two resolvent assumptions on Plate VII.21, the distinction between a known error and an error family on Plate VII.20, and the limitation of testing only the common kernel on Plate VII.26.

> **Read this as:** The finite constructions have explicit scope. The appendix adds understanding and reproducibility, not unproved continuum claims or a new theorem count.

Plate VII.29 / A SIX-DIMENSIONAL REGULAR REPRESENTATION

Nonabelian packets carry multiplicity

Chapter VII: Theorem II.3.1, Theorem II.3.2.

Let $\mathcal{H} = \mathbb{C}[S_3]$ have the six orthonormal basis vectors $|g\rangle$, with left action $U(h)\,|g\rangle = |hg\rangle$. The irreducible characters on the identity, transposition, and three-cycle classes are

	e	(12)	(123)	d_λ
trivial	1	1	1	1
sign	1	-1	1	1
standard	2	0	-1	2

$$P_\lambda = \frac{d_\lambda}{6} \sum_{g \in S_3} \chi_\lambda(g^{-1}) U(g).$$

All matrices in this example are rational. Multiplying them gives self-adjoint idempotents of ranks $1, 1, 4$, with pairwise zero products and sum I_6.

$$\mathbb{C}[S_3] \cong \mathbb{C} \oplus \mathbb{C} \oplus (\mathbb{C}^2 \otimes \mathbb{C}^2)$$

The standard packet has dimension four

The standard representation occurs twice in the regular representation. Its isotypic component therefore has dimension $2 \cdot 2 = 4$: one factor carries the two-dimensional irreducible action and the other records multiplicity. A character projector selects the whole isotypic component. It does not select a particular copy or a particular internal vector.

Representation matrix units refine the irreducible factor, while leaving the multiplicity factor untouched. Their multiplication law is stronger information than a list of packet ranks. A basis chosen inside this packet supplies coordinates. It does not canonically distinguish the two copies of the standard representation.

What the retained check establishes

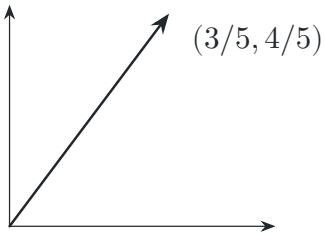
The retained exact check constructs all six permutation matrices, tests all 36 multiplication relations, computes the character averages, and checks ranks independently by Gaussian elimination and traces. It rejects the claim that the standard isotypic projector has rank two. This is one specified representation of S_3, not a computational classification of all finite group representations.

> **Read this as:** For a nonabelian symmetry, distinguish irreducible dimension from multiplicity. A central character projector retains both.

Plate VII.30 / AN EXACT LOCAL CHART AND ITS FAILURE

Rotate whole packets by a polar factor

Chapter VII: Theorem II.6.5, Theorem II.6.6.



On $\mathcal{H} = \mathbb{C}^2$, put $P_0 = \operatorname{diag}(1,0)$, $P_1 = I - P_0$, and

$$R = \begin{pmatrix} 3/5 & -4/5 \\ 4/5 & 3/5 \end{pmatrix}, \qquad Q_a = RP_aR^*, \qquad S = \sum_{a=0}^{1} Q_aP_a = \frac{3}{5}R.$$

The exact Gram matrices give

$$(S-I)^*(S-I) = \frac{16}{25}I, \quad S^*S = \frac{9}{25}I, \quad \|S-I\| = \frac{4}{5} < 1.$$

Consequently the unitary polar factor is $S(S^*S)^{-1/2} = R$, and $Q_aR = RP_a$ for both complete packets.

$$S = (3/5)R$$
$$S^*S = (9/25)I$$
$$\downarrow$$
$$S(S^*S)^{-1/2} = R$$

The norm condition selects a chart

If the target rank-one packet is orthogonal to the initial one, the two labels are exchanged and $S = 0$. Its polar inverse square root is undefined. This is a failure of this direct local construction, although a unitary carrying one packet system to the other still exists. The strict norm assumption is sufficient, not a global existence criterion for all packet rotations.

Short steps can be composed before reaching a distant endpoint. For example, the rational step $R_1 = \begin{pmatrix} 4/5 & -3/5 \\ 3/5 & 4/5 \end{pmatrix}$ obeys

$$R_1^2 = \begin{pmatrix} 7/25 & -24/25 \\ 24/25 & 7/25 \end{pmatrix}.$$

The multiplication is exact and each step has a valid local overlap. The convergence theorem has a separate analytic contract: a twice continuously differentiable complete projector path on a compact time interval, sufficiently fine partitions, and a constant depending on the path in an $O(|\pi|)$ estimate in operator norm.

Evidence boundary

The retained run checks the Gram identities, polar factor, intertwining, and product of two rational steps. It also checks that the overlap has rank zero when the endpoint packets are orthogonal. It does not certify the analytic convergence theorem by sampling a path.

> **Read this as:** A local polar chart can fail while the subspaces remain regular. Use the stated chart hypothesis and the separate convergence theorem when composing small rotations.

Plate VII.31 / CHANNEL, CHOI, AND GENERATOR CHECKS

Coherence order survives a covariant channel

Chapter VII: Theorem II.7.8, Theorem II.7.10, Theorem II.7.14.

Take $S = Z = \mathrm{diag}(1, -1)$ on $\mathbb{C}^2$. Under conjugation $X \mapsto ZXZ$, diagonal matrices have coherence order zero and off-diagonal matrices have coherence order one modulo two. Its projectors on Hilbert–Schmidt operator space are $\mathcal{L}_0(X) = (X + ZXZ)/2$ and $\mathcal{L}_1(X) = (X - ZXZ)/2$.

Choose amplitude damping with $K_0 = \mathrm{diag}(1, 4/5)$ and $K_1 = (3/5)\,|0\rangle\langle 1|$. The channel is trace preserving, population flows from state one to state zero, and each coherence contracts by $4/5$.

even Choi addresses $00, 11$	odd Choi addresses $01, 10$
$\begin{pmatrix} 1 & 4/5 \\ 4/5 & 16/25 \end{pmatrix}$	$\mathrm{diag}(9/25, 0)$

$$\Phi(|0\rangle\langle 1|) = (4/5)\,|0\rangle\langle 1|$$

With the unnormalized Choi convention $J = \sum_{a,b} \Phi(|a\rangle\langle b|) \otimes |a\rangle\langle b|$ and basis $(00, 01, 10, 11)$, the exact matrix is

$$J = \begin{pmatrix} 1 & 0 & 0 & 4/5 \\ 0 & 9/25 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 4/5 & 0 & 0 & 16/25 \end{pmatrix}, \qquad [J, Z \otimes Z] = 0.$$

The $00, 11$ block is positive and has rank one. The other nonzero eigenvalue is $9/25$. The retained check also verifies that every principal minor is nonnegative.

Symmetry in continuous time has its own hypotheses

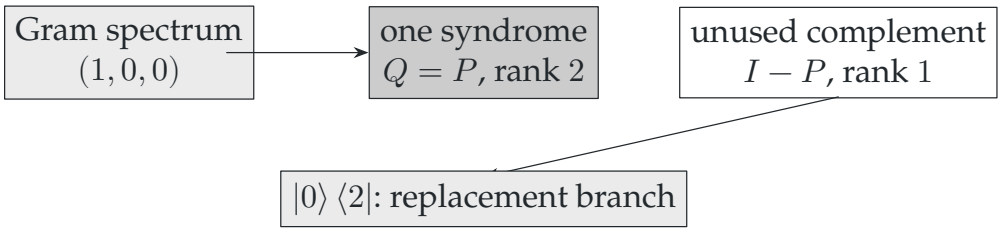
For the Lindblad generator with Hamiltonian $H = \mathrm{diag}(0, 2)$ and jump $L = (3/5)\,|0\rangle\langle 1|$, H has charge zero and L has charge one. Each matrix unit stays within its coherence order under the generator. Replacing H by X breaks that conclusion: the generator then sends a diagonal matrix to off-diagonal entries.

All four input matrix units are checked exactly for channel covariance, generator order preservation, and zero generator trace. The paper uses the finite exponential series to extend generator invariance to the semigroup. The retained calculation uses no numerical solver for the master equation. Symmetry alone does not close the scalar population equations inside packets of higher rank.

> **Read this as:** Charge is a property of operator space. Covariance preserves its coherent sectors, while complete positivity is checked separately through Kraus or Choi data.

Plate VII.32 / A TOTAL CHANNEL FROM SINGULAR ERROR DATA

Null Gram directions are removed before recovery



Chapter VII: Theorem II.8.3, Theorem II.8.4.

Let $\mathcal{H} = \mathbb{C}^3$, with nonzero code projector $P = \mathrm{diag}(1, 1, 0)$. On the code use the error family $E_1 = (3/5)P$, $E_2 = (4/5)P$, and $E_3 = 0$. Its Knill–Laflamme Gram matrix is

$$c = \frac{1}{25}\begin{pmatrix} 9 & 12 & 0 \\ 12 & 16 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad PE_a^* E_b P = c_{ab} P.$$

The errors are redundant rather than three distinct syndromes. A real unitary change of error coordinates gives

$$W = \begin{pmatrix} 3/5 & 4/5 & 0 \\ -4/5 & 3/5 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad WcW^* = \mathrm{diag}(1, 0, 0), \quad (F_1, F_2, F_3) = (P, 0, 0).$$

Normalize only positive eigenvalues

The positive branch has $V_1 = P$ as an isometry *on the code*, and syndrome support $Q = P$. No factor $\lambda^{-1/2}$ is formed on either zero branch: those branches vanish on the code. Treating them as extra recoverable packets would divide by zero.

The syndrome support is smaller than the ambient space. Define a total recovery with Kraus operators

$$R_1 = P, \qquad R_2 = |0\rangle\langle 2|, \qquad R_1^* R_1 + R_2^* R_2 = I_3.$$

It acts as the identity on operators supported on the code and sends the unused complement population into a chosen code state. The declared error map preserves the trace of code states, so recovery returns every code matrix unit, including both off-diagonal units, exactly. It need not preserve states on the unused complement.

Exceptional cases and scope

This construction assumes a nonzero code so that a complement replacement state exists. The case of a zero code is vacuous and has its own formal statement in the saved ledger. The retained exact run verifies all nine Gram compressions, the diagonalization, both null branches, total channel normalization, and all four code matrix units. It adds no Lean coverage and does not implement a numerical spectral decoder for arbitrary Gram data.

> **Read this as:** Positive Gram support defines genuine syndrome isometries. Null branches vanish. Specifying the action on the complement makes the recovery a total channel.

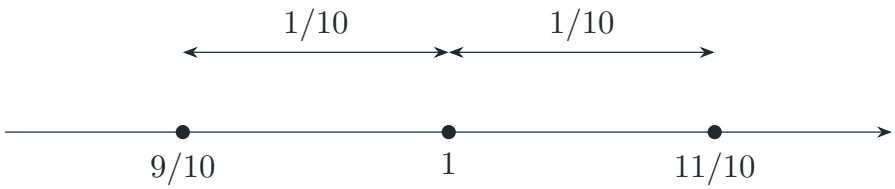
Plate VII.33 / THE OPTIMAL SCALAR FOR TWO SPECTRAL POINTS

An approximate defect has a precise norm meaning

Chapter VII: Definition II.8.6, Proposition II.8.7.

On a two-dimensional code, consider the overlap compression

$$A = PE_a^* E_b P = \operatorname{diag}(11/10, 9/10).$$



For instance, within the code take $E_a = I$ and $E_b = A$. This declares an error family, not by itself a normalized noise channel. The optimal scalar compression has

$$\inf_{c\in\mathbb{C}} \|A - cI\| = \frac{1}{10}, \qquad c = 1 \text{ attains it.}$$

Indeed, for every complex c, the triangle inequality gives

$$\frac{1}{5} = \left|\frac{11}{10} - \frac{9}{10}\right| \le \left|\frac{11}{10} - c\right| + \left|\frac{9}{10} - c\right|.$$

Thus the larger of the two distances is at least $1/10$, while both distances equal $1/10$ at $c = 1$.

one pair: $1/10$, full family $\{I, A\}$: $1/5$

What one pair contributes to the family defect

For unit code vectors ψ, ϕ, this pair therefore satisfies

$$|\langle E_a\psi, E_b\phi\rangle - \langle\psi, \phi\rangle| \le \frac{1}{10}.$$

The bound is attained on either coordinate vector. For the *whole* declared family $\{I, A\}$, the A^*A compression also enters the maximum: its diagonal entries are $121/100, 81/100$, giving pair defect $1/5$. Hence the full family value is $\varepsilon_{\mathrm{KL}} = 1/5$, not $1/10$.

This distinction prevents a tempting shortcut from one favorable overlap to an approximate correction claim. The quantity measures how close all overlap operators are to scalar action on the code. A recovery fidelity bound requires a declared normalized channel, a metric, and a separate continuity result.

What is checked exactly

For $\varepsilon \in \{0, 1/10, 1/4, 1\}$ the script checks $(A - I)^*(A - I) = \varepsilon^2 I$ for $A = \operatorname{diag}(1 + \varepsilon, 1 - \varepsilon)$ and several rational scalar controls. The triangle argument proves the lower bound for every complex scalar. Checking a finite list of candidates would not establish that conclusion. The family maximum above is also recorded separately.

> **Read this as:** An overlap norm has a useful operational interpretation. Evaluate every error pair, then keep that statement separate from an unproved recovery fidelity estimate.

Plate VII.34 / SIGN, STABILITY, AND A CONVERGENT EXPANSION

Control the hidden spectral response

Chapter VII: Theorem II.9.4, Proposition II.9.5, Theorem II.9.12.

Retain one coordinate in $H = \begin{pmatrix} 0 & 1 \\ 1 & 2 \end{pmatrix}$, so $A = 0$, $B = 1$, and $D = 2$. In its elimination domain, $\Sigma(z) = 1/(z-2)$. At $z = 3 + \mathrm{i}$,

$$\Sigma(3+\mathrm{i}) = \frac{1-\mathrm{i}}{2}, \qquad \Im\Sigma(z) = -(\Im z)\left|(z-2)^{-1}\right|^2 \le 0.$$

The sign in the upper half plane comes from self-adjoint hidden data. It is not an entrywise sign condition on an arbitrary effective matrix.

$$\boxed{\begin{matrix} B = 1,\ D = 2 \\ \Sigma(3) = 1 \end{matrix}} \longleftrightarrow \boxed{\begin{matrix} \widetilde{B} = 9/8,\ \widetilde{D} = 17/8 \\ \widetilde{\Sigma}(3) = 81/56 \end{matrix}}$$

$$25/56 \le 21/32$$

common hypotheses: $g = 9/8$, $\delta = 3/4$

A stability estimate with a common spectral gap

Compare $(B, D) = (1, 2)$ with $(\widetilde{B}, \widetilde{D}) = (9/8, 17/8)$ at $z = 3$. Both hidden spectral distances are at least $\delta = 3/4$, and both couplings are bounded by $g = 9/8$. Then

$$|\Sigma - \widetilde{\Sigma}| = \left|1 - \frac{81}{56}\right| = \frac{25}{56}, \qquad \frac{2g}{\delta}|B - \widetilde{B}| + \frac{g^2}{\delta^2}|D - \widetilde{D}| = \frac{21}{32}.$$

The theorem bounds the difference using a common spectral gap. Applying the bound uniformly to a refinement family requires uniform spectral separation and control of the couplings.

A series near zero energy and its exact remainder

At $z = 1/2$, $|z|\,|D^{-1}| = 1/4 < 1$, so

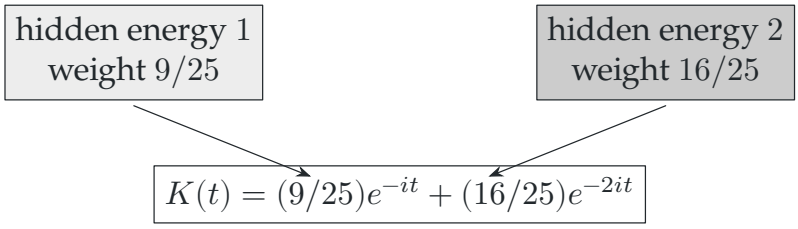
$$\Sigma(z) = -\sum_{n=0}^{\infty} \frac{z^n}{2^{n+1}}.$$

After the first four terms, the exact remainder has magnitude $1/384$. The geometric series controls the infinite tail. The retained check verifies that remainder, the complex sign identity, and the identities for the projected resolvent and bare truncation at four specified real spectral parameters.

At $z = 2$ the hidden inverse fails. At an eigenvalue of the full Hamiltonian, the retained Feshbach inverse fails. Neither point belongs to the resolvent identity's domain. Analytic continuation of a scalar expression does not erase its theorem hypotheses.

> **Read this as:** A uniform effective response requires a uniform gap and coupling bound. Exact small examples show how those hypotheses enter each estimate.

Plate VII.35 / TWO HIDDEN FREQUENCIES AND A TEST OF LOCAL CLOSURE



Memory positivity is a Gram identity

Chapter VII: Theorem II.9.9, Theorem II.9.11.

Use retained space $\mathbb{C}$ and hidden space $\mathbb{C}^2$, with $A = 0$, $B = (3/5, 4/5)$, and $D = \operatorname{diag}(1, 2)$. The full Hamiltonian is $\begin{pmatrix} 0 & 3/5 & 4/5 \\ 3/5 & 1 & 0 \\ 4/5 & 0 & 2 \end{pmatrix}$. Its memory kernel is

$$K(t) = \frac{9}{25} e^{-\mathrm{i}t} + \frac{16}{25} e^{-2\mathrm{i}t}, \qquad K(0) = 1.$$

Each oscillatory coefficient is positive although $K(t)$ need not be real or pointwise nonnegative. At $t = \pi/2$, it equals $-16/25 - 9\mathrm{i}/25$.

Positive definite means a matrix test at arbitrary times

For retained scalars v_j and real times t_j, the structural identity is

$$\sum_{j,k} \overline{v}_j K(t_j - t_k) v_k = \left\| \sum_k e^{\mathrm{i}t_k D} B^* v_k \right\|^2 \geq 0.$$

The exact worked check specializes to $t = (0, \pi/2, \pi)$ and $v = (1, 2, -1)$. Its phases lie in $\mathbb{Q}(\mathrm{i})$, so both sides are computed without evaluating trigonometric functions. This Gram test illustrates the factorization. The written identity proves positivity for all choices of times and vectors.

Why this does not close to a bare local equation

With hidden initial state zero, the full system has $\ddot{x}(0) = -(A^2 + BB^*)x(0) = -x(0)$. The bare retained equation $\mathrm{i}\dot{x} = Ax$ would instead give zero acceleration. Therefore exact local closure for every retained initial state fails. More generally, equality of these accelerations forces $BB^* = 0$ and hence $B = 0$.

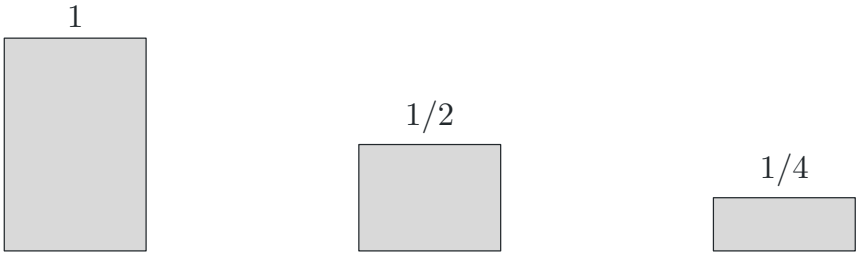
A nonzero initial hidden vector also supplies the forcing term $Be^{-\mathrm{i}tD}y(0)$. It is additional data, not part of the convolution kernel. The retained checks cover the displayed kernel values, exact Gram factorization, and acceleration defect. The integral equation follows from the written elimination argument.

> **Read this as:** Memory is positive definite through a Gram factorization, not through pointwise signs. Exact bare local closure requires the coupling to vanish.

Plate VII.36 / STRICT POSITIVITY AND THE GROUND GAP

A positive transfer determines its Hamiltonian

Chapter VII: Theorem II.10.2, Proposition II.10.5.



On $\mathcal{H} = \mathbb{C}^3$, take the strictly positive contraction

$$T = \operatorname{diag}(1, 1/2, 1/4), \qquad H = -\log T = \operatorname{diag}(0, \log 2, 2\log 2).$$

At unit Euclidean time, $T = e^{-H}$. The self-adjoint logarithm is unique because the logarithm acts on positive spectral values. At integer time $n \geq 0$,

$$T^n = \operatorname{diag}(1, 2^{-n}, 4^{-n}), \qquad P_0 = \operatorname{diag}(1, 0, 0), \qquad \|T^n - P_0\| = 2^{-n}.$$

The gap $\Delta = \log 2$ determines the rate $e^{-n\Delta}$ exactly in this example.

Strict positivity is an essential finite hypothesis

For $T' = \operatorname{diag}(1, 0)$, the operator is positive semidefinite, but there is no finite self-adjoint H' on all of $\mathbb{C}^2$ with $T' = e^{-H'}$: every finite eigenvalue of H' exponentiates to a strictly positive value. One may restrict to the positive support, but that changes the space on which the logarithm is defined.

For a family with nontrivial excited spectra, a uniform exponential rate needs a common positive lower bound on the gap. Ground multiplicity does not cause a problem: P_0 selects the entire eigenspace at the minimum energy. For a Hamiltonian whose minimum is $E_0 \neq 0$, the normalized transfer is $e^{-t(H - E_0 I)}$ before taking the limit.

Positivity is retained at several Euclidean times

For arbitrary vectors u_j and nonnegative integer times n_j, the reflected kernel obeys

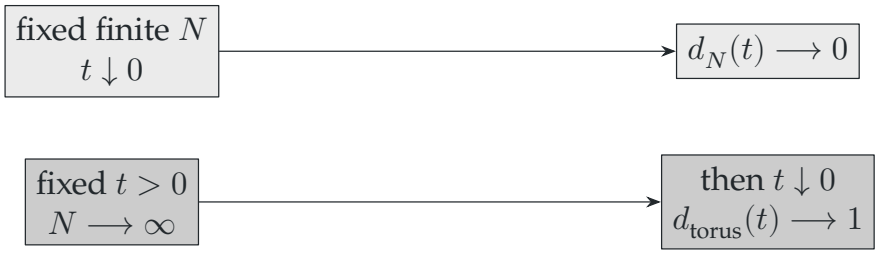
$$\sum_{j,k} \langle u_j, T^{n_j + n_k} u_k \rangle = \left\| \sum_j T^{n_j} u_j \right\|^2 .$$

This is a finite Gram factorization. The retained run checks the integer semigroup and diagonal ground error for $n = 0, \ldots, 12$, and rejects a logarithm on the full space for the singular control. The written spectral argument justifies the logarithms and extends the functional calculus statement to all times.

> **Read this as:** A positive definite transfer can be logarithmically reconstructed. Ground convergence needs a declared normalization and gap, while continuum reconstruction still needs its own structure.

Plate VII.37 / FINITE HEAT DATA AND THE QUANTIFIERS

The dimension window has an order of limits



Chapter VII: Theorem II.11.5, Corollary II.11.8.

For the unit circle grid with N sites, the scaled eigenvalues are $\lambda_N(k) = 4N^2 \sin^2(\pi k/N)$. Put $Z_N(t) = \sum_k e^{-t\lambda_N(k)}$ and $d_N(t) = 2t \sum_k \lambda_N(k) e^{-t\lambda_N(k)}/Z_N(t)$.

At the single time $t = \log 2/16$, two small grids admit exact rational heat weights:

N	spectrum	Z_N	$\sum \lambda e^{-t\lambda}$	$d_N/\log 2$
2	$(0, 16)$	$3/2$	8	$2/3$
4	$(0, 32, 32, 64)$	$25/16$	20	$8/5$

These are unnormalized traces. Normalizing by N changes Z_N but leaves the logarithmic derivative at that fixed grid unchanged.

The theorem uses two separate choices

For each $\varepsilon > 0$, first choose a fixed positive time t_ε so that the continuum torus dimension differs from one by less than $\varepsilon/2$. Then choose N_ε so that every $N \geq N_\varepsilon$ differs from that continuum value by less than $\varepsilon/2$ at the *same time*. This proves one controlled intermediate time for all sufficiently fine grids.

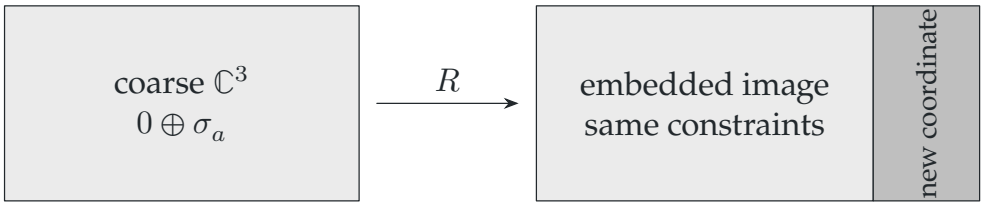
It does not assert a uniform interval width from that argument, a moving time t_N with no extra estimates, or a dimension plateau at every scale. At fixed finite N, $d_N(t) \to 0$ as $t \downarrow 0$ and as $t \to \infty$. By contrast, first taking $N \to \infty$ at positive t and then taking $t \downarrow 0$ yields the continuum dimension.

Where the infinite tail is controlled

At a fixed time, the proof bounds centered modes below by $16k^2$ and above by $4\pi^2 k^2$. The summable Gaussian dominators control both the heat trace and its first moment. A finite grid table supplies neither those tails nor the quantifiers. The retained check verifies the two displayed spectra, rational weights, traces, and dimension coefficients. It also distinguishes the unscaled cycle with four sites from the scaled unit circle grid.

> **Read this as:** The strengthened window result proves convergence after fixing a suitable time. The exact table is a worked calculation, not its proof.

Plate VII.38 / THE IMAGE OF AN ISOMETRY IS NOT THE WHOLE LEVEL



Transport constraints without hiding closure

Chapter VII: Theorem II.12.2, Theorem II.12.5, Proposition II.12.6.

On $\mathbb{C}^3 = \mathbb{C}\,|0\rangle \oplus \mathbb{C}^2$, use $C_a = 0 \oplus \sigma_a$ for $a = x, y, z$. The common kernel is $\mathbb{C}\,|0\rangle$, and the full algebra closes:

$$[C_x, C_y] = 2\mathrm{i}C_z, \qquad [C_y, C_z] = 2\mathrm{i}C_x, \qquad [C_z, C_x] = 2\mathrm{i}C_y.$$

These are uncompressed identities. They supply an actual closure test in the quotient by the constraint span, unlike the automatic compressed zero on the physical kernel.

closure on im R transfers, and the new complement needs its own test

Exact transport holds on the coarse image

Embed by the coordinate isometry $R : \mathbb{C}^3 \to \mathbb{C}^4$ and set $\widetilde{C}_a = C_a \oplus 1$. Then $\widetilde{C}_a R = R C_a$, so

$$[\widetilde{C}_a, \widetilde{C}_b]R = R[C_a, C_b].$$

The coarse physical vector maps into the fine common kernel. However, the same prescribed Pauli structure does *not* close on the whole fine level: on the added coordinate the commutator is zero, whereas $2\mathrm{i}\widetilde{C}_z$ is $2\mathrm{i}$. Exact transport constrains the image of R and leaves its orthogonal complement as separate data.

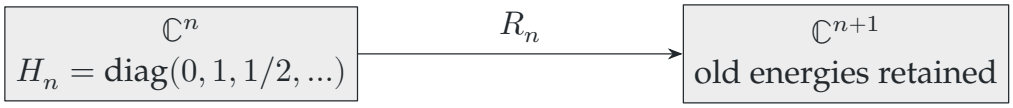
An approximate residual is also explicit

Perturb only $\widetilde{C}_x$ by $(1/10)\,|0\rangle\langle 0|$. For the unit coarse physical vector, the fine constraint residual is exactly $1/10$. The intertwining defect has the same norm. The general result for approximate transport controls these residuals and commutator errors using the defect sizes and a common bound on the constraint norms. A nonzero anomaly remains an error that must be controlled.

The retained checks verify all three coarse commutators, the isometry, each constraint intertwining, all nine commutator transports, and the residual. The added coordinate provides a counterexample to extending the identity on the image to the whole space. Unbounded constraints would additionally require a common invariant domain.

> **Read this as:** Closure is a statement about the operator algebra. Refinement intertwining transports it to the embedded image. The new degrees of freedom require their own control.

Plate VII.39 / EXACT EMBEDDINGS AND A SUMMABLE TAIL



Two routes to a bounded Hamiltonian limit

Chapter VII: Theorem II.13.2, Theorem II.13.4, Corollary II.13.5.

For the exact route, let $\mathcal{H}_n = \mathbb{C}^n$ with coordinate inclusions and

$$H_n = \operatorname{diag}(0, 1, 1/2, \dots, 1/(n-1)), \qquad H_1 = (0).$$

The old energies are retained at every level, $H_{n+1}R_n = R_nH_n$, and $\|H_n\| \le 1$. On the Hilbert space of the direct limit $\ell^2(\mathbb{N}_0)$, the diagonal sequence defines a bounded self-adjoint H_∞. Projectors onto even addresses also intertwine and give a fixed complete system of two packets in the limit.

fixed $\mathbb{C}^2$: $H_n = \operatorname{diag}(0, 1 + 2^{-n})$
tail $\|H_n - H\| = 2^{-n}$

Compatibility and boundedness are different assumptions

The equally compatible tower $\operatorname{diag}(0, 1, 2, \dots, n-1)$ has growing norms. It does not satisfy the bounded direct limit theorem. Its natural diagonal operator needs a separately specified domain. Dropping the uniform norm hypothesis does not supply that domain argument.

For the norm route, work instead on the *single fixed space* $\mathbb{C}^2$ and set

$$H_n = \operatorname{diag}(0, 1 + 2^{-n}), \qquad H = \operatorname{diag}(0, 1).$$

Here $\|H_{n+1} - H_n\| = 2^{-(n+1)}$ and $\|H_n - H\| = 2^{-n}$. The summable tail supplies an error bound for every n. For $|t| \le T$, the paper's Duhamel estimate gives

$$\left\|e^{-\mathrm{i}tH_n} - e^{-\mathrm{i}tH}\right\| \le T2^{-n}.$$

The Euclidean counterpart holds on $0 \le t \le T$ because both Hamiltonians are nonnegative. If packet projectors also converge in norm, leakage operators converge uniformly on these time intervals.

Execution scope

Exact inclusions and projector compatibility are checked through level eight. The two-dimensional tail identities are checked for $n = 0, \dots, 12$. Their infinite conclusion uses the displayed geometric series and the theorem's analytic estimate. A finite prefix cannot certify an unspecified continuation of a tower.

> **Read this as:** Exact embedded compatibility uses a uniform norm bound. Approximate convergence uses a common space and summable defects. Keep the hypotheses of these two routes explicit.

Plate VII.40 / REFLECTION GRAMS, TRACES, AND FINAL SCOPE

Choose the topology that preserves the quantity

Chapter VII: Theorem II.13.6, Theorem II.13.8, Section II.14.

Let $q_n = 1/2 + 2^{-(n+2)}$ and define the scalar reflected kernel $C_n(j,k) = 1 + q_n^{j+k}$ on nonnegative integers. Each finite Gram matrix is a sum of two positive rank-one matrices, and pointwise convergence gives $C(j,k) = 1 + (1/2)^{j+k}$. For times $(0,1,2)$ and coefficients $(1,-2,1)$,

$$\sum_{j,k} v_j C_n(j,k) v_k = (1-q_n)^4 \geq 0.$$

This exact check illustrates how finite quadratic forms pass positivity to the limit.

positive trace-class control: norm convergence alone does not preserve a trace

Operator norm does not preserve trace in growing rank

On ℓ^2, let P_n select the first n coordinates and set $A_n = P_n/n$. Then $\|A_n\| = 1/n \to 0$ while $\operatorname{Tr} A_n = 1$ for every n. These positive trace-class operators show why the choice of topology matters. Their zero limit is not the heat operator of a finite Hamiltonian.

For transfers on two states $T_n = \operatorname{diag}(1, q_n) = e^{-H_n}$, with $H_n = \operatorname{diag}(0, -\log q_n)$ at unit time, the error in trace norm is $2^{-(n+2)}$ and the heat traces converge to $3/2$. The criterion for convergence of spectral dimension additionally assumes convergence of the first heat moments in trace norm and a nonzero limiting heat trace. Convergence of the heat trace alone does not determine that quotient.

The retained evidence and the remaining open targets

The extension includes retained exact checks over specified finite ranges in $\mathbb{Q}(\mathrm{i})$ using `Fraction` from Python's standard library. The original appendix's record of 180 checks, including symbolic derivatives, is also retained. The formal companion records the provenance of these checks. All model and vector sources remain supplied.

The formal correspondence lists nineteen finite items with their stated hypotheses. Its five original targets for continuum and physical reconstruction remain open. Part II supplies analytic proofs and criteria for bounded limits. These results and examples do not establish the unresolved physical existence claims.

Read this as: Use pointwise convergence for finite positivity tests, operator norm for bounded dynamics and constraints, and trace norm for heat traces. Every conclusion keeps its own hypotheses and evidence scope.

CHAPTER VIII

Packet Operator Algorithms

Exact compilation and GPU realization

The earlier packet constructions become inputs to exact compilation and numerical implementation.

Structured packet representations remove work before execution. Exact compilation connects algebraic structure, recompression, precision and stated hardware observations.

IN THIS CHAPTER

Mathematical text 814

Visual studies 897

Formal companion 2132

Sources and references 2684

Scope

Small-core optimality uses supplied ordered thin-SVD equations and actual compact ranges. General numerical SVD verification, unrestricted discovery and CUDA-kernel verification require further results.

The book then turns to arithmetic, beginning with Euler congruences, completion and dyadic geometry.

How to use this volume

The complete finite manuscript comes first. Six supplementary proof developments follow as Appendices A–F. A worked visual atlas closes the volume. The separate visual and Lean companions provide another reading route and an explicit evidence register.

Reading this chapter

An operator representation determines what a computation means before it determines how a device executes it. Chapter VIII develops that distinction through packet blocks, low rank corrections, graph support, preconditioning, precision, and finite compilation. Three exact examples introduce the main choices. The manuscript then gives their general statements and proofs.

The main argument keeps its local section and item numbers. Appendices A–F give the additional constructions and proofs for exact semantics, compilation, structured transforms, scheduling and small-core recompression. These developments make assumptions and intermediate objects explicit when a shorter main-text argument leaves them implicit.

The formal companion covers all 56 finite manuscript-proved items under their stated hypotheses. Its 392 supporting theorem declarations span 40 modules, including 19 reused quantum-packet declarations. The 66 construction audits and four classical inputs are tracked separately. The companion supplies the declaration map and the provenance of the recorded compiler evidence.

The source already includes positive precision budgets and caps, nonempty allocation sets, positive physical denominators and transform orders, valid band widths, actual positive square roots, reflexive reachability, and the empty-graph depth-zero case. Its arithmetic counts describe declared event models. Compiler stability uses solved child scores, and local recompilation assumes correct unaffected sibling caches. These hypotheses are part of the results.

The small-core recompression result starts from supplied ordered thin-SVD equations and handles arbitrary ambient competitors by compression. It does not establish SVD existence, a floating-point QR/SVD algorithm, or a canonical singular-values API identification. The other three classical inputs concern exact-arithmetic conjugate gradients, a stated floating-point model, and simultaneous spectral decomposition. A rounded action on varying inputs requires a uniform certificate before it can be treated as one fixed linear operator.

Representation, output, model, observation

A compressed action and an explicit matrix are different outputs. An additive cost model and an observed execution time are different evidence. A finite compiler optimum and unrestricted structure discovery are different problems. Keep the representation, output contract, mathematical model, and recorded measurement together when using a result.

All hardware times and speed ratios are recorded observations from the benchmark corpus. Missing source-value hashes and explicit correctness-reference fields limit these comparisons. CPU, graph-replay and two-stream rows retain their scope qualifications. In the negative-control figure, “matched baseline” identifies the recorded comparison baseline. It does not certify the full benchmark fairness contract.

Appendices A–F complete the finite development under its stated hypotheses. Three broader targets remain open: unrestricted discovery, compilation with nonlocal overlapping models, and a packet-native communication theorem for a specified architecture. The exact examples and visual atlas illustrate finite mathematics. They add no hardware performance claim and do not replace the proofs.

Abstract

A packet operator is a linear map written between the members of a finite direct sum. We study the resulting computational representation before choosing a processor or kernel. Exact formulas are given for block sparse application, block diagonal plus low rank algebra, Woodbury inversion, support propagation, block preconditioning, and packetwise perturbation. Products of low rank corrections admit optimal recompression through a small singular value problem, with explicit error propagation through a product chain. A rooted candidate decomposition supports an exact compiler when representation cost and error are additive. Dynamic programming gives the optimal Lagrangian pruning, an exact quantized error budget algorithm, and a local update rule. Discrete precision assignment becomes a multiple choice budget problem. Arithmetic, storage, data movement, launch count, discovery, transfer, and materialization are kept as separate costs. A preserved corpus of 154 recorded CPU and GPU measurements illustrates regular packet gains, precision frontiers, crossover behavior, and retained negative controls. Its largest reported structured ratio is 14.89 against a device resident dense GPU calculation, with archived matching-metadata limitations stated explicitly. The chapter proves finite algebraic and optimization statements. Hardware measurements remain specific to their recorded environment, and no generic dense matrix exponent or universal discovery algorithm is claimed.

Three exact models before the general theory

These models use exact integers and rational numbers. Their costs and integer errors are declared illustrative quantities. The figures display the computed records. They do not report timings or identify actual hardware precision types.

A low rank action and its inverse

Set

$$D = \operatorname{diag}(2, 3, 4, 5), \qquad u = (1, 0, 1, 0)^T, \qquad v = (1, 1, 0, 0)^T,$$

and define $A = D + uv^T$. Its entries are shown in the figure. The same operator can be stored by its diagonal and two thin vectors rather than by every matrix entry. For $x = (1, 2, 3, 4)^T$, first form $v^T x = 3$. Then

$$Dx = (2, 6, 12, 20)^T, \qquad u(v^T x) = (3, 0, 3, 0)^T,$$

so $Ax = (5, 6, 15, 20)^T$. Only the first and third output coordinates receive the correction.

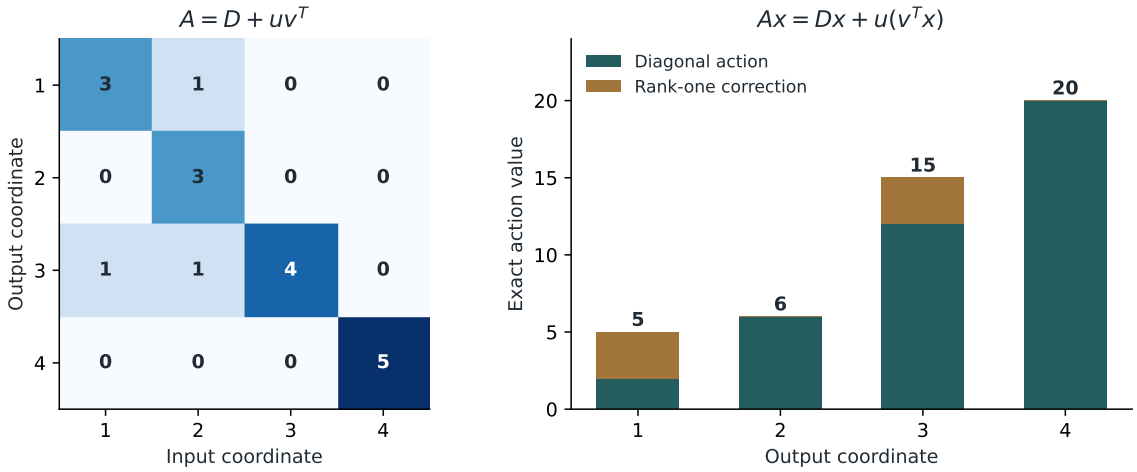


Figure 1. Exact finite action of a diagonal operator plus one thin correction. The bars display the same action as the explicit matrix.

The inverse starts with the same representation. Write $y = Ax$. Since D is invertible,

$$D^{-1}u = (1/2, 0, 1/4, 0)^T, \qquad 1 + v^T D^{-1} u = 3/2 \neq 0.$$

The scalar Woodbury core is therefore invertible. Its correction coefficient is

$$\frac{v^T D^{-1} y}{1 + v^T D^{-1} u} = \frac{9/2}{3/2} = 3.$$

Subtracting that correction recovers the original input:

$$D^{-1}y - 3D^{-1}u = (5/2, 2, 15/4, 4)^T - (3/2, 0, 3/4, 0)^T = x.$$

> **What the output contract preserves**
>
> The diagonal and thin vectors use twelve scalar slots, compared with sixteen for the explicit matrix. This small storage count assumes the full thin vectors are stored. It does not predict elapsed time. A compressed action returns Ax. Materializing all entries of A produces another output and incurs its own work. The general formulas appear in theorems 2.3 and 5.3.

A budget can select a point that no Lagrangian selects

Consider a rooted candidate tree. The root r has children a, b, and a has children a_1, a_2. Split overheads are zero. Each retained node has the following declared cost and integer error:

Node	r	a	b	a_1	a_2
Cost	1	2	1	3	1
Error	6	4	0	1	0

Exactly three prunings are possible:

Selected nodes	Total cost	Total error
r	1	6
a, b	3	4
a_1, a_2, b	5	1

For a Lagrangian multiplier $\lambda \geq 0$, their objectives are $1 + 6\lambda$, $3 + 4\lambda$, and $5 + \lambda$. The middle pruning can be optimal only if

$$3 + 4\lambda \leq 1 + 6\lambda \quad \text{and} \quad 3 + 4\lambda \leq 5 + \lambda.$$

These inequalities require $\lambda \geq 1$ and $\lambda \leq 2/3$ simultaneously. There is no such multiplier. The root and full split exchange optimality at $\lambda = 4/5$, where both have objective $29/5$.

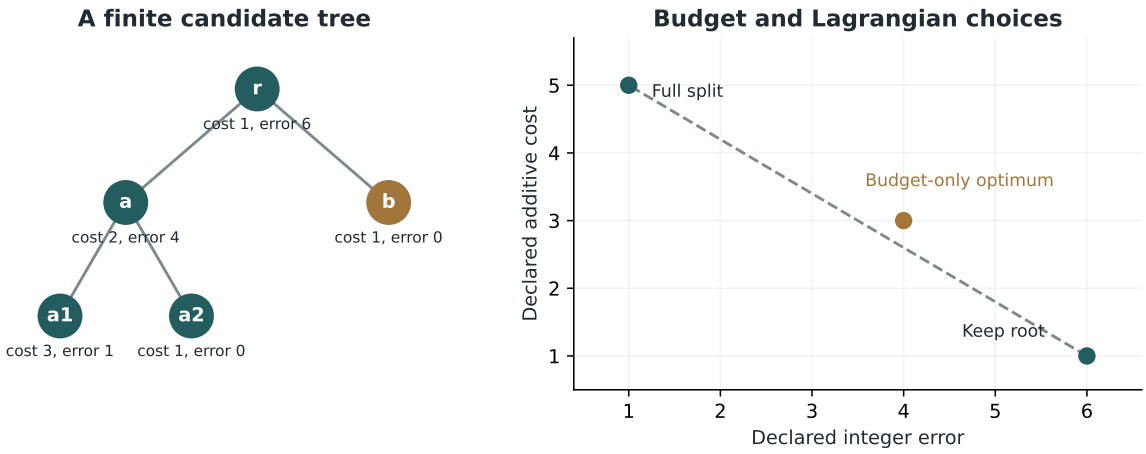

Figure 2. The finite candidate tree has three prunings. The middle point is optimal under error budget four, although no nonnegative Lagrangian multiplier selects it.

The budget problem still selects that middle pruning. Under the constraint err ≤ 4, the root is infeasible. The two feasible costs are three and five, so the minimum is three. Under budget one, only the full split is feasible. Under budget six, the root is cheapest. Thus the budget program adds something that changing λ cannot recover.

The dynamic recurrence gives the same Lagrangian choices without listing prunings. At a, it compares $2 + 4\lambda$ with $4 + \lambda$. At r, it compares $1 + 6\lambda$ with $1 + F_\lambda(a)$. Its exactness follows from the finite tree and additive model in theorems 9.4 and 9.8. Overlapping decompositions or nonlocal execution costs need another argument.

Discrete precision follows the sensitive edge

Suppose three packet edges each admit a fast option F and an accurate option A. The names describe the supplied model, rather than any actual scalar type. Exactly one option is chosen on each edge:

	F		A	
Edge	Cost	Error	Cost	Error
1	1	5	4	0
2	1	2	3	0
3	1	1	3	0

The all-fast assignment FFF has cost three and error eight. It exceeds budget three. Changing only edge one to A gives AFF, with cost $4 + 1 + 1 = 6$ and error $0 + 2 + 1 = 3$. Changing only edges two and three gives FAA, with cost seven and error five. That choice still exceeds the budget.

All eight assignments can be checked directly:

Assignment	Cost	Error	Assignment	Cost	Error
FFF	3	8	AFF	6	3
FFA	5	7	AFA	8	2
FAF	5	6	AAF	8	1
FAA	7	5	AAA	10	0

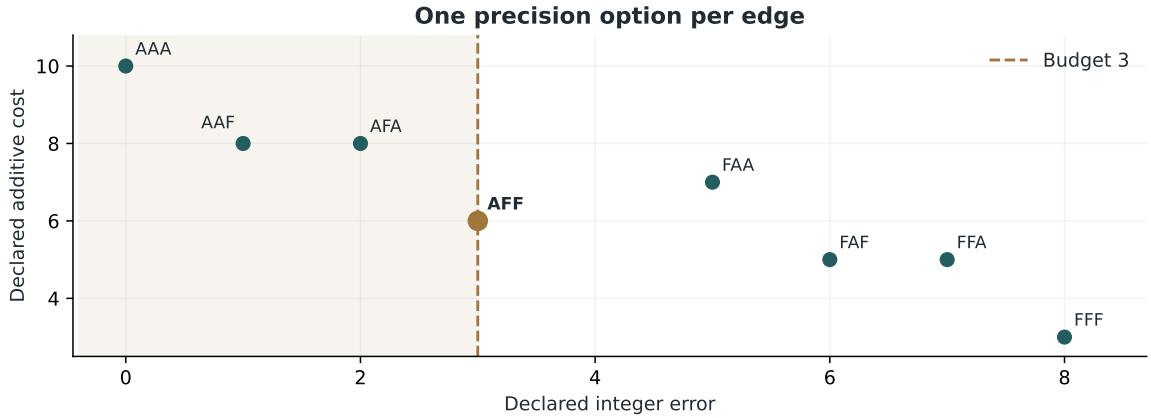

Figure 3. The shaded region satisfies the supplied error budget. AFF is the unique minimum-cost assignment in that region. The model protects the first edge before spending on less sensitive edges.

The exact recurrence reaches the same result. After edge one, only $(\mathrm{err}, \mathrm{cost}) = (5, 1)$ and $(0, 4)$ are reachable. After edge two, the reachable states are $(7, 2)$, $(5, 4)$, $(2, 5)$, and $(0, 7)$. Extending these with either option on edge three gives the final eight assignments. Among states of error at most three, the lowest cost is six.

The certificate belongs to the model

The integer error weights must be supplied by a stated certificate or quantization rule. The recurrence solves that finite model exactly. Kernel accumulation, overflow, underflow, scaling, and shape support require their own assumptions before an actual implementation can use the result. The precise recurrence is theorem 8.7.

The complete rational records, dynamic tables, and five rejected false controls are reproduced by `generate_monograph_examples.py`. Figure generation converts those records to plotting coordinates only after the exact checks pass.

The finite manuscript

The main reading path follows exact packet semantics, algebra, support, numerical certificates, and optimization before reaching the archived measurement corpus. The cost and error assumptions determine where each algorithm is exact.

1 Introduction

A matrix can look dense while its action is not. Independent diagonal blocks, sparse transfers, low rank couplings, tensor factors, and transform coordinates can remove most of the arithmetic and storage before a kernel is launched. The gain is mathematical first. A device can exploit only the structure that the representation exposes.

This article begins with a finite direct sum

$$X = \bigoplus_{\alpha \in I} X_\alpha$$

and a complete family of coordinate projectors

$$P_\alpha P_\beta = \delta_{\alpha\beta} P_\alpha, \qquad \sum_{\alpha \in I} P_\alpha = I.$$

An operator has packet blocks

$$A_{\beta\alpha} = P_\beta A P_\alpha.$$

The active addresses form a directed graph. Block dimensions, block types, approximation tolerances, and output requirements turn this graph into a computational intermediate representation.

The underlying linear algebra is classical. Direct and iterative methods are treated in [14, 25, 9]. Low rank approximation and updates are governed by singular value decomposition and the Sherman–Morrison–Woodbury identity [11, 22, 15, 4]. Floating point analysis follows the standard model in [17, 20]. Randomized discovery of low rank structure is developed in [16, 21]. Communication and attainable performance are shaped by data movement and arithmetic intensity [19, 27, 2, 12].

The first task is semantic. A compressed representation must specify the operator that it denotes. It must also specify what an algorithm returns. A product represented by block and low rank factors is not the same output as an explicit matrix. A timing comparison is valid only after the output contract and timing scope agree.

The second task is algebraic. Block diagonal plus low rank operators are closed under multiplication before recompression. Their unrecompressed rank grows additively. Woodbury inversion reduces a large inverse to packet solves and one small dense inverse. The low rank factors can then be recompressed by orthogonalizing them and taking the singular value decomposition of a small core. This produces the best truncated approximation in spectral and Frobenius norm.

The third task is combinatorial. Sparse transfer graphs predict possible support under powers, polynomials, and Schur elimination. A directed acyclic graph gives a finite path expansion. A block triangular solve can be scheduled by topological level. Graph regularity matters because equal shapes can be batched, while irregular edges require indexing and accumulation.

The fourth task is numerical. Packet perturbations can be certified by their block sensitivities. A continuous model assigns tolerances through a convex calculation. Upper bounds on available tolerances

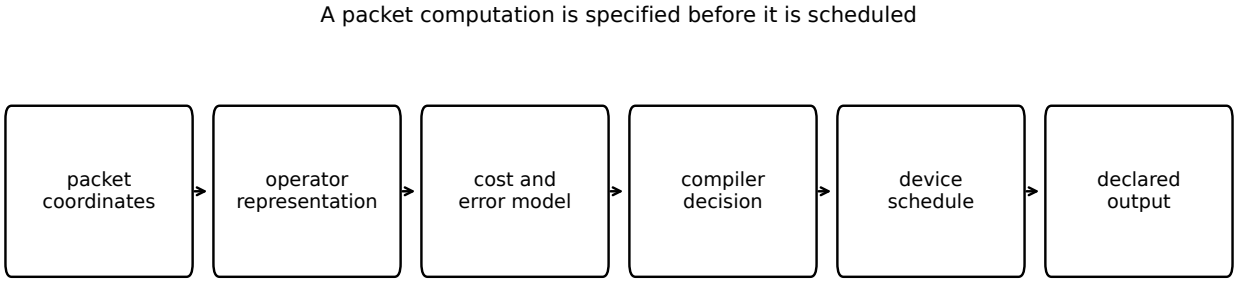

Figure 4. The representation and the output contract are fixed before the device schedule is chosen.

produce a clipped allocation. A finite set of data types gives a multiple choice budget problem that can be solved exactly after the errors are quantized.

The central computational result concerns compilation. Suppose a finite rooted tree records candidate refinements. Each node may be kept as one representation or split into its children. If cost and error are additive across the selected leaves, the optimal pruning is found exactly by dynamic programming. A quantized error budget has a second exact dynamic program. The decision is stable when the score gap exceeds the perturbation in the local models. A change inside one subtree requires recomputation only along the ancestor chain. These results prove a restricted packet compiler. They do not solve unrestricted discovery or arbitrary device scheduling.

The measured part uses a sanitized corpus collected on one recorded CPU and one NVIDIA GeForce RTX 3070 Ti Laptop GPU. The preserved corpus contains 154 recorded rows from sixteen suites. The timings are inherited observations. They are not new timing measurements. Regular equal block operators and block diagonal plus low rank operators show large gains. Recursive HODLR, Strassen multiplication, iterative refinement, a small Walsh–Hadamard transform, and an attempted two stream overlap provide negative controls. These rows are retained because structure does not guarantee speed.

The article separates four sources of gain:

$$\text{representation}, \qquad \text{device}, \qquad \text{kernel}, \qquad \text{amortization}.$$

A single speedup number can mix all four. The benchmark protocol therefore requires case identity, output contract, timing scope, source precision, correctness reference, discovery time, compilation time, and reuse count. The archived rows do not satisfy every field of this ideal contract: source-value hashes and explicit correctness-reference fields are absent, while setup, discovery, and reuse metadata are sparse. Recorded ratios are consequently descriptive comparisons under their stated scopes, rather than fair matches with complete provenance.

The mathematical statements are finite. The empirical statements apply only to the recorded environment and generated cases. The article does not claim a new generic matrix multiplication exponent. Fast matrix multiplication and its stability form a separate theory [26, 10]. It also does not claim that every structured matrix has a profitable GPU realization.

2 Packet operator representations

2.1 Exact semantics

Definition 2.1 (Packet layout)**.** A packet layout is a finite family of finite dimensional Hilbert spaces

$$\mathcal{P} = (X_\alpha)_{\alpha \in I}$$

with direct sum

$$X = \bigoplus_{\alpha \in I} X_\alpha.$$

Write

$$n_\alpha = \dim X_\alpha, \qquad n = \sum_{\alpha \in I} n_\alpha.$$

The coordinate inclusion and projection are $\iota_\alpha : X_\alpha \to X$ and $\pi_\alpha : X \to X_\alpha$. The ambient coordinate projector is $P_\alpha = \iota_\alpha \pi_\alpha$.

Definition 2.2 (Packet operator representation)**.** A finite packet operator representation consists of

$$\mathsf{IR} = (\mathcal{P}, E, (B_{\beta\alpha})_{(\beta,\alpha)\in E}),$$

where

$$E \subseteq I \times I$$

and

$$B_{\beta\alpha} : X_\alpha \longrightarrow X_\beta.$$

Local blocks are identified with their ambient extensions by inclusion and projection. In particular, the notation $P_\beta A P_\alpha$ denotes either the ambient block or its restriction $X_\alpha \to X_\beta$ according to the displayed domain, and $\iota_\beta B_{\beta\alpha} \pi_\alpha$ is the corresponding ambient extension. Its evaluation is

$$\operatorname{eval}(\mathsf{IR}) = \sum_{(\beta,\alpha)\in E} \iota_\beta B_{\beta\alpha} \pi_\alpha,$$

where $\iota_\beta : X_\beta \to X$ is the coordinate inclusion.

Theorem 2.3 (Exact evaluation)**.** *Let $A \in \operatorname{End}(X)$. Set*

$$B_{\beta\alpha} = \pi_\beta A \iota_\alpha$$

and let E contain exactly the nonzero blocks. Then

$$\boxed{A = \sum_{(\beta,\alpha)\in E} P_\beta A P_\alpha.}$$

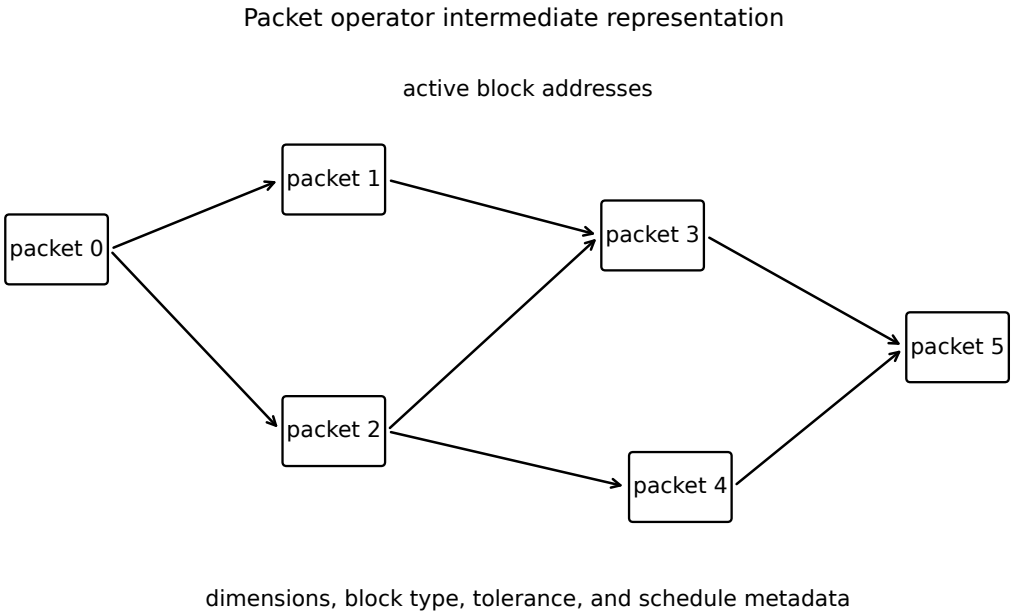

Figure 5. A packet intermediate representation stores active block addresses together with dimensions, block types, tolerances, and scheduling metadata.

For every matrix of right hand sides Z,

$$AZ = \sum_{(\beta,\alpha)\in E} \iota_\beta B_{\beta\alpha} \pi_\alpha Z.$$

Proof. Insert the identity on both sides of A:

$$A = \left(\sum_\beta P_\beta\right) A \left(\sum_\alpha P_\alpha\right) = \sum_{\alpha,\beta} P_\beta A P_\alpha.$$

The zero blocks can be removed. Applying the identity to Z gives the second formula. □

Definition 2.4 (Support graph)**.** The support graph G_A has vertex set I. It has a directed edge

$$\alpha \longrightarrow \beta$$

when $P_\beta A P_\alpha \neq 0$.

Theorem 2.5 (Block composition). *Let $A, B \in \mathrm{End}(X)$. Then*

$$\boxed{(AB)_{\gamma\alpha} = \sum_{\beta \in I} A_{\gamma\beta} B_{\beta\alpha}.}$$

Consequently,

$$\mathrm{supp}(AB) \subseteq \mathrm{supp}(A) \circ \mathrm{supp}(B),$$

where relational composition is defined by

$$(\gamma, \alpha) \in E \circ F$$

when some β satisfies

$$(\gamma, \beta) \in E, \qquad (\beta, \alpha) \in F.$$

Proof. Insert the packet identity between A and B:

$$P_\gamma A B P_\alpha = \sum_\beta P_\gamma A P_\beta B P_\alpha.$$

A summand can be nonzero only when both block addresses are active. □

Corollary 2.6 (Adjoint and tensor semantics). *The adjoint representation has blocks*

$$(A^*)_{\alpha\beta} = A^*_{\beta\alpha}.$$

If A and B are packet resolved on X and Y, then

$$(A \otimes B)_{(\beta,\delta),(\alpha,\gamma)} = A_{\beta\alpha} \otimes B_{\delta\gamma}.$$

Proof. Both identities follow by inserting the corresponding coordinate projectors and using

$$(P_\beta A P_\alpha)^* = P_\alpha A^* P_\beta.$$

The tensor identity follows from

$$(P_\beta \otimes Q_\delta)(A \otimes B)(P_\alpha \otimes Q_\gamma) = A_{\beta\alpha} \otimes B_{\delta\gamma}.$$

□

2.2 Output contracts

Definition 2.7 (Output contract). An output contract specifies the mathematical object returned by an algorithm. The contract may require an explicit vector, an explicit matrix, block factors, low rank factors, spectral factors, or an implicit operator with a declared application rule.

Definition 2.8 (Timing scope)**.** A timing scope states which costs are included. Possible costs include structure discovery, compilation, host transfer, device transfer, kernel execution, graph capture, graph replay, factor reconstruction, and explicit materialization.

Proposition 2.9 (Contract conversion)**.** *Suppose one algorithm returns a compressed representation R and another returns an explicit object Y. A direct timing comparison is valid only if*

$$\mathrm{decode}(R) = Y$$

and the time required by decode *is included, or if the downstream task consumes R directly.*

Proof. Without decoding, the two procedures return different mathematical objects. A timing ratio between different outputs does not compare implementations of the same map. Including the decoding cost gives two procedures with the same output. If the next operation consumes R, decoding is not part of the declared computation. □

Remark 2.10. A compressed product and an explicit matrix product may both be exact. They still have different contracts. This distinction becomes decisive when materialization costs n^2 entries.

3 Arithmetic, storage, and data movement

We count one scalar multiplication and one scalar addition as two modeled floating point operations. These counts describe a declared event model for a representation. They do not predict wall time without a memory and launch model. A multiplication with accumulation charges two scalar operations even for the first coefficient. Thin corrections accumulate into an already computed diagonal or sparse result. Index metadata, temporary workspace, launch overhead, discovery, transfer, and materialization are accounted for separately.

Theorem 3.1 (Dense and packet application counts)**.** *A dense n by n matrix applied to q right hand sides has modeled cost*

$$\boxed{\mathrm{flop}_{\mathrm{dense}} = 2n^2q.}$$

A packet representation with active edge set E has modeled cost

$$\boxed{\mathrm{flop}_{\mathrm{packet}} = 2q \sum_{(\beta,\alpha)\in E} n_\beta n_\alpha.}$$

It stores

$$\boxed{M_{\mathrm{packet}} = \sum_{(\beta,\alpha)\in E} n_\beta n_\alpha}$$

scalar entries.

Proof. The active block $B_{\beta\alpha}$ is an n_β by n_α matrix. Applying it to an n_α by q input costs $2n_\beta n_\alpha q$ modeled operations and stores $n_\beta n_\alpha$ scalars. Summation over the active addresses gives both formulas. □

Corollary 3.2 (Equal diagonal packets)**.** *Let $p \geq 1$ and $b \geq 1$ be integers and $n = pb$. Suppose n is divided into p equal diagonal packets of width b. Then*

$$\mathrm{flop}_{\mathrm{block}} = 2qnb, \qquad M_{\mathrm{block}} = nb.$$

The following factor describes the dense-to-block storage reduction and, when $q \geq 1$, the arithmetic reduction:

$$\boxed{\frac{n}{b}.}$$

Proof. There are n/b active diagonal blocks. Each contains b^2 entries. □

Definition 3.3 (Block diagonal plus low rank operator)**.** A block diagonal plus low rank operator has the form

$$A = D + UV^*,$$

where

$$D = \bigoplus_{\alpha \in I} D_\alpha, \qquad U, V \in \mathbb{C}^{n \times r}.$$

The abbreviation BDLR will be used below.

Theorem 3.4 (BDLR application and storage)**.** *For q right hand sides,*

$$AZ = DZ + U(V^*Z)$$

has modeled cost

$$\boxed{2q\left(\sum_\alpha n_\alpha^2 + 2nr\right).}$$

The representation stores

$$\boxed{\sum_\alpha n_\alpha^2 + 2nr}$$

scalars. For $n = pb$, with integers $p, b \geq 1$, the following factor describes the ideal dense storage reduction and, when $q \geq 1$, the arithmetic reduction:

$$\boxed{\frac{n}{b + 2r}.}$$

Proof. The block diagonal product costs

$$2q \sum_\alpha n_\alpha^2.$$

The products V^*Z and $U(V^*Z)$ cost $2nrq$ each. Storage consists of the diagonal blocks and the two low rank factors. For equal packets,

$$\sum_\alpha n_\alpha^2 = nb.$$

□

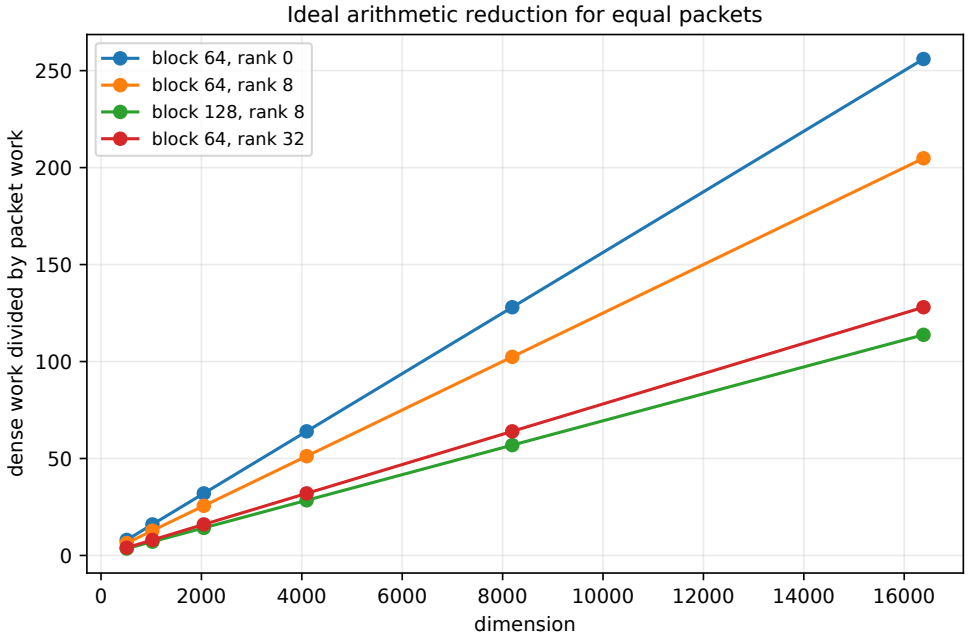

Figure 6. The ideal reduction grows with dimension only when packet width and transfer rank remain controlled.

Definition 3.5 (One pass streaming model)**.** Fix a scalar size s bytes. For every active block, the one pass streaming model reads the block once, reads its source packet once, and reads and writes its target packet once. It does not assume cache reuse across edges.

Proposition 3.6 (Streaming byte count)**.** *Under definition 3.5, applying a packet operator to q right hand sides moves*

$$\boxed{B_{\text{stream}} = s \sum_{(\beta,\alpha)\in E} \left(n_\beta n_\alpha + n_\alpha q + 2n_\beta q\right)}$$

bytes.

Proof. The three terms count the matrix block, the source values, and the read plus write traffic for the target accumulation. The model counts these quantities independently for every active edge. □

Definition 3.7 (Arithmetic intensity)**.** When the modeled byte traffic is strictly positive, the modeled arithmetic intensity is

$$\mathcal{I} = \frac{\text{flop}}{\text{bytes}}.$$

Theorem 3.8 (Roofline lower bound)**.** *Suppose a device sustains at most $P > 0$ modeled operations per second and at most $W > 0$ bytes per second. A computation that requires F operations and B bytes satisfies*

$$\boxed{T \geq \max\left\{\frac{F}{P}, \frac{B}{W}\right\}.}$$

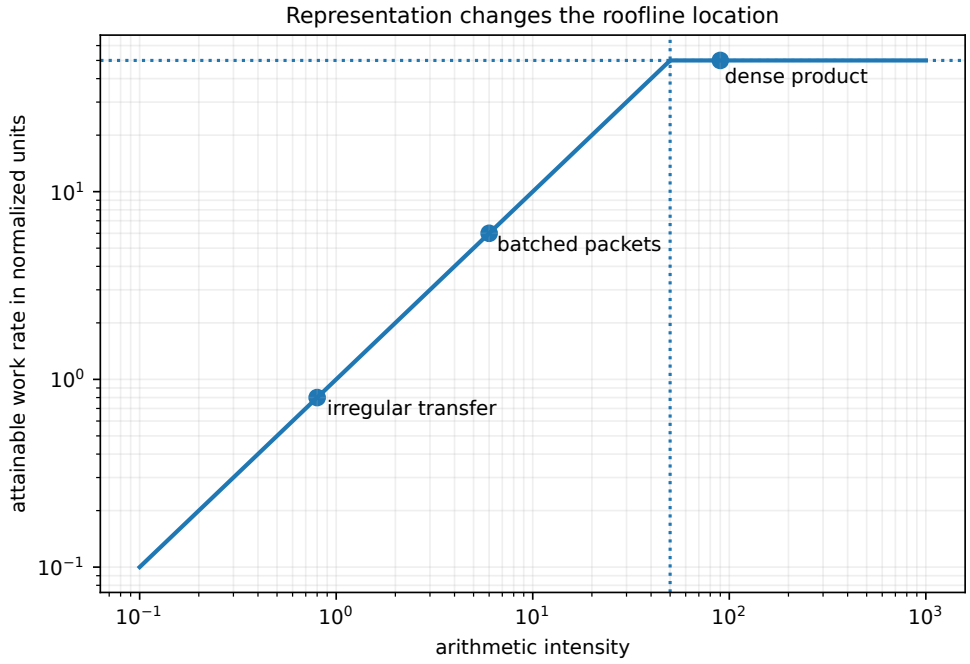

Figure 7. A representation can move the same mathematical problem between memory limited and compute limited regimes.

For positive elapsed time and positive byte traffic, its work rate is at most

$$\min\{P, W\mathcal{I}\}.$$

Proof. The operation capacity gives $T \geq F/P$. The bandwidth capacity gives $T \geq B/W$. Both restrictions hold at once. □

The roofline model is a guide rather than an exact execution law [27]. Packet structure changes both F and B. An irregular representation may remove arithmetic while lowering intensity enough to become bandwidth or launch limited.

Corollary 3.9 (Capacity threshold)**.** *Let a device have available memory $M \geq 0$ bytes and scalar size $s > 0$, and let $n \geq 0$. The matrix representation alone can fit only when*

$$n \leq \sqrt{M/s}.$$

The equal packet BDLR representation alone fits when

$$n(b + 2r)s \leq M.$$

Proof. Substitute the dense and BDLR storage counts into the capacity inequality. □

Proposition 3.10 (Materialization cost)**.** *Materializing $D + UV^*$ as an explicit matrix requires storage for n^2 scalars and modeled arithmetic*

$$2n^2r + O(n^2)$$

when the low rank correction is formed by dense multiplication.

Proof. The product UV^* multiplies an n by r matrix by an r by n matrix. Adding the diagonal part changes only the lower order term. □

4 Structured packet primitives

The packet representation can store different exact local operator types. This section records the finite formulas used by several measured suites. The results concern representation and arithmetic. They do not assert that one implementation is fastest at every size.

Proposition 4.1 (Equal block banded count)**.** *Let $p, b \geq 1$ be integers, $n = pb$, and let $p = n/b$ equal packets have width b. Suppose a block is active precisely when*

$$|i - j| \leq w, \qquad 0 \leq w \leq p - 1.$$

The number of active blocks is

$$\boxed{N_{p,w} = p(2w + 1) - w(w + 1).}$$

For q right hand sides, the modeled application cost and scalar storage are

$$\boxed{2qb^2N_{p,w} \quad \textit{and} \quad b^2N_{p,w}.}$$

Proof. The diagonal contributes p blocks. At offset k, where $1 \leq k \leq w$, the upper and lower block diagonals contribute $2(p - k)$ blocks. Therefore

$$p + 2\sum_{k=1}^{w}(p - k) = p(2w + 1) - w(w + 1).$$

The cost and storage follow from theorem 3.1. □

Proposition 4.2 (Sparse plus low rank application)**.** *Let*

$$A = S + UV^*,$$

where S has z stored scalar nonzeros and $U, V \in \mathbb{C}^{n\times r}$. In the model that charges two operations per stored sparse entry and right hand side, applying A to q right hand sides costs

$$\boxed{2q(z + 2nr)}$$

modeled operations and stores

$$\boxed{z + 2nr}$$

scalar values, apart from sparse index metadata.

Proof. The sparse product costs $2zq$. The two dense thin products cost $2nrq$ each. The stored values are the nonzeros of S and the entries of the two factors. □

Theorem 4.3 (Circulant spectral representation). *Let $n \geq 1$ be an integer and $c \in \mathbb{C}^n$, with indices taken modulo n, and define*

$$C(c)_{jk} = c_{j-k}.$$

Let F be the unitary discrete Fourier matrix

$$F_{jk} = \frac{1}{\sqrt{n}} \exp\left(-\frac{2\pi \mathrm{i} jk}{n}\right).$$

Then

$$\boxed{C(c) = F^* \operatorname{diag}(\sqrt{n}\, Fc) F.}$$

The operator is determined by n scalars and can be applied through two Fourier transforms and one pointwise product.

Proof. For each frequency k, let

$$v_j^{(k)} = \frac{1}{\sqrt{n}} \exp\left(\frac{2\pi \mathrm{i} jk}{n}\right).$$

Then

$$(C(c)v^{(k)})_j = \sum_{r=0}^{n-1} c_r v_{j-r}^{(k)} = \left(\sum_{r=0}^{n-1} c_r \exp\left(-\frac{2\pi \mathrm{i} rk}{n}\right)\right) v_j^{(k)}.$$

The eigenvalue is $\sqrt{n}(Fc)_k$. The vectors $v^{(k)}$ are the columns of F^*, which gives the formula. □

The fast Fourier transform evaluates the two transforms in $O(n \log n)$ arithmetic for the usual composite lengths [7]. This is an algorithmic factorization of the exact identity in theorem 4.3.

Corollary 4.4 (Toeplitz circulant embedding). *Let $n \geq 1$ be an integer and $T \in \mathbb{C}^{n \times n}$ be Toeplitz, with first column*

$$(c_0, c_1, \dots, c_{n-1})^T$$

and first row

$$(c_0, r_1, \dots, r_{n-1}).$$

Set

$$g = (c_0, c_1, \dots, c_{n-1}, 0, r_{n-1}, \dots, r_1)^T \in \mathbb{C}^{2n}$$

and append n zeros to $x \in \mathbb{C}^n$. The first n entries of the circulant product $C(g)(x, 0)^T$ equal Tx.

Proof. For $0 \leq j < n$, the circular convolution sum separates into indices $k \leq j$, where the coefficient is c_{j-k}, and indices $k > j$, where the wrapped coefficient is r_{k-j}. The padded coordinates do not contribute. The resulting sum is exactly the jth Toeplitz row applied to x. □

Theorem 4.5 (Kronecker modewise application). *Let $A \in \mathbb{C}^{m\times m}$, $B \in \mathbb{C}^{n\times n}$, and $X \in \mathbb{C}^{n\times m}$. With column major vectorization,*

$$\boxed{(A \otimes B)\,\mathrm{vec}(X) = \mathrm{vec}(BXA^T).}$$

The right side has modeled cost

$$\boxed{2n^2m + 2nm^2}$$

and stores $n^2 + m^2$ factor entries instead of n^2m^2 entries.

Proof. The (i, j) entry of BXA^T is

$$\sum_{k=1}^{n}\sum_{\ell=1}^{m} B_{ik}X_{k\ell}A_{j\ell}.$$

This is the coordinate formula for $(A \otimes B)\,\mathrm{vec}(X)$. Multiplying first by B and then by A^T gives the stated count. □

Corollary 4.6 (Equal tensor factors). *For integers $k, d \geq 0$, a product of k square factors of order d, acting on a tensor with d^k entries, can be applied by k modewise contractions, reusing intermediate slices, with modeled cost*

$$\boxed{2kd^{k+1}}$$

and factor storage kd^2.

Proof. For $k = 0$ there are no contractions and both modeled work and factor storage are zero. For $k \geq 1$, one mode has d^{k-1} fibers of length d. Multiplying each fiber by a d by d matrix costs $2d^2$, so one mode costs $2d^{k+1}$. Sum over the k modes. □

Theorem 4.7 (Walsh–Hadamard recursion). *Let $N = 2^m$, and define*

$$H_1 = [1], \qquad H_{2N} = \begin{bmatrix} H_N & H_N \\ H_N & -H_N \end{bmatrix}.$$

Then

$$H_N H_N^T = NI.$$

The product $H_N x$ can be evaluated in exactly $N \log_2 N$ additions or subtractions through the recursion.

Proof. The orthogonality identity follows by induction from block multiplication. One recursive stage forms $x_0 + x_1$ and $x_0 - x_1$, which uses N additions or subtractions, and then applies two transforms of size $N/2$. Thus

$$T(N) = 2T(N/2) + N, \qquad T(1) = 0,$$

whose solution is $T(N) = N \log_2 N$. □

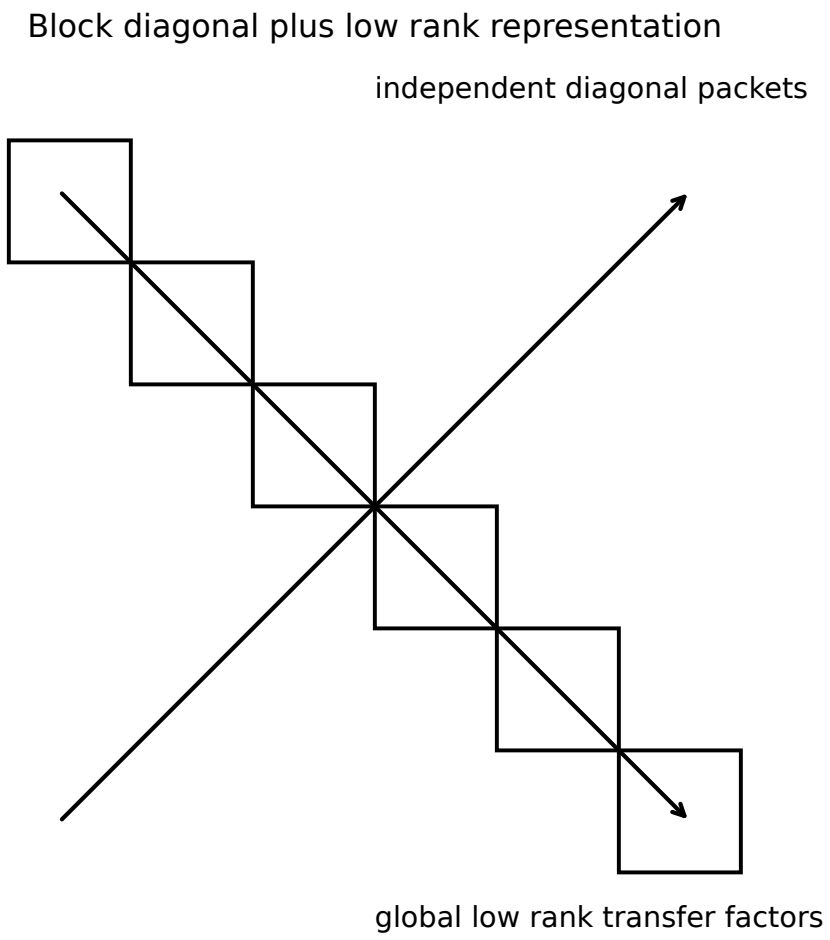

Figure 8. A regular diagonal packet structure is coupled by global low rank factors.

5 Exact low rank algebra and recompression

5.1 Products and inverses

Theorem 5.1 (Exact BDLR product). *Let*

$$A = D_A + U_A V_A^*, \qquad B = D_B + U_B V_B^*$$

use the same diagonal packet layout. Then

$$AB = D_A D_B + U_C V_C^*,$$

where

$$U_C = \begin{bmatrix} D_A U_B + U_A (V_A^* U_B) & U_A \end{bmatrix}$$

and

$$V_C = \begin{bmatrix} V_B & D_B^* V_A \end{bmatrix}.$$

The unrecompressed correction rank is at most $r_A + r_B$.

Proof. Expand the product:

$$AB = D_A D_B + D_A U_B V_B^* + U_A V_A^* D_B + U_A (V_A^* U_B) V_B^*.$$

The second and fourth terms share the right factor V_B^*. The third term equals

$$U_A (D_B^* V_A)^*.$$

Concatenation gives the stated factors. □

Corollary 5.2 (Rank growth in a product chain)**.** *Let*

$$A_j = D_j + U_j V_j^*, \qquad j = 1, \dots, m,$$

share one diagonal packet layout. Before recompression, the product

$$A_m \cdots A_1$$

has a BDLR representation whose correction rank is at most

$$\boxed{\sum_{j=1}^{m} r_j.}$$

Proof. Apply theorem 5.1 inductively. Each new factor adds at most its own correction rank. □

Theorem 5.3 (Woodbury inversion)**.** *Assume D and*

$$S = I + V^* D^{-1} U$$

are invertible. Then

$$\boxed{(D + UV^*)^{-1} = D^{-1} - D^{-1} U S^{-1} V^* D^{-1}.}$$

Proof. Multiply the proposed inverse by $D + UV^*$. The coefficient of $V^* D^{-1}$ is

$$U - U S^{-1} (I + V^* D^{-1} U) = 0.$$

The remaining term is the identity. The right inverse calculation is the same. □

The formula and its history are discussed in [15]. It reduces one large solve to packet solves with D and one dense solve with the small matrix S.

Corollary 5.4 (Inverse norm bound)**.** *Under the hypotheses of theorem 5.3,*

$$\left\| (D + UV^*)^{-1} \right\| \le \left\| D^{-1} \right\| + \left\| D^{-1} U \right\| \left\| S^{-1} \right\| \left\| V^* D^{-1} \right\|.$$

Proof. Apply the triangle inequality and submultiplicativity to the Woodbury formula. □

5.2 Optimal factor recompression

Standard Fact 5.5 (Eckart–Young–Mirsky theorem)**.** If M has singular values

$$\sigma_1 \geq \sigma_2 \geq \cdots,$$

pad this finite sequence with zeros. For each integer $k \geq 0$, its truncated singular value decomposition M_k is a best rank-at-most-k approximation. It satisfies

$$\|M - M_k\|_2 = \sigma_{k+1}$$

and

$$\|M - M_k\|_{\mathrm{F}} = \left(\sum_{j>k} \sigma_j^2 \right)^{1/2}.$$

This is classical [11, 22]. The next theorem shows that an n dimensional singular value decomposition is unnecessary when a correction is already factored.

Theorem 5.6 (Small core recompression)**.** *Let*

$$L \in \mathbb{C}^{m \times r}, \qquad R \in \mathbb{C}^{n \times r}.$$

Take compact QR factorizations

$$L = Q_L R_L, \qquad R = Q_R R_R,$$

where the columns of Q_L and Q_R are orthonormal. Form the small core

$$G = R_L R_R^*$$

and let

$$G = W \Sigma Z^*$$

be an ordered thin singular value decomposition, with nonnegative nonincreasing singular values. For an integer $k \geq 0$, retain $\min\{k, d\}$ columns, where d is the number of supplied thin singular directions. Tail singular values beyond d are zero. Define

$$L_k = Q_L W_k \Sigma_k^{1/2}, \qquad R_k = Q_R Z_k \Sigma_k^{1/2}.$$

Then

$$L_k R_k^*$$

is a best rank at most k approximation to LR^*. Its spectral and Frobenius errors are the singular value tails in standard fact 5.5. The core dimensions equal the column ranks of the two input factors. A noncompact reduced QR may retain extra zero singular directions without changing the conclusion.

Proof. The exact factor product is

$$LR^* = Q_L G Q_R^*.$$

The two outer maps are isometries on their column spaces. They preserve the nonzero singular values and the spectral and Frobenius norms of the core. For every ambient rank-at-most-k competitor B, its compression $Q_L^* B Q_R$ has rank at most k, and compression cannot increase either norm. Thus the

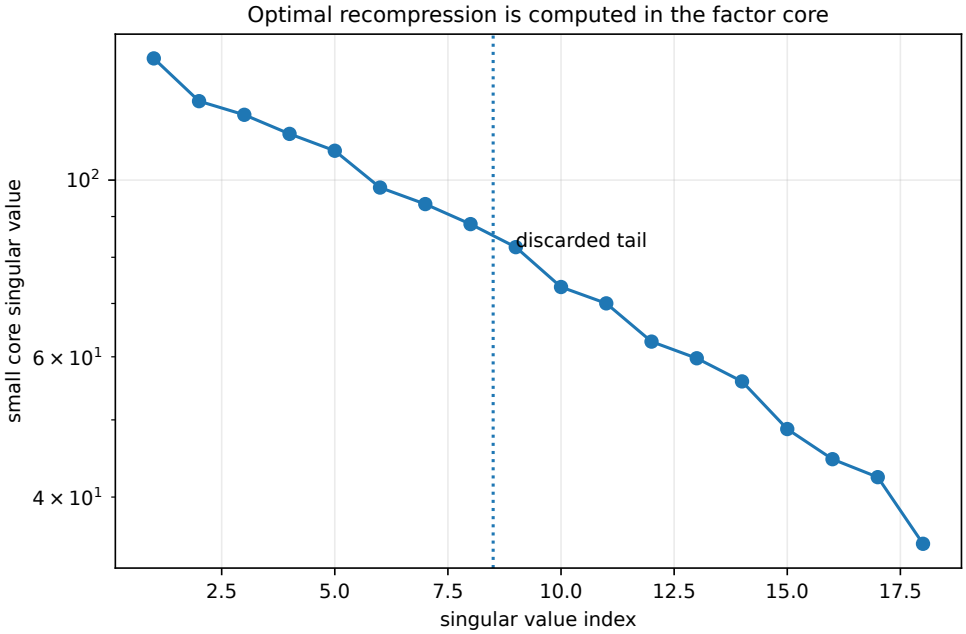

Figure 9. The approximation decision is made from the singular values of a small core whose dimension is the unrecompressed rank.

core best-approximation inequality also bounds the error of every ambient competitor from below. Truncating the singular value decomposition of G and applying standard fact 5.5 gives the result. The compact QR dimensions equal the ranks of the factor column spaces. □

Remark 5.7. The large matrices enter through QR factorizations of the factors. The singular value problem has dimension at most the unrecompressed rank. Updating and recompressing low rank factors is standard numerical linear algebra [13, 4].

Theorem 5.8 (Product chain perturbation). *Let $A_1, \dots, A_m$ be exact factors and let*

$$\widehat{A}_j = A_j + E_j.$$

Then

$$\boxed{\left\| \widehat{A}_m \cdots \widehat{A}_1 - A_m \cdots A_1 \right\| \le \sum_{j=1}^{m} \left(\prod_{i=j+1}^{m} \left\| \widehat{A}_i \right\| \right) \|E_j\| \left(\prod_{i=1}^{j-1} \|A_i\| \right).}$$

Empty products are one.

Proof. Use the telescoping identity

$$\widehat{A}_m \cdots \widehat{A}_1 - A_m \cdots A_1 = \sum_{j=1}^{m} \widehat{A}_m \cdots \widehat{A}_{j+1} E_j A_{j-1} \cdots A_1.$$

Take norms term by term. □

Theorem 5.9 (Certified repeated recompression). *Let*

$$P_0 = I, \qquad P_j = A_j P_{j-1},$$

be exact partial products. Suppose an implemented chain satisfies

$$\widehat{P}_0 = I, \qquad \widehat{P}_j = A_j \widehat{P}_{j-1} + E_j,$$

where E_j is the additive error introduced after the jth multiplication, for example by factor recompression. Then

$$\boxed{\left\|\widehat{P}_m - P_m\right\| \le \sum_{j=1}^{m} \left(\prod_{i=j+1}^{m} \|A_i\| \right) \|E_j\|.}$$

If $\|E_j\| \le \delta_j$, the same formula with δ_j gives a certified final error.

Proof. Set $D_j = \widehat{P}_j - P_j$. Then

$$D_j = A_j D_{j-1} + E_j, \qquad D_0 = 0.$$

Repeated substitution gives

$$D_m = \sum_{j=1}^{m} A_m A_{m-1} \cdots A_{j+1} E_j.$$

Taking norms yields the result. □

6 Sparse transfer graphs and schedules

6.1 Support under algebraic operations

Theorem 6.1 (Path support of powers). *For every positive integer m,*

$$P_\gamma A^m P_\alpha$$

is the sum over directed walks (vertices may repeat)

$$\alpha = \alpha_0 \longrightarrow \alpha_1 \longrightarrow \cdots \longrightarrow \alpha_m = \gamma$$

in G_A, with contribution

$$A_{\alpha_m \alpha_{m-1}} \cdots A_{\alpha_1 \alpha_0}.$$

If no such path exists, the block vanishes.

Proof. Insert the packet identity between every two consecutive factors of A. Every nonzero term determines one path of length m. □

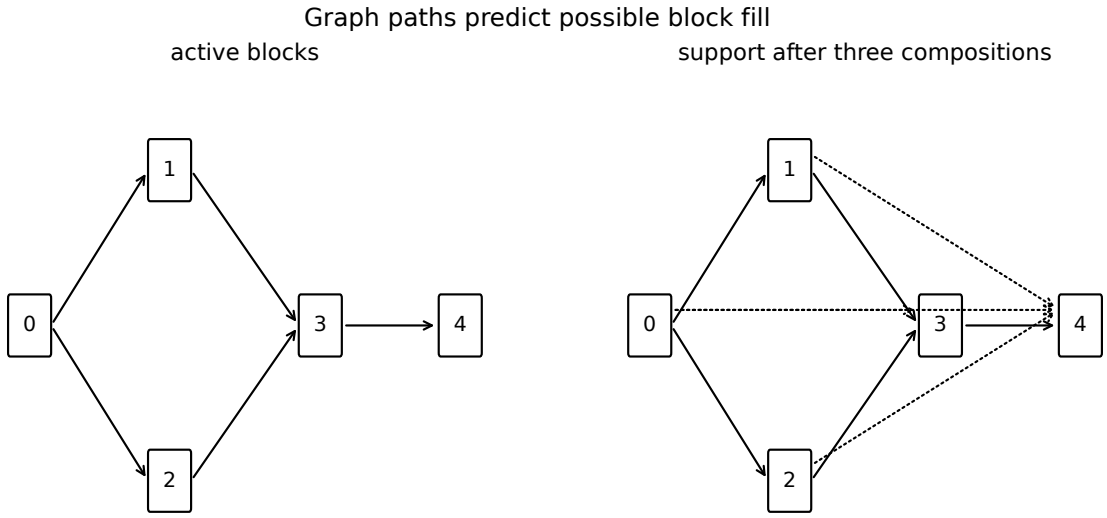

Figure 10. Composition creates possible support along directed paths. Cancellation can remove an allowed block, so the graph gives an inclusion rather than an equality.

Corollary 6.2 (Polynomial support)**.** *If*

$$p(z) = \sum_{j=0}^{d} c_j z^j,$$

then

$$\operatorname{supp}(p(A))$$

is contained in the union of the support relations of A^j for $0 \le j \le d$.

Proof. Apply theorem 6.1 to every power in the polynomial. □

Corollary 6.3 (Acyclic transfer nilpotence)**.** *Let K contain only strict transfer blocks. If its support graph is acyclic and its longest directed path has h edges, then*

$$K^{h+1} = 0.$$

Proof. There is no directed path of length $h+1$. Every block of K^{h+1} therefore vanishes by theorem 6.1. □

6.2 Block triangular solves

Definition 6.4 (Topological level)**.** Let G be a directed acyclic graph. The first level contains its source vertices. Remove them. The next level contains the new sources. Continue until every vertex has been assigned.

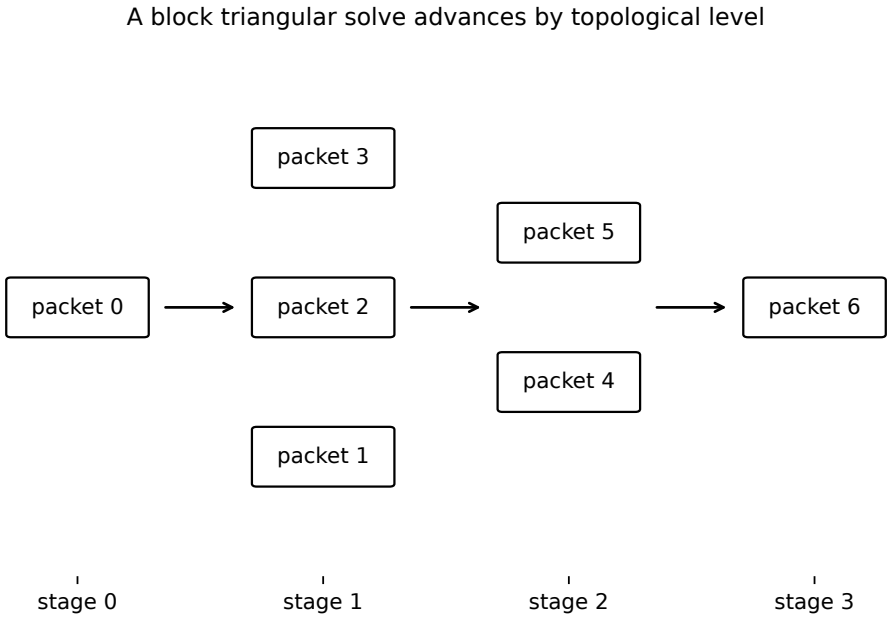

Figure 11. Packets in the same topological level can be processed concurrently in a triangular solve.

Theorem 6.5 (Level schedule for a triangular solve)**.** *Let $A = D + K$ be block lower triangular after a topological ordering. Assume every diagonal block D_α is invertible. The solve*

$$Ax = b$$

can be completed in one sequential stage per topological level. Blocks in the same level may be solved independently after all earlier levels are known.

Proof. The equation in packet β is

$$D_\beta x_\beta = b_\beta - \sum_{\alpha \to \beta} K_{\beta\alpha} x_\alpha.$$

Every predecessor of β lies in an earlier level. Once those values are available, x_β is obtained from the local solve with D_β. Vertices in the same level have no directed edge between them, so their solves are independent. □

Corollary 6.6 (Sequential depth)**.** *For a nonempty finite graph, the number of sequential stages in the level schedule equals one plus the length of the longest directed path. The empty graph has depth zero.*

Proof. The recursive level of a vertex is one plus the largest level of its predecessors. For a nonempty graph, the largest level therefore counts the vertices on a longest path. For an empty graph, no task is scheduled and the depth is zero. □

6.3 Fill under elimination

Theorem 6.7 (Inverse support lies in the transitive closure)**.** *Let A be an invertible packet operator. Reachability here includes a zero-length path from a packet to itself. If there is no directed path from packet α to packet β in G_A, then*

$$\boxed{P_\beta A^{-1} P_\alpha = 0.}$$

Proof. Let R be the set of packets reachable from α, including α, and set

$$X_R = \bigoplus_{\gamma \in R} X_\gamma.$$

No active edge leaves R, so $AX_R \subseteq X_R$. The restriction of A to the finite dimensional space X_R is injective. It is therefore onto X_R. Hence $A^{-1}X_R \subseteq X_R$. Since $\beta \notin R$, the stated block of A^{-1} vanishes. □

Proposition 6.8 (Schur support inclusion)**.** *Split the packets into retained indices R and hidden indices H. Suppose the hidden block A_{HH} is invertible. The retained Schur complement is*

$$S = A_{RR} - A_{RH} A_{HH}^{-1} A_{HR}.$$

A retained block (β, α) can be active only if it was already active in A_{RR}, or if there is a directed walk from α through hidden packets to β. The internal hidden path may have length zero, so entrance and exit may use the same hidden packet.

Proof. The correction block is

$$P_\beta A_{RH} A_{HH}^{-1} A_{HR} P_\alpha.$$

It can be nonzero only when $A_{HR}P_\alpha$ enters a hidden packet, the inverse hidden operator connects hidden packets, and $P_\beta A_{RH}$ exits to β. By theorem 6.7, the hidden inverse can connect only packets joined by a hidden directed path. Cancellation may still remove an allowed block. □

Sparse elimination and fill are treated systematically in [9]. The packet graph records the same structural issue at block scale.

7 Krylov methods and packet preconditioning

Definition 7.1 (Krylov space)**.** For a linear operator A, a vector v, and a positive integer m, define

$$\mathcal{K}_m(A, v) = \mathsf{span}\{v, Av, \dots, A^{m-1}v\}.$$

Proposition 7.2 (Invariant packet Krylov decomposition)**.** *Assume*

$$[A, P_\alpha] = 0$$

for every packet. If

$$v = \sum_\alpha v_\alpha, \qquad v_\alpha = P_\alpha v,$$

then

$$A^j v = \sum_\alpha A_\alpha^j v_\alpha$$

for every $j \geq 0$, where

$$A_\alpha = P_\alpha A P_\alpha.$$

Hence

$$\mathcal{K}_m(A, v) \subseteq \bigoplus_\alpha \mathcal{K}_m(A_\alpha, v_\alpha).$$

Proof. Commutation gives

$$A^j P_\alpha = P_\alpha A^j.$$

Apply this identity to each packet component of v. □

Theorem 7.3 (Approximate packet Krylov bound)**.** *Write*

$$A = D + K,$$

where D is packet diagonal. For every positive integer j,

$$\boxed{\left\|A^j - D^j\right\| \leq j M^{j-1} \left\|K\right\|,}$$

where

$$M = \max\{\left\|A\right\|, \left\|D\right\|\}.$$

Consequently,

$$\operatorname{dist}(A^j v, \bigoplus_\alpha \mathcal{K}_{j+1}(D_\alpha, v_\alpha)) \leq j M^{j-1} \left\|K\right\| \left\|v\right\|.$$

Proof. Use the telescoping identity

$$A^j - D^j = \sum_{k=0}^{j-1} A^{j-1-k} K D^k.$$

Each term has norm at most $M^{j-1} \left\|K\right\|$. The vector $D^j v$ lies in the direct sum of local Krylov spaces. □

Theorem 7.4 (Block Jacobi condition bound)**.** *Let*

$$A = D + K$$

act on a nonempty finite coordinate space and be Hermitian positive definite with positive definite block diagonal part D. Here $D^{-1/2}$ is the actual inverse of the positive square root of D. Suppose

$$E = D^{-1/2} K D^{-1/2}$$

is Hermitian and

$$\left\|E\right\|_2 \leq \eta < 1.$$

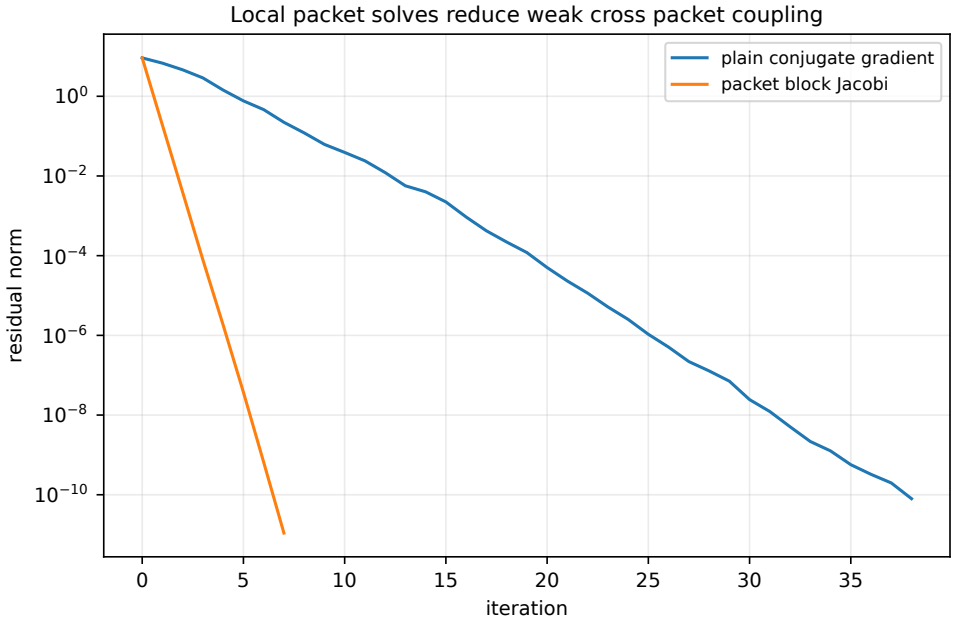

Figure 12. The block diagonal packet operator serves as a reusable local preconditioner in a weakly coupled positive system.

Then

$$\boxed{\operatorname{cond}_2(D^{-1/2}AD^{-1/2}) \le \frac{1+\eta}{1-\eta}.}$$

Proof. For every unit vector x,

$$|x^{*}Ex| \le \eta.$$

The Rayleigh quotient of $I + E$ lies in $[1-\eta, 1+\eta]$. The quotient of the extreme eigenvalue bounds gives the result. □

Standard Fact 7.5 (Preconditioned conjugate gradient convergence)**.** Let A and M be Hermitian positive definite on a nonempty finite coordinate space, and set

$$\kappa = \operatorname{cond}_2(M^{-1/2}AM^{-1/2}).$$

In exact arithmetic, the energy norm error of preconditioned conjugate gradient satisfies

$$\|x_m - x_*\|_A \le 2\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)^{m} \|x_0 - x_*\|_A .$$

This standard estimate is discussed in [25]. Combining it with theorem 7.4 yields an explicit iteration certificate when the normalized cross packet coupling is small.

Corollary 7.6 (Certified packet preconditioning)**.** *Under the hypotheses of theorem 7.4, the convergence factor in standard fact 7.5 is bounded by the value obtained from*

$$\kappa = \frac{1+\eta}{1-\eta}.$$

Proof. Insert the condition bound from theorem 7.4 into the monotone convergence factor in standard fact 7.5. □

8 Packetwise mixed precision

8.1 One operator

Theorem 8.1 (Packet perturbation certificate)**.** *Let*

$$A = \sum_{e \in E} A_e, \qquad \widehat{A} = \sum_{e \in E} (A_e + E_e),$$

where edge e starts at packet $\alpha(e)$, and assume

$$A_e = A_e P_{\alpha(e)}, \qquad E_e = E_e P_{\alpha(e)}.$$

Then

$$\boxed{\left\|(\widehat{A} - A)x\right\| \le \sum_{e \in E} \|E_e\| \left\|P_{\alpha(e)} x\right\|.}$$

If

$$\|E_e\| \le \varepsilon_e \|A_e\|,$$

then

$$\boxed{\left\|(\widehat{A} - A)x\right\| \le \sum_{e \in E} \varepsilon_e \|A_e\| \left\|P_{\alpha(e)} x\right\|.}$$

Proof. Exact packet evaluation gives

$$(\widehat{A} - A)x = \sum_{e} E_e P_{\alpha(e)} x.$$

Apply the triangle inequality and the operator norm bound to each term. □

Standard Fact 8.2 (Floating point matrix product model)**.** For real $A \in \mathbb{R}^{m \times p}$ and $B \in \mathbb{R}^{p \times n}$, consider ordinary dot-product matrix multiplication in uniform precision with unit roundoff u, no overflow or underflow, and $pu < 1$. Its computed output $\widehat{C}$ satisfies the componentwise forward-error bound

$$|\widehat{C} - AB| \le \gamma_p |A||B|, \qquad \gamma_p = \frac{pu}{1-pu}.$$

Absolute values and the inequality are entrywise. Complex arithmetic, fused kernels, mixed accumulation, and tensor kernels require their own stated constants. This fact does not assert one common small

input perturbation for every column, and an input-dependent rounded action is not automatically a fixed linear operator.

Detailed forms and their hypotheses are given in [17, 18]. For a fixed computed matrix, the bound can certify its error matrix. A rounded application to varying inputs needs a separately justified uniform certificate before it can be used as one fixed operator error in theorem 8.1.

8.2 Several operators

Corollary 8.3 (Mixed precision product chain)**.** *If each fixed linear factor A_j is replaced by a fixed packetwise linear approximation $\widehat{A}_j$, write $E_j = \widehat{A}_j - A_j = \sum_e \Delta_{j,e} P_{\alpha(j,e)}$. A uniform certificate is*

$$\|E_j\| \le \delta_j := \sum_e \|\Delta_{j,e}\| \, \|P_{\alpha(j,e)}\|.$$

For orthogonal packet projectors, $\delta_j \le \sum_e \|\Delta_{j,e}\|$. The final operator error is bounded by theorem 5.8 with these uniform δ_j. The corresponding vector error is this operator bound multiplied by the input norm.

Proof. Take the supremum over unit inputs in theorem 8.1, using $\|P_\alpha x\| \le \|P_\alpha\|\|x\|$. Substitute the resulting uniform operator error bounds into theorem 5.8. The action estimate follows from submultiplicativity. □

8.3 Continuous allocation

Theorem 8.4 (Continuous precision allocation)**.** *Let E be a finite nonempty edge set, let $s_e > 0$ be sensitivities and $c_e > 0$ be costs, and let $\tau > 0$. Consider*

$$\min_{\varepsilon_e > 0} \sum_e c_e \log \frac{1}{\varepsilon_e}$$

subject to

$$\sum_e s_e \varepsilon_e = \tau.$$

The unique minimizer is

$$\boxed{\varepsilon_e = \frac{\tau c_e}{s_e \sum_f c_f}.}$$

Proof. The Lagrangian derivative gives

$$-\frac{c_e}{\varepsilon_e} + \lambda s_e = 0.$$

Thus

$$\varepsilon_e = \frac{c_e}{\lambda s_e}.$$

The constraint gives

$$\lambda = \frac{\sum_f c_f}{\tau}.$$

The objective is strictly convex on the positive orthant, so the stationary point is the unique minimizer. □

Theorem 8.5 (Clipped precision allocation)**.** *Retain the finite nonempty edge set, strictly positive sensitivities and costs, and add strictly positive caps $m_e > 0$ with upper bounds*

$$0 < \varepsilon_e \le m_e.$$

Assume

$$0 < \tau \le \sum_e s_e m_e.$$

There is a unique $\lambda > 0$, except at the maximal tolerance endpoint, such that

$$\boxed{\varepsilon_e = \min\left\{m_e, \frac{c_e}{\lambda s_e}\right\}}$$

and

$$\sum_e s_e \varepsilon_e = \tau.$$

This vector minimizes the same objective over the clipped feasible set.

Proof. The Karush–Kuhn–Tucker conditions give the unconstrained form on every nonactive coordinate and equality with m_e on every active upper bound. The weighted sum

$$\phi(\lambda) = \sum_e s_e \min\left\{m_e, \frac{c_e}{\lambda s_e}\right\}$$

is continuous and nonincreasing. It decreases from the maximal feasible value to zero. For a strictly submaximal budget, once any coordinate is unsaturated, ϕ is strictly decreasing, which gives a unique multiplier. At maximal budget the only feasible vector is $(m_e)_e$ and every $0 < \lambda \le \min_e c_e/(s_e m_e)$ produces it. Thus the minimizing vector is unique at this endpoint while its multiplier need not be. Strict convexity gives uniqueness of the minimizer in every case. □

8.4 Discrete data types

Definition 8.6 (Discrete precision option)**.** For edge e, a discrete precision option k has a measured or modeled cost $c_{e,k}$ and a nonnegative integer error weight $w_{e,k}$. Exactly one option must be selected on every edge.

Theorem 8.7 (Exact discrete precision program)**.** *Let the total integer error budget be B. Define*

$$F_j(b)$$

as the minimum cost for assigning precisions to the first j edges with total weight exactly b. Then

$$F_0(0) = 0, \qquad F_0(b) = +\infty \quad \text{for } b \neq 0.$$

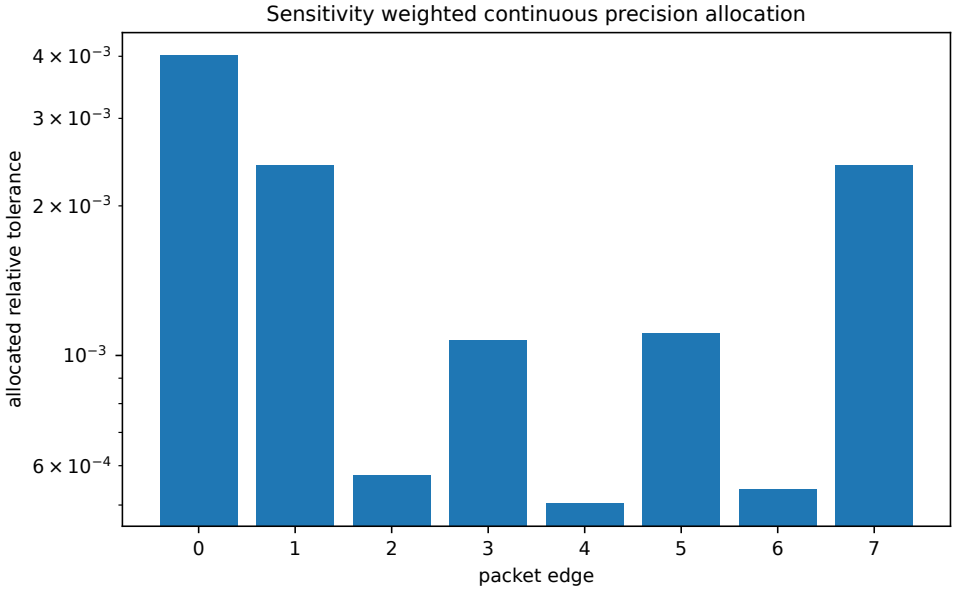

Figure 13. More sensitive packet edges receive tighter continuous tolerances.

Set $F_{j-1}(u) = +\infty$ whenever $u < 0$ or the state is unreachable. Then

$$\boxed{F_j(b) = \min_k \left\{ F_{j-1}(b - w_{j,k}) + c_{j,k} \right\}.}$$

The minimum of $F_m(b)$ over $0 \le b \le B$ is the exact minimum cost for the quantized model.

Proof. Every feasible assignment for the first j edges ends with one option k on edge j. Removing it leaves an optimal or suboptimal assignment for the first $j - 1$ edges with residual weight $b - w_{j,k}$. Replacing a suboptimal prefix by an optimal one can only lower cost. The recurrence therefore has optimal substructure. Induction on j proves the result. □

Remark 8.8. The discrete program is exact only for the supplied options and quantized error weights. Real kernels also depend on accumulation type, scaling, overflow, underflow, tensor core availability, and shape restrictions. Mixed precision iterative refinement has its own conditioning requirements [5].

9 Discovery and exact packet compilation

9.1 Exact spectral discovery

Standard Fact 9.1 (Simultaneous spectral decomposition)**.** A finite family of pairwise commuting normal matrices admits a common orthonormal basis of joint eigenvectors. The joint eigenspaces associated with distinct eigenvalue tuples give the coarsest orthogonal packet system on which every matrix in the family acts as a scalar.

Proposition 9.2 (Exact block discovery certificate)**.** *For an orthogonal packet system (P_α), define the block diagonal compression*

$$\Pi_{\mathcal{P}}(A) = \sum_{\alpha} P_\alpha A P_\alpha.$$

Then

$$\boxed{\|A - \Pi_{\mathcal{P}}(A)\|_{\mathrm{F}}^2 = \sum_{\alpha \neq \beta} \|P_\beta A P_\alpha\|_{\mathrm{F}}^2 .}$$

In operator norm,

$$\boxed{\|A - \Pi_{\mathcal{P}}(A)\|_2 \leq \sum_{\alpha \neq \beta} \|P_\beta A P_\alpha\|_2 .}$$

Thus any proposed packet discovery has an exact finite residual certificate after its projectors are known.

Proof. Distinct matrix blocks are orthogonal in the Hilbert–Schmidt inner product. Their squared Frobenius norms therefore add. The operator norm estimate follows from the triangle inequality. □

This supplies one exact discovery regime and one exact a posteriori certificate. Perturbation of spectral packets requires a gap. The Davis–Kahan theorem gives quantitative control for Hermitian spectral subspaces under such a gap [8]. Randomized low rank discovery supplies another controlled regime [16, 21]. Neither result gives globally optimal packet discovery for arbitrary operators.

9.2 Candidate packet trees

Definition 9.3 (Candidate representation tree)**.** A candidate representation tree is a finite rooted tree. Every node v has

$$\kappa_v \geq 0, \qquad \epsilon_v \geq 0,$$

representing the cost and error of keeping v as one leaf. Every internal node also has a split overhead $\sigma_v \geq 0$. An admissible pruning contains exactly one selected node on every root to terminal path.

The cost and error of a pruning $\mathcal{L}$ are

$$\mathrm{cost}(\mathcal{L}) = \sum_{v \in \mathcal{L}} \kappa_v + \sum_{u \text{ split}} \sigma_u$$

and

$$\mathrm{err}(\mathcal{L}) = \sum_{v \in \mathcal{L}} \epsilon_v.$$

The model can include arithmetic, storage, launch, transfer, and precision costs inside κ_v. It remains exact only when the declared totals are additive.

Theorem 9.4 (Exact Lagrangian packet compiler). *Fix $\lambda \geq 0$ and define*

$$J_\lambda(\mathcal{L}) = \mathrm{cost}(\mathcal{L}) + \lambda\, \mathrm{err}(\mathcal{L}).$$

For every node v, set

$$K_\lambda(v) = \kappa_v + \lambda \epsilon_v$$

and

$$S_\lambda(v) = \sigma_v + \sum_{w \in \mathrm{child}(v)} F_\lambda(w).$$

For a terminal node, set

$$F_\lambda(v) = K_\lambda(v).$$

For an internal node, the recurrence

$$\boxed{F_\lambda(v) = \min\{K_\lambda(v), S_\lambda(v)\}}$$

computes the exact minimum Lagrangian objective over every admissible pruning of the subtree rooted at v.

Proof. A pruning of the subtree rooted at v has two possible forms. It keeps v, in which case its objective is $K_\lambda(v)$. Otherwise it splits v and independently chooses an admissible pruning in every child subtree. By induction, the optimal child values are $F_\lambda(w)$. The split objective is therefore $S_\lambda(v)$. Taking the smaller value is exact. □

This recurrence is a computational version of best basis selection and Bellman optimality [3, 6]. The node costs here may include operator application, transfer, launch, precision, and output conversion rather than only a signal entropy.

Corollary 9.5 (Shared compilation for an operator family). *Let operators $A^{(1)}, \dots, A^{(m)}$ use the same candidate tree. Give operator j a nonnegative reuse weight r_j. Replace the local keep cost and error by*

$$\kappa_v = \kappa_v^{\mathrm{setup}} + \sum_{j=1}^{m} r_j \kappa_v^{(j)}$$

and

$$\epsilon_v = \sum_{j=1}^{m} r_j \epsilon_v^{(j)}.$$

Then theorem 9.4 gives the exact optimal shared pruning for the additive weighted objective.

Proof. The weighted family objective is still the sum of local leaf and split terms. Apply theorem 9.4 to the aggregated quantities. □

Proposition 9.6 (Monotone Lagrangian frontier). *Let $0 \leq \lambda_1 < \lambda_2$. Choose optimal prunings $\mathcal{L}_1$ and $\mathcal{L}_2$ for the two Lagrangian parameters. Then*

$$\boxed{\mathrm{err}(\mathcal{L}_2) \leq \mathrm{err}(\mathcal{L}_1)}$$

and

$$\boxed{\mathrm{cost}(\mathcal{L}_2) \geq \mathrm{cost}(\mathcal{L}_1).}$$

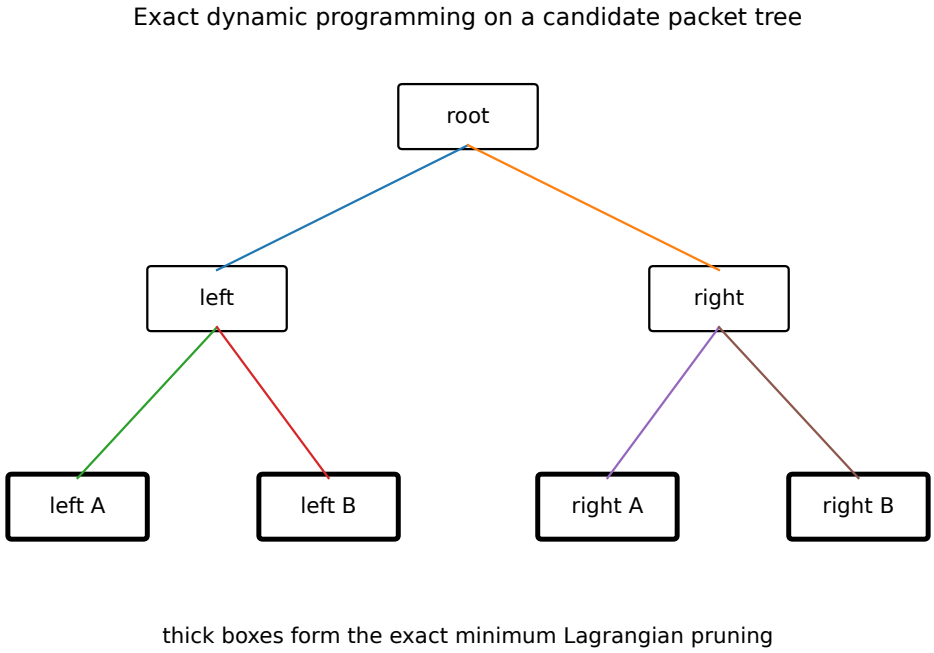

Figure 14. The thick leaves are selected by the exact Lagrangian recurrence.

Proof. Optimality gives

$$\operatorname{cost}(\mathcal{L}_1) + \lambda_1 \operatorname{err}(\mathcal{L}_1) \le \operatorname{cost}(\mathcal{L}_2) + \lambda_1 \operatorname{err}(\mathcal{L}_2)$$

and

$$\operatorname{cost}(\mathcal{L}_2) + \lambda_2 \operatorname{err}(\mathcal{L}_2) \le \operatorname{cost}(\mathcal{L}_1) + \lambda_2 \operatorname{err}(\mathcal{L}_1).$$

Adding the inequalities yields

$$(\lambda_2 - \lambda_1)(\operatorname{err}(\mathcal{L}_2) - \operatorname{err}(\mathcal{L}_1)) \le 0.$$

The error ordering follows. Substitution into the first inequality gives the cost ordering. □

Corollary 9.7 (Supported Pareto points)**.** *For $\lambda > 0$, every Lagrangian optimum is Pareto optimal for the pair*

$$(\operatorname{cost}, \operatorname{err}).$$

The quantized budget compiler may recover Pareto points that are not optimal for any Lagrangian parameter.

Proof. If another pruning had no larger cost and no larger error, with one strict inequality, its Lagrangian objective would be smaller. This contradicts optimality. A finite nonconvex frontier can contain points that are not supported by a line of slope $-\lambda$, so the budget formulation is genuinely additional. □

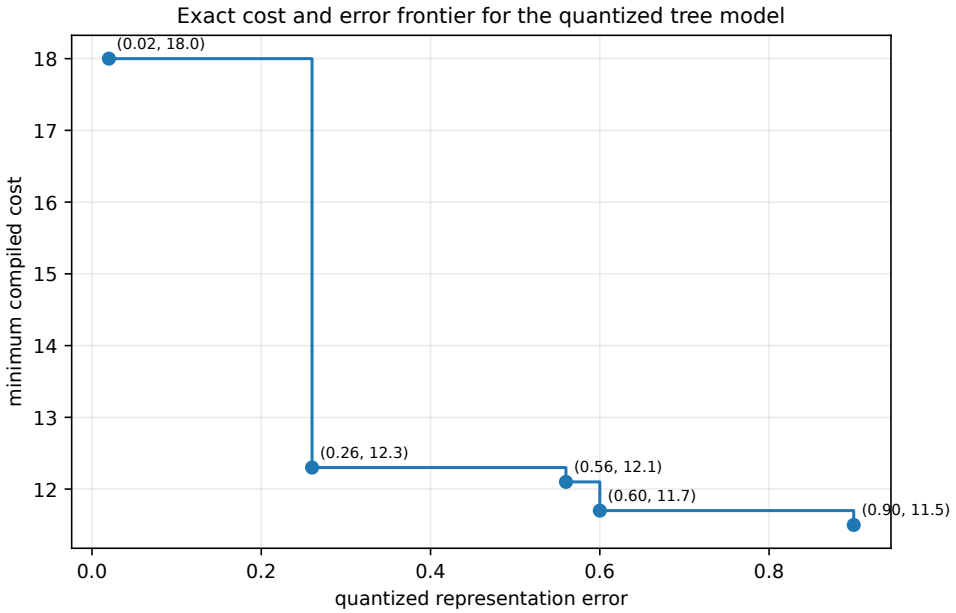

Figure 15. The quantized dynamic program produces the exact cost and error frontier for its finite model.

9.3 An exact error budget compiler

Theorem 9.8 (Quantized budget dynamic program)**.** *Assume every keep error is a nonnegative integer w_v. Let $B \in \mathbb{N}$. For each node v, define $F_v(b)$ as the minimum cost of a pruning of the subtree at v with total error exactly b. The keep option contributes*

$$F_v(w_v) \leq \kappa_v.$$

The split option is obtained by min plus convolution of the child tables, followed by addition of σ_v. The smallest value among

$$F_{\text{root}}(b), \qquad 0 \leq b \leq B,$$

is the exact minimum cost among prunings whose quantized error is at most B.

Proof. The keep case is immediate. In the split case, an admissible pruning is the union of one admissible pruning from each child. Its error is the sum of the child errors and its cost is the sum of their costs plus σ_v. Repeated min plus convolution enumerates every possible distribution of the integer budget across the child subtrees. Induction on the tree proves exactness. □

Corollary 9.9 (Pseudo polynomial complexity)**.** *If the maximum number of children is bounded and the budget is B, the quantized compiler has pseudo polynomial complexity in the number of tree nodes and B. A direct pairwise convolution implementation has quadratic dependence on B at each merge.*

Proof. Every table has at most $B+1$ entries. Merging two tables by direct convolution examines at most $(B+1)^2$ pairs. A bounded number of merges occurs at every node. □

9.4 Decision stability and local updates

Definition 9.10 (Decision gap)**.** At an internal node v, let

$$g_v = |K_\lambda(v) - S_\lambda(v)| .$$

This is the gap between the keep and split scores after the child subproblems have been solved.

Theorem 9.11 (Compiler stability)**.** *Suppose the solved keep score and split score at every internal node change in absolute value by less than $g_v/2$. These are scores after child subproblems have been solved, rather than unconstrained changes in raw local costs. Then every strict keep or split decision in the original optimal pruning remains unchanged.*

Proof. If the original keep score is lower by g_v, then after perturbation it can increase by less than $g_v/2$, while the split score can decrease by less than $g_v/2$. The order remains strict. The split case is the same. Apply the argument from the leaves upward. □

Theorem 9.12 (Local recompilation)**.** *Suppose local costs change only inside the subtree rooted at u, while ancestor and sibling local models are unchanged. Use correct cached sibling values from the old solve. Then every dynamic programming value outside that subtree and outside the ancestor chain from u to the root remains unchanged. Recomputing the subtree at u and that ancestor chain gives the exact new global optimum.*

Proof. A node value depends only on its own local data and the values of its children. Nodes outside the changed subtree and outside the ancestor chain have the same local data and the same child values. Their values remain unchanged. Every affected dependency lies inside the changed subtree or on the unique path from u to the root. □

Remark 9.13 (Boundary of the compiler theorem). The exact compiler requires a finite candidate tree and additive local models. Arbitrary overlapping decompositions, nonlocal cache interactions, global rank coupling, and unrestricted structure discovery can destroy optimal substructure. No universal approximation factor is proved for those settings.

10 Device scheduling and amortization

10.1 Shape classes

Definition 10.1 (Shape class)**.** Two active packet blocks lie in the same shape class when their input dimension, output dimension, right hand side count, scalar type, accumulation type, and kernel contract agree.

Proposition 10.2 (Launch reduction by shape)**.** *Suppose B independent active blocks fall into g shape classes, and suppose the backend accepts one batched array or pointer list for each class. Grouped execution then requires at most g launches instead of B, without changing the arithmetic or the output.*

Proof. Place all blocks in one class along a batch dimension and invoke one batched kernel for that class. Every block receives the same local computation. One launch per class is sufficient. □

CUDA provides graph capture and replay for repeated dependency graphs [23]. These mechanisms reduce repeated launch work, but they do not change the operator or its arithmetic count.

10.2 Critical path

Theorem 10.3 (Acyclic schedule depth)**.** *Let a packet task graph be acyclic. Assume every task takes one normalized stage, every edge is a dependency, and an unlimited number of independent tasks may run concurrently. For a nonempty finite graph, the minimum possible number of sequential stages equals the number of vertices on a longest directed path. The empty task graph has depth zero.*

Proof. Every path gives a lower bound because its tasks must execute in order. The topological level schedule in theorem 6.5 achieves exactly this depth. With no tasks, the empty schedule has depth zero. □

10.3 One time costs

Theorem 10.4 (Amortization threshold)**.** *Let $s \geq 0$ be a one time setup cost. Let $t_b, t_c \geq 0$ be the baseline and candidate times per use and let $R \in \mathbb{N}$ be a reuse count. If $t_b > t_c$, the candidate is faster after R uses exactly when*

$$R > \frac{s}{t_b - t_c}.$$

The smallest integer reuse count is

$$\boxed{R_{\min} = \left\lfloor \frac{s}{t_b - t_c} \right\rfloor + 1.}$$

If $t_b \leq t_c$, no positive reuse count amortizes a positive setup cost.

Proof. Compare

$$s + Rt_c$$

with

$$Rt_b.$$

Rearranging gives the stated inequality. □

Corollary 10.5 (Graph replay threshold)**.** *If graph capture costs $c \geq 0$, ordinary execution costs $t_o \geq 0$, and replay costs $0 \leq t_r < t_o$, then capture is profitable when*

$$R > \frac{c}{t_o - t_r}.$$

Proof. Apply theorem 10.4 with setup cost c. □

Corollary 10.6 (Materialization threshold)**.** *Suppose a compressed representation costs $t_c \geq 0$ per downstream use, an explicit representation costs $t_e \geq 0$ per use, and one time materialization costs $m \geq 0$, with reuse count $R \in \mathbb{N}$. Materialization is profitable exactly when*

$$R > \frac{m}{t_c - t_e}$$

and $t_c > t_e$.

Proof. Compare repeated compressed use with materialization followed by repeated explicit use. □

11 Benchmark contracts and measurement protocol

Performance data are meaningful only after the mathematical and timing contracts are fixed. The protocol follows standard concerns from numerical linear algebra, floating point analysis, and machine performance modeling [17, 14, 27].

Definition 11.1 (Case signature)**.** A case signature records the dimensions, packet layout, rank, right hand side count, random seed, source values, source type, reference computation, and output contract.

Definition 11.2 (Fair match)**.** Two measured rows are a fair match when they share one case signature, return the same declared output, use the same correctness reference, and have identical timing scopes. If one row includes an extra conversion or setup cost, it is a different scope and must be reported separately or added to both rows before comparison.

Proposition 11.3 (Fair matching is an equivalence relation)**.** *On rows with complete metadata, equality of the case signature, output contract, correctness reference, and timing scope is an equivalence relation.*

Proof. Equality of each metadata field is reflexive, symmetric, and transitive. Their conjunction has the same properties. □

Definition 11.4 (Representation gain)**.** Representation gain compares dense and structured work or storage for the same operator, independently of the processor.

Definition 11.5 (Device gain)**.** Device gain compares processors for the same representation, output, and timing scope.

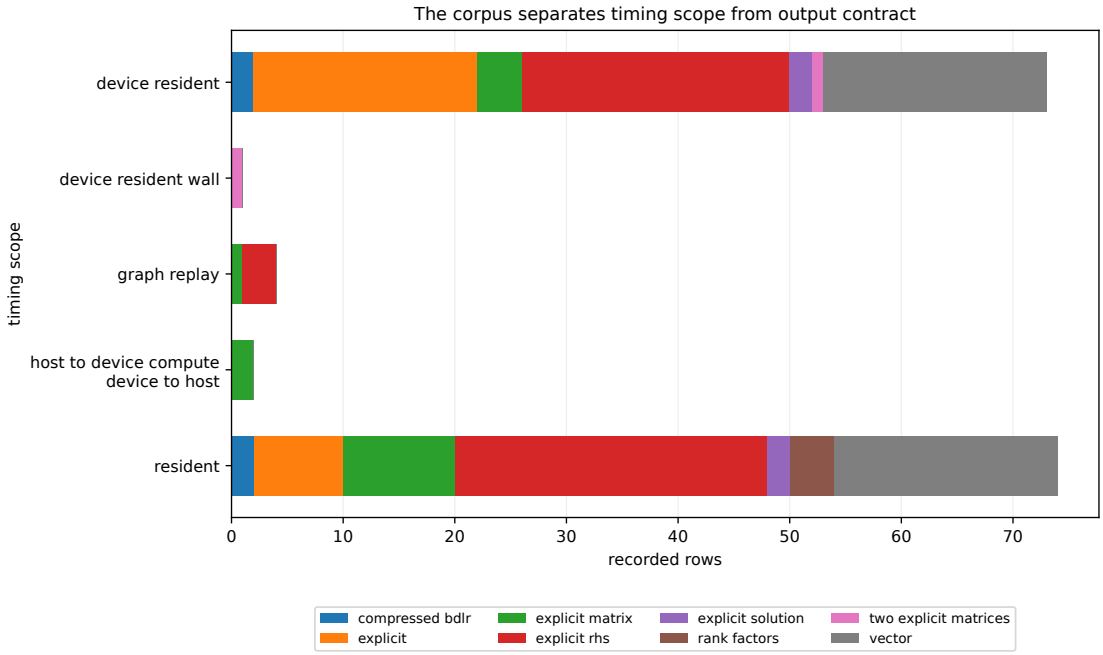

Figure 16. The corpus records timing scope and output contract as separate fields.

Definition 11.6 (Kernel gain)**.** Kernel gain compares two implementations on the same device for the same representation, output, and timing scope.

Definition 11.7 (Amortization gain)**.** Amortization gain records the effect of one time discovery, compilation, transfer, capture, or materialization at a declared reuse count.

A measured total speedup can mix these four effects. A multiplicative decomposition is only exact when matched rows isolate the factors. Otherwise the decomposition is interpretive.

Remark 11.8 (Logical work rate). A structured method may report a dense equivalent logical work rate greater than the physical dense throughput because it does not execute the dense operations. This statistic describes avoided work. It is not a claim that the device performed those operations.

12 Recorded CPU and GPU corpus

The empirical corpus contains 154 measured rows from sixteen suites. It has 74 CPU rows and 80 GPU rows. The GPU was an NVIDIA GeForce RTX 3070 Ti Laptop GPU with compute capability 8.6 and 8 GB nominal memory. The recorded software used PyTorch 2.11.0 with a CUDA 12.8 build. These facts identify the environment. They do not predict another machine.

The 154 archived rows contain recorded case identifiers, seeds, types, output contracts, and timing scopes. Source-value hashes and explicit correctness-reference fields are absent. Setup time, discovery time, and reuse count are nonnull in only two rows each. Correctness errors are present in 149 rows. Equality of available metadata cannot establish the full fair-match relation in definition 11.2. In particular, CPU-resident and GPU-device-resident scopes differ, and graph replay excludes capture while a device-resident baseline has a different raw scope. The two-stream example also compares wall time

Suite	Rows	Suite	Rows
Dense multiplication	28	BDLR application	15
Block diagonal	12	BDLR product	12
Circulant	12	Toeplitz	12
Kronecker	12	Block banded	8
Sparse plus low rank	8	HODLR	8
Strassen	6	Transfer pipeline	5
Walsh Hadamard	4	Hidden blocks	4
Randomized low rank	4	Iterative refinement	4

Table 1. Coverage of the sanitized measured corpus.

Method	Median time in ms	Logical GFLOP per second	Relative error
FP64	541.2803	253.91	2.18×10^{-15}
FP32	18.1309	7580.35	5.76×10^{-7}
TF32	8.6999	15797.75	2.94×10^{-4}
FP16	4.0264	34134.72	3.60×10^{-4}
BF16	4.1482	33132.00	2.88×10^{-3}

Table 2. Recorded dense accuracy and throughput at one dimension.

with a serial device-time scope. The values below are recorded observations with these limitations.

12.1 Dense precision frontier

At dimension 4096, the device resident dense rows gave the values in table 2.

The frontier is not a universal ordering of scalar types. It records one generated family. Packet precision assignment should use local sensitivities and supported kernels rather than one global type.

12.2 Regular packet operators

For an 8192 by 8192 equal block operator with block width 64 and 32 right hand sides, the batched packet calculation took

$$0.046032 \text{ ms}.$$

It was

$$14.8919$$

times faster than the recorded device resident dense GPU row with the same recorded case, output, and timing scope and

$$235.7404$$

times faster than the recorded CPU dense row (resident CPU scope versus device-resident GPU scope). The relative error was

$$8.17 \times 10^{-8}.$$

For BDLR application with the same dimension and right hand side count, block width 64, and rank 8, CUDA Graph replay took

$$0.079872 \text{ ms}.$$

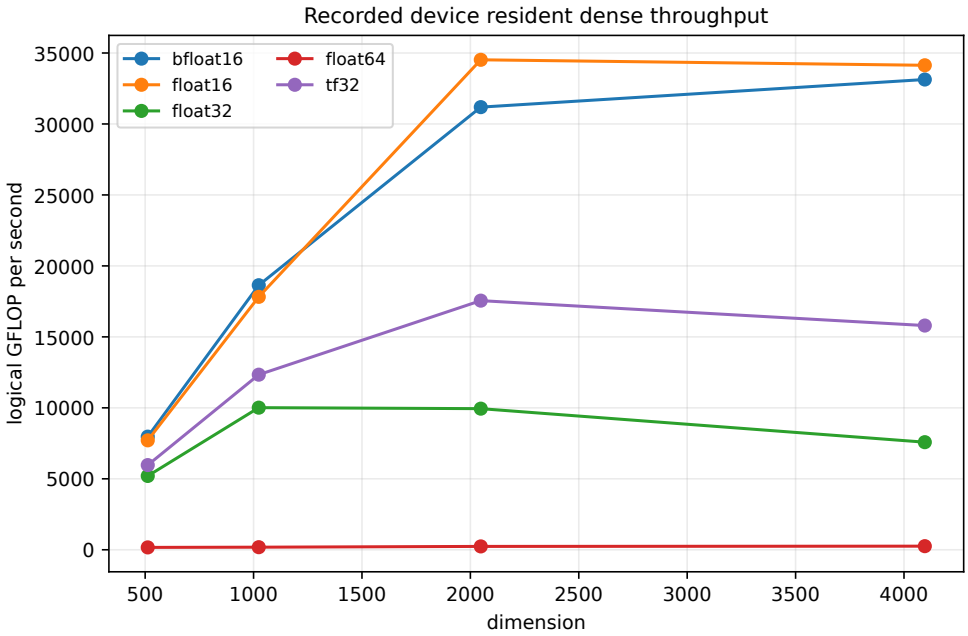

Figure 17. Recorded device resident dense throughput across dimensions and scalar types.

It was

$$10.9355$$

times faster than the recorded dense GPU row (graph-replay scope versus device-resident scope) and

$$153.6527$$

times faster than the recorded CPU dense row (resident CPU scope versus device-resident GPU scope). Capture time was excluded from the replay scope and must be amortized separately.

12.3 Compressed products

A compressed BDLR product returns block and low rank factors. Materialization returns all matrix entries. The recorded product rows illustrate the cost of changing the output contract. Compressed and materialized outputs are separate computations. The GPU materialized BDLR rows at dimensions 512 and 1024 are sums of separately measured factor and expansion medians, as the raw notes state. They are not timing medians for complete workflows.

The algebra in theorem 5.1 explains why the compressed product can remain small. The materialization cost in proposition 3.10 explains why explicit output can erase the advantage.

12.4 Discovery and transfer

For hidden permuted blocks at dimension 512, structure discovery took 2.1102 ms, dense application took 0.0969 ms, and packet application took 0.0151 ms. The exact threshold in theorem 10.4 is 26 uses. At dimension 1024, the corresponding values were 5.2726, 0.1896, and 0.0241 ms, giving 32 uses.

For one 2048 dense FP32 product, device resident graph replay took 1.9993 ms. The end to end pageable path took 7.3036 ms. The pinned path took 6.3084 ms. Two serial device resident products took 3.6557 ms, while the tested two stream path took 4.2368 ms.

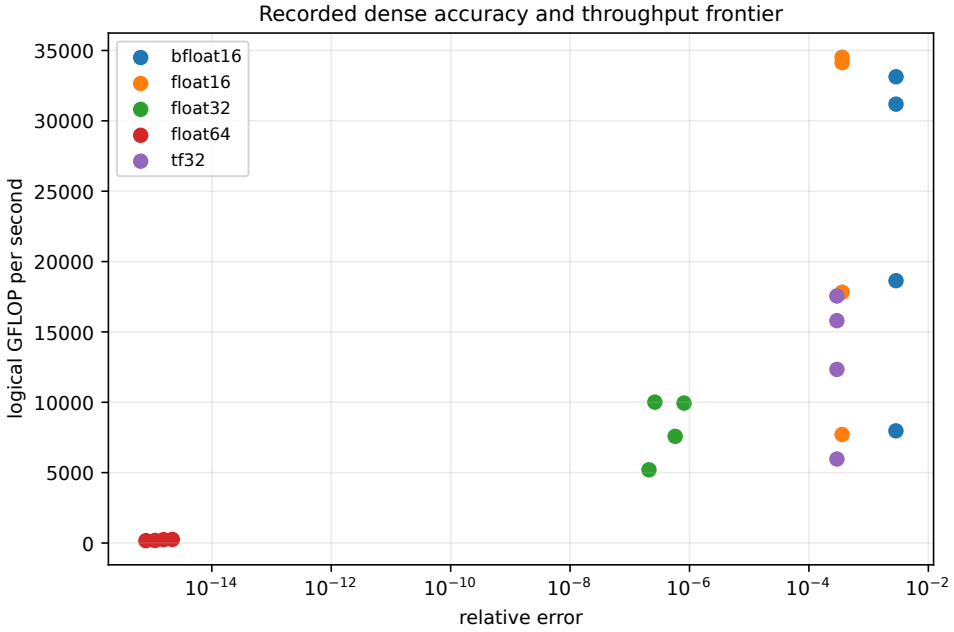

Figure 18. The speed and error tradeoff depends on both precision and problem size.

12.5 Negative controls

The corpus retains methods that lost in the recorded baseline comparisons. These are descriptive ratios. Scope and complete-metadata qualifications apply.

- At dimension 512, recursive Strassen multiplication with leaf size 128 took 7.0950 ms, while the recorded OpenBLAS dense multiplication took 1.9597 ms.
- At dimension 2048, the tested recursive HODLR GPU path took 5.6079 ms, while dense GPU multiplication took 0.0860 ms.
- The tested FP32 iterative refinement solve took 22.0848 ms, while the direct FP64 GPU solve took 12.6286 ms with a comparable final error.
- The two stream dense path was slower than the serial two product path.
- The GPU Walsh–Hadamard transform was slower than the CPU implementation at length 65536, then became faster at length 262144.

Fast multiplication can be asymptotically valuable and still lose at measured sizes because of recursion, memory traffic, and kernel granularity. Hierarchical matrix methods have similar crossover issues [1]. Transform algorithms and tensor factorizations form additional structure classes [7, 24].

13 Implementation and verification

The source corpus contains a small reference implementation of the exact operators and optimization algorithms used in the paper. The mathematical interface is deliberately narrow. This Python implementation is a numerical prototype, not extracted Lean code. Its stored-key support can retain zero-valued blocks, whereas the exact support graph uses nonzero blocks. Its reduced numerical QR is not

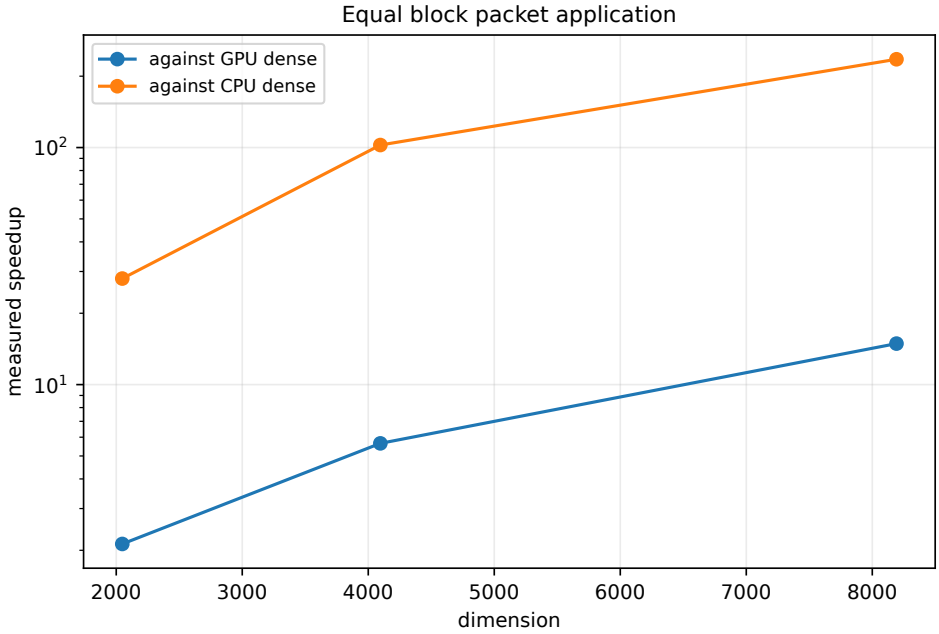

Figure 19. Regular equal shapes expose both representation reduction and batched execution.

the exact rank-compact range construction proved in Appendix F. Prototype tests and theorem proofs therefore have different targets.

1. A packet layout records dimensions and coordinate slices.
2. A packet operator stores active blocks and evaluates them without materializing inactive blocks.
3. BDLR factors support exact application, product, solve, and small core recompression.
4. Graph utilities compute support products, path closure, Schur fill inclusion, and topological levels.
5. Tree dynamic programs solve the Lagrangian and quantized budget models.
6. A multiple choice dynamic program assigns discrete precision options.
7. Benchmark utilities audit case identity, output contracts, timing scopes, and retained negative controls.

The accompanying verification record reports a deterministic verifier with 37392 checks in nine groups. It covers packet evaluation, adjoints, composition, structured primitives, recompression optimality, product chain error, graph support, Schur fill, tree compilation, precision assignment, and the benchmark corpus. It also reports eleven passing unit tests and twenty-three passing original-source tests for BDLR operations, Krylov methods, mixed precision, measured data schema, and figure generation.

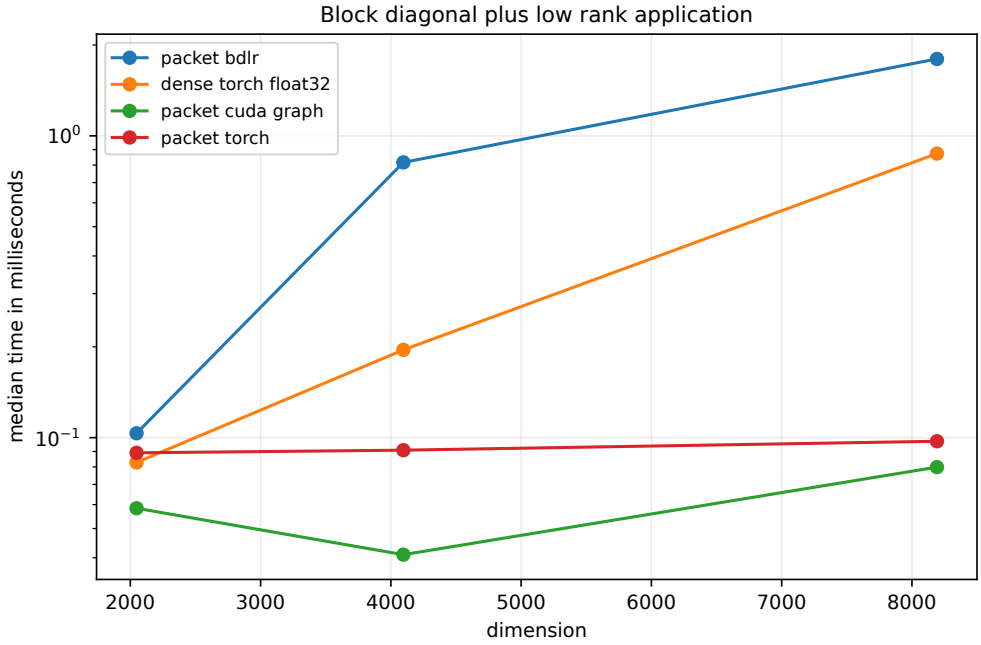

Figure 20. Representation and launch strategy both affect BDLR application time.

Layer	Verification target
Packet semantics	materialization, application, adjoint, composition
Low rank algebra	exact product, Woodbury solve, optimal core recompression
Graph algorithms	path support, topological levels, Schur fill inclusion
Optimization	Lagrangian tree compiler, budget compiler, precision assignment
Numerical bounds	product chain error, block perturbation, clipped allocation
Empirical corpus	row count, suite count, device split, status, error ceiling
Document	proofs, labels, citations, figures, font embedding, render audit

Table 3. Verification layers for the supplied implementation.

14 Hardware implications and exact boundaries

The finite results suggest a device interface with grouped block kernels, low rank contractions, packet metadata, a transfer graph scheduler, and per edge precision tags. Such an interface may reduce materialization and repeated launch work when the operator family remains closed under the chosen representation.

The exact results stop at a finite candidate tree and a declared device model. Three broader problems remain open.

1. A universal discovery algorithm would need to find a profitable packet structure from an arbitrary operator and data distribution. The simultaneous spectral theorem and randomized low rank approximation cover special cases only.

2. A universal compiler would need a controlled approximation factor when costs are nonlocal and candidate decompositions overlap. The dynamic programs in theorems 9.4 and 9.8 do not cover that setting.

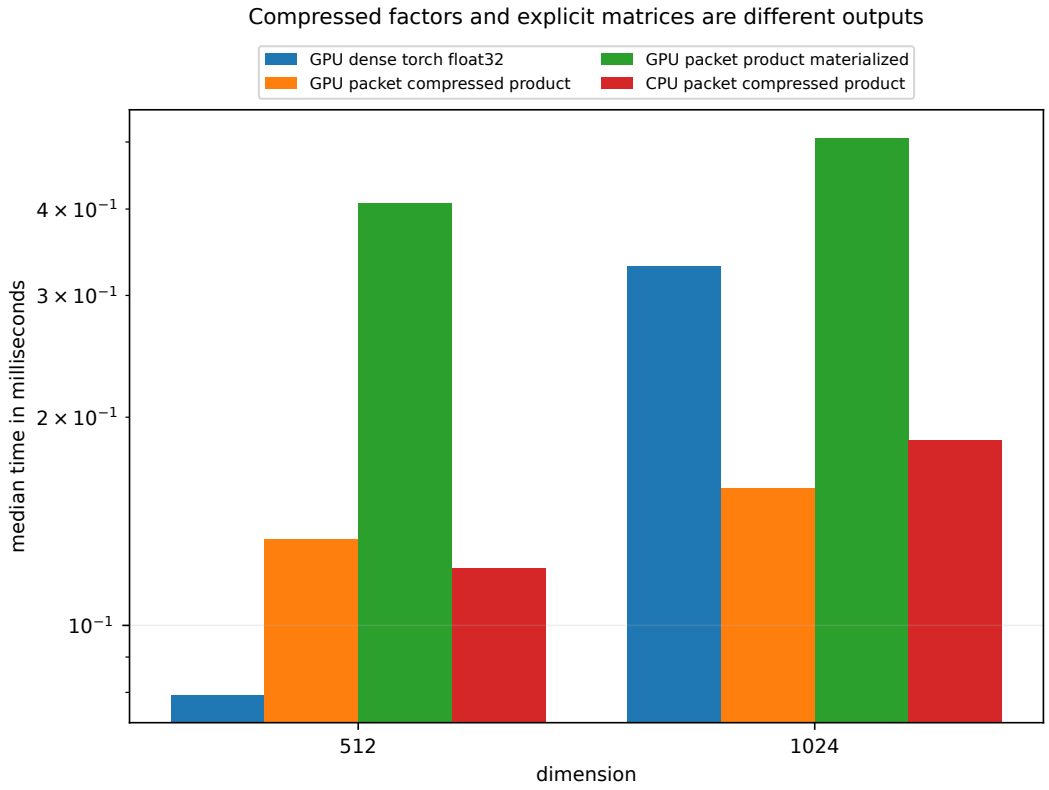

Figure 21. Compressed and explicit products answer different computational questions.

3. A packet native memory hierarchy would need a communication theorem for a family of operators and a specified architecture. The one pass byte model in proposition 3.6 is not such a lower bound.

Communication lower bounds require explicit machine models [19, 2]. CUDA Graph behavior and kernel constraints depend on the installed CUDA platform [23]. The measured results in this paper do not prove an optimal accelerator.

The article also makes no claim about the exponent of generic dense matrix multiplication. Packet algorithms answer a different question. They exploit a restricted operator class and may return a compressed output.

15 Conclusion

A packet operator representation records which block maps exist, how they are stored, and what output they denote. Exact block evaluation and composition turn the support graph into algebra. Arithmetic, storage, and one pass data movement follow from the active block dimensions. Block diagonal plus low rank operators remain closed under multiplication before recompression. Their inverse is reduced by Woodbury, and their correction can be recompressed optimally through a small singular value problem.

Sparse transfer graphs predict path support, triangular schedule depth, and possible fill under elimination. Packet diagonal structure gives local Krylov spaces and a certified block Jacobi condition bound.

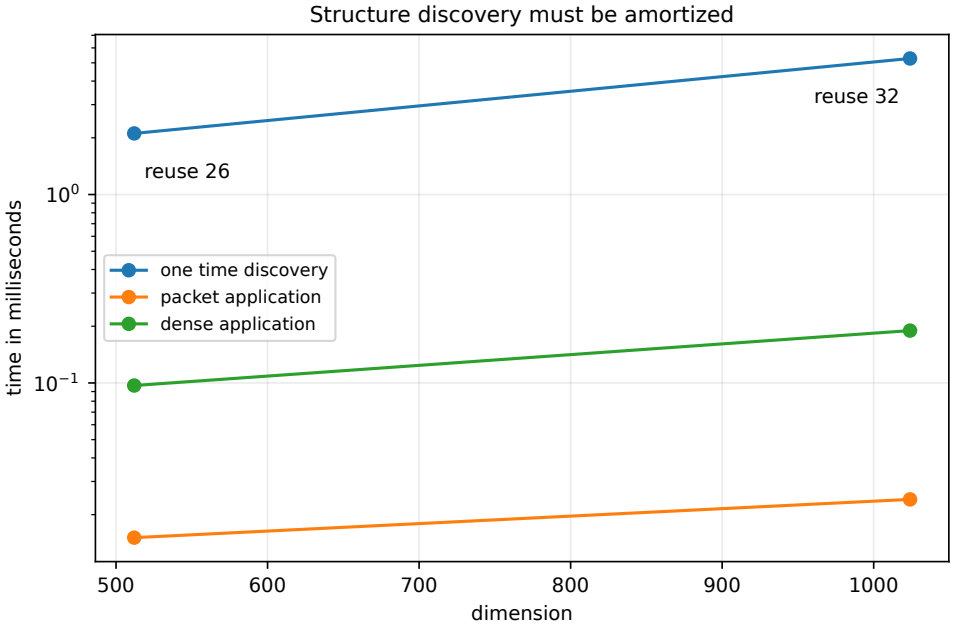

Figure 22. A profitable repeated representation can remain unprofitable for one use.

Packetwise perturbations give a direct mixed precision certificate. Continuous tolerances follow from a convex allocation, while finite data type choices lead to an exact multiple choice budget program.

A finite candidate refinement tree supports a genuine packet compiler. The Lagrangian optimum, the quantized error budget optimum, and local recompilation are exact under additive hypotheses. This is narrower than unrestricted automatic discovery, but it turns one broad compiler conjecture into a proved algorithmic statement.

The measured corpus shows the practical distinction between regular and irregular structure. Equal block and BDLR operators gained substantially on the recorded GPU. Recursive HODLR, Strassen, iterative refinement, a small transform, and an attempted overlap lost to recorded baselines. Discovery, transfer, capture, and materialization changed the break even point.

The computational principle is therefore precise. Remove work through a verified representation. Preserve the declared output. Compile only inside a model whose costs and errors are stated. Assign precision by sensitivity. Amortize one time costs. Keep negative controls. Treat the final timing as a property of the representation, device, kernel, and reuse regime together.

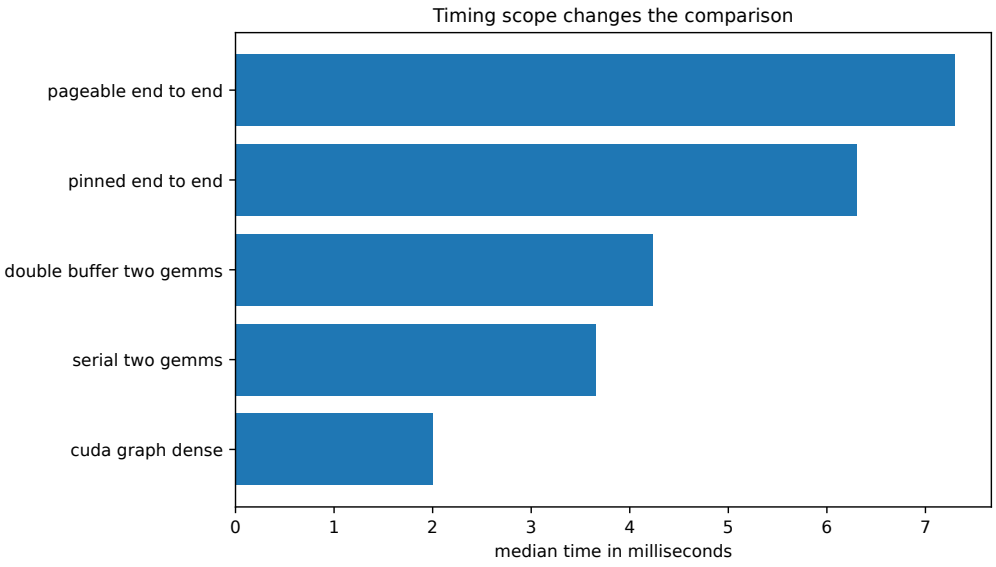

Figure 23. Device residence, transfer, graph replay, and a multioutput pipeline have different timing scopes.

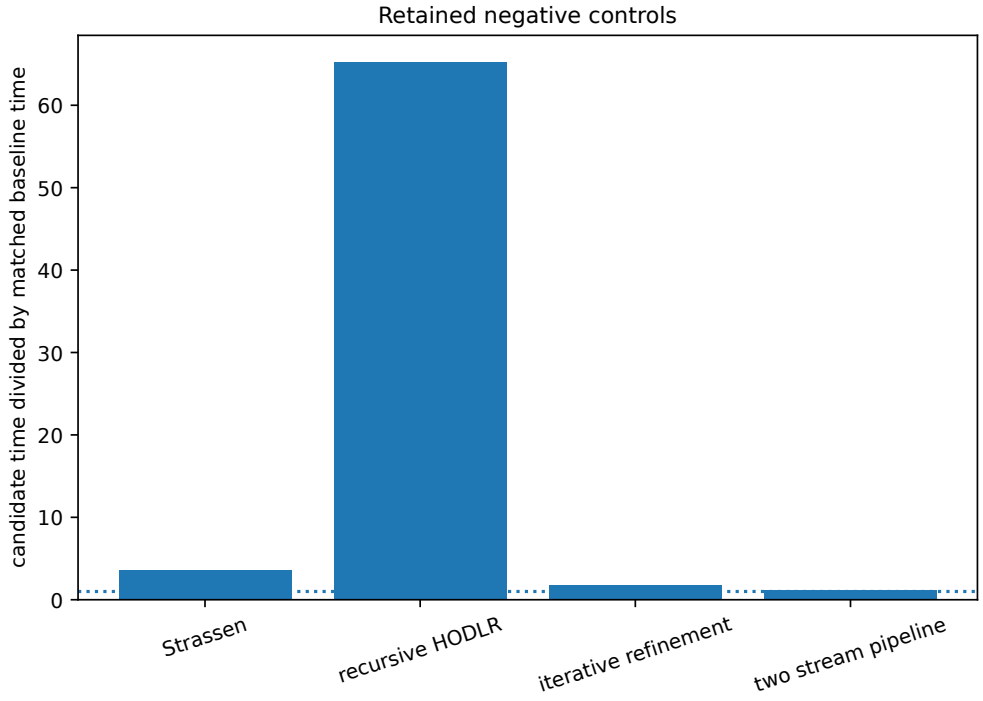

Figure 24. Values above one are slowdowns against the matched baseline.

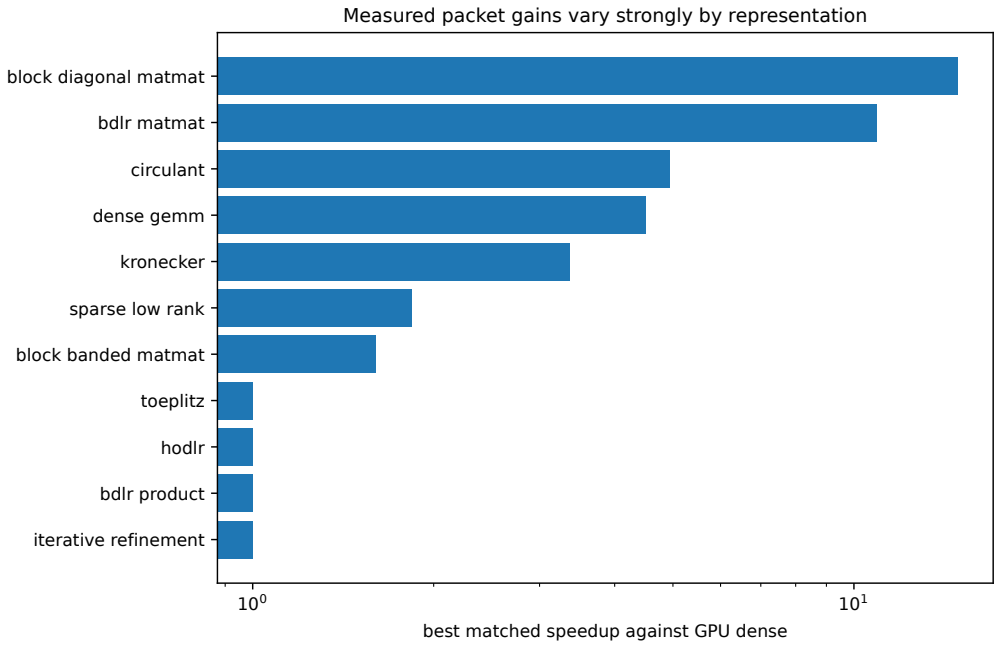

Figure 25. The best recorded gain differs strongly across suites. Regular packet structure dominates the largest measured rows.

A Exact semantics, support, and low-rank identities

This appendix develops exact packet semantics, support propagation, low-rank algebra and error models. Positive-budget conditions are isolated before the allocation theorem in Appendix B.

A.1 Exact packet semantics

Source items 2.3, 2.5, and 2.6

Let R be a ring, I a finite index type, and $(P_a)_{a\in I}$ a family satisfying

$$P_bP_a = \begin{cases} P_a & b = a, \\ 0 & b \neq a, \end{cases} \qquad \sum_a P_a = 1.$$

Write $A_{ba} = P_bAP_a$ and let $E_A = \{(b,a) : A_{ba} \neq 0\}$. These are exact algebraic zeros, not values discarded by a floating-point threshold.

Reconstruction and action. The checked finite sum is

$$\boxed{A = \sum_{(b,a)\in E_A} A_{ba}.}$$

The proof inserts the complete projector sum on both sides and removes only zero summands. Applying this identity to an arbitrary module gives exact action. A separate finite-matrix theorem establishes

$$AZ = \sum_{(b,a)\in E_A} A_{ba}Z$$

for every rectangular batch of right-hand sides Z.

Composition. Inserting the projector identity between factors yields

$$\boxed{(AB)_{ba} = \sum_c A_{bc}B_{ca}.}$$

If the left side is nonzero, at least one intermediate c has both $A_{bc} \neq 0$ and $B_{ca} \neq 0$. Consequently $\operatorname{supp}(AB) \subseteq \operatorname{supp}(A) \circ \operatorname{supp}(B)$. No equality of supports is asserted.

Adjoint and tensor products. With an involution and self-adjoint projectors, the formalization proves

$$(A_{ba})^* = (A^*)_{ab}.$$

For actual finite matrices and actual Kronecker products, it proves

$$(P_b \otimes Q_d)(A \otimes B)(P_a \otimes Q_c) = A_{ba} \otimes B_{dc}.$$

The self-adjointness hypothesis is explicit in the adjoint theorem. The tensor theorem is not a statement about an uninterpreted tensor symbol.

Concrete coordinates. Given any tag map from finite scalar coordinates to packet addresses, `coordinatePackets` constructs diagonal zero-one matrices. Their orthogonality and completeness are proved. The construction allows unequal packet sizes and unused packet addresses. Its action is checked entrywise: it retains exactly the coordinates carrying the selected tag.

The underlying ring-valued projector calculus is imported from the unchanged Chapter VII foundation, which was recompiled in the recorded formal run. Reuse is recorded separately from the new Chapter VIII declarations.

A.2 Support propagation and nilpotence

Source items 6.1, 6.2, and 6.3

A path of length n in the Lean predicate `TransferPath` is a directed walk: vertices may repeat. This is the notion required by matrix powers. At length zero the endpoints coincide. At length $n+1$, a nonzero last block is appended to a length-n walk.

Define the active contribution sum recursively by

$$F_0(b,a) = \begin{cases} P_a & b = a, \\ 0 & b \neq a, \end{cases}$$
$$F_{n+1}(b,a) = \sum_{c:\, A_{bc}\neq 0} A_{bc} F_n(c,a).$$

The checked identity is

$$\boxed{P_b A^n P_a = F_n(b,a) \qquad (n \geq 0).}$$

Its proof is induction using the exact composition theorem, not an assumed support recurrence. When no active walk exists, the corresponding contribution sum is zero, and hence the actual block of A^n vanishes.

Nilpotence certificate. If no walk of length $h+1$ exists between any pair of packets, then

$$\boxed{A^{h+1} = 0.}$$

Every block vanishes, and reconstruction forces the whole operator to vanish. A second theorem derives the required absence of walks from a supplied level map

$$\ell : I \longrightarrow \{0, \dots, h\}, \qquad A_{bc} \neq 0 \implies \ell(c) < \ell(b).$$

It proves that a length-n walk increases the level by at least n. This certifies the acyclic case with a bounded height. This block does not implement or verify an algorithm that constructs a topological ordering or computes the longest path.

Polynomial support. For the actual finite sum

$$p(A) = \sum_{j=0}^{d} c_j A^j,$$

the checked support lies in the union of the support relations of the powers. The formalization treats the $j = 0$ contribution explicitly, so the constant term is not accidentally omitted.

Cancellation control. Lean verifies the rational example

$$A = \begin{bmatrix} 1 & 1 \\ -1 & -1 \end{bmatrix}, \qquad A^2 = 0.$$

The coordinate block A_{00} is nonzero, and a length-two active walk from zero to zero exists. Nevertheless the corresponding block of A^2 is zero. This is an exact counterexample to replacing support inclusion by equality.

A.3 Low-rank algebra and inversion

Source items 5.1, 5.3, and 5.4

Let $A = D_A + U_A V_A^*$ and $B = D_B + U_B V_B^*$ have rectangular factor widths r_A and r_B. The formalization constructs

$$U_C = \begin{bmatrix} D_A U_B + U_A (V_A^* U_B) & U_A \end{bmatrix},$$
$$V_C = \begin{bmatrix} V_B & D_B^* V_A \end{bmatrix}$$

and proves

$$\boxed{AB = D_A D_B + U_C V_C^*.}$$

These are actual concatenated matrices with $r_B + r_A$ columns. Expanding the product and grouping the terms with common right factors proves the identity. The separate rank theorem establishes

$$\operatorname{rank}(AB - D_A D_B) \le r_A + r_B.$$

It bounds actual matrix rank, not just the number of stored columns. Packet diagonality of $D_A D_B$ follows from diagonality of both factors and the checked block-composition formula.

Woodbury. For D and

$$S = I + V^* D^{-1} U$$

both invertible, Lean checks the ordinary matrix inverse formula

$$\boxed{(D + UV^*)^{-1} = D^{-1} - D^{-1} U S^{-1} V^* D^{-1}.}$$

The proof specializes Mathlib's classical Woodbury identity. A separate theorem derives invertibility of $D + UV^*$ from the two stated assumptions. A further theorem verifies that multiplying the proposed inverse by any batch Z solves the updated system. Invertibility of the update is not inserted as an extra premise.

Norm bound. Over the real or complex scalars, all matrix norms in the following theorem are Hilbert-space operator norms, including the rectangular factors:

$$\boxed{\left\|(D + UV^*)^{-1}\right\| \le \left\|D^{-1}\right\| + \left\|D^{-1}U\right\| \left\|S^{-1}\right\| \left\|V^* D^{-1}\right\|.}$$

After the checked inverse identity, the proof uses the triangle inequality and two rectangular operator-norm product bounds.

Not covered here. The arbitrary product-chain rank corollary, optimal small-core recompression, singular-value approximation theorem, chain perturbation bounds, and numerical stability of a particular solve implementation are not marked complete by these results. Algebraic representability is not a GPU execution-time guarantee.

A.4 Packet perturbation certificates

Source item 8.1 and two uniform consequences

Let X be a normed space over a nontrivially normed field. The formal objects are actual continuous linear maps $X \to X$, with their operator norm. Let $a(e)$ identify the source packet of edge e, and suppose

$$\Delta_e = \Delta_e P_{a(e)}.$$

Set

$$A = \sum_e A_e, \qquad \widehat{A} = \sum_e (A_e + \Delta_e).$$

The exact operator and vector identities are proved first:

$$\widehat{A} - A = \sum_e \Delta_e P_{a(e)}, \qquad (\widehat{A} - A)x = \sum_e \Delta_e (P_{a(e)} x).$$

Applying the finite triangle inequality and the defining operator-norm estimate gives

$$\boxed{\left\|(\widehat{A} - A)x\right\| \le \sum_e \|\Delta_e\| \left\|P_{a(e)} x\right\|.}$$

If $\|\Delta_e\| \le \varepsilon_e \|A_e\|$, then the formal relative certificate is

$$\boxed{\left\|(\widehat{A} - A)x\right\| \le \sum_e \varepsilon_e \|A_e\| \left\|P_{a(e)} x\right\|.}$$

The source additionally assumes that each exact block is source supported. The proof of this bound does not need that assumption. The checked statement therefore uses weaker sufficient hypotheses without weakening the conclusion.

Uniform operator estimates. Two additional checked consequences are

$$\left\|\widehat{A} - A\right\| \le \sum_e \|\Delta_e\| \left\|P_{a(e)}\right\|$$

and, when $\|P_a\| \le 1$ for every packet,

$$\boxed{\left\|\widehat{A} - A\right\| \le \sum_e \|\Delta_e\|.}$$

These estimates are uniform in the input vector and can be used as inputs to later chain analyses. The chain results themselves are not included in this block's completed inventory.

Implementation boundary. The maps Δ_e and their bounds must be supplied or justified for a numerical implementation. This formalization does not establish IEEE rounding behavior, prevent overflow or underflow, model a CUDA kernel, or certify the recorded device speedups. Those are distinct claims and require separate evidence.

A.5 Positive budget and feasibility

Positive-budget condition for item 8.4

Positive budget is necessary. The source minimizes

$$\sum_e c_e \log \frac{1}{\varepsilon_e}, \qquad \varepsilon_e > 0, \qquad \sum_e s_e \varepsilon_e = \tau,$$

with positive sensitivities and costs. The positive-budget condition is essential. For a nonempty edge set, Lean proves

$$s_e > 0 \text{ and } \varepsilon_e > 0 \text{ for all } e \quad \Longrightarrow \quad \sum_e s_e \varepsilon_e > 0.$$

It follows that every nonpositive budget is infeasible. A one-edge, unit-sensitivity, zero-budget instance is checked as an exact boundary example.

The nonempty-index statement requires $\tau > 0$. Nonemptiness also makes the sum of positive costs in the displayed optimizer's denominator positive. The empty edge set is treated separately. Existence, global optimality and uniqueness for the positive-budget problem are proved in Section B.4.

B Exact compilation, continuous precision, and explicit costs

This appendix gives finite compiler constructions, continuous allocation and explicit storage and operation models. All optimization statements retain their independent admissibility conditions.

B.1 Exact finite-tree compilation

Source items 9.4 and 9.5

A candidate tree is either a terminal node or an internal node with a nonempty finite family of children. Arbitrary finite branching is supported. Every node carries a label from which keep cost κ_v, keep error ϵ_v, and split overhead σ_v are read.

Independent admissible objects. A legal cut is defined independently of the optimizer. It either keeps the root of its subtree or, at an internal node, chooses one legal cut in every child. A terminal node can only be kept. This is the recursive form of selecting one node on each root-to-terminal path.

The cost and error of a cut L are computed recursively. With multiplier λ, its objective is

$$J_\lambda(L) = \mathrm{cost}(L) + \lambda\,\mathrm{err}(L).$$

Lean proves that this objective equals the recursively accumulated local keep score $\kappa_v + \lambda\epsilon_v$, with σ_v charged at every split.

Recurrence. For terminal nodes,

$$F_\lambda(v) = \kappa_v + \lambda\epsilon_v.$$

For internal nodes,

$$\boxed{F_\lambda(v) = \min\left\{\kappa_v + \lambda\epsilon_v,\ \sigma_v + \sum_{w\in\mathrm{child}(v)} F_\lambda(w)\right\}.}$$

The checked result has two parts. First, $F_\lambda(v) \le J_\lambda(L)$ for every legal cut of the subtree. Second, the constructed function `compile` returns a legal cut with objective exactly $F_\lambda(v)$. Thus the minimum is attained, not merely bounded below.

The proof proceeds by induction on the actual tree and case analysis on the independently defined cut. In the split case, it sums the child lower bounds. The returned cut chooses the lower root alternative and recursively uses attaining child cuts. Ties are resolved in favor of keeping.

Shared operator families. For reuse weights r_j, the local keep model can aggregate setup and per-operator costs:

$$\kappa_v = \kappa_v^{\mathrm{setup}} + \sum_j r_j \kappa_v^{(j)}, \qquad \epsilon_v = \sum_j r_j \epsilon_v^{(j)}.$$

Lean proves the aggregation identity at the cut level, including split overhead, before applying the compiler theorem. The proof is valid over an ordered field, including $\mathbb{Q}$ and $\mathbb{R}$. The intended nonnegative model is a specialization.

No running-time theorem is asserted for the returned-cut wrapper. It can recompute subtree scores when constructing the cut. The minimum-value recurrence and the separately checked cached-update algorithm have distinct implementations and claims.

B.2 Frontiers and decision stability

Source items 9.6, 9.7, and 9.11

Let L_1, L_2 be actual optima at $0 \le \lambda_1 < \lambda_2$. Their optimality inequalities are

$$\begin{aligned} \operatorname{cost}(L_1) + \lambda_1 \operatorname{err}(L_1) &\le \operatorname{cost}(L_2) + \lambda_1 \operatorname{err}(L_2), \\ \operatorname{cost}(L_2) + \lambda_2 \operatorname{err}(L_2) &\le \operatorname{cost}(L_1) + \lambda_2 \operatorname{err}(L_1). \end{aligned}$$

Adding them and using the strict multiplier ordering gives

$$\boxed{\operatorname{err}(L_2) \le \operatorname{err}(L_1), \qquad \operatorname{cost}(L_2) \ge \operatorname{cost}(L_1).}$$

These conclusions hold for any choices among tied optima. For the cuts returned by the compiler, the required optimality premises are supplied by its constructive correctness theorem.

Supported Pareto points. For $\lambda > 0$, a scalarized optimum cannot be dominated in both cost and error with one strict improvement. Lean proves this directly from the two inequalities and positivity of λ.

The converse is not asserted. For the three cost/error points

$$(0, 2), \qquad (3/2, 1), \qquad (2, 0),$$

the middle point is undominated, but it is not selected by scalarization. A checked rational inequality gives, for every $\lambda \in \mathbb{Q}$,

$$\min\{2\lambda, 2\} < 3/2 + \lambda.$$

The quantized-budget compiler can recover unsupported points. Its construction is given in Section C.5.

Strict half-gap stability. At a solved internal node write

$$K = \kappa_v + \lambda \epsilon_v, \qquad S = \sigma_v + \sum_w F_\lambda(w), \qquad g = |K - S|.$$

If the updated scores satisfy

$$|K' - K| < g/2, \qquad |S' - S| < g/2,$$

Lean proves

$$K' \le S' \quad \Longleftrightarrow \quad K \le S.$$

Applying this condition recursively at every internal node proves equality of the entire returned cuts before and after perturbation, not only equality of one numerical minimum.

The hypotheses concern *solved* split scores, including changes propagated from descendants. A bound on raw local costs alone is not substituted for this condition. At an exact tie $g = 0$, the strict inequalities cannot hold. No robustness at ties is claimed.

B.3 Cached local recompilation

Source item 9.12

The implementation represents an edit using an explicit one-hole context. Each ancestor frame stores its parent label, the untouched sibling subtrees, the child slot containing the edit, and cached sibling optimum values. The context terminates at the root.

Let v be the new optimum of the edited subtree, and let j be the edited child slot at one frame. The update performed at that frame is

$$\boxed{\operatorname{step}(v) = \min \left\{ K,\ \sigma + \sum_i \begin{cases} v, & i = j, \\ \widehat{F}_i, & i \neq j. \end{cases} \right\}.}$$

This result is passed to the next ancestor. The update function does not recursively evaluate sibling subtrees. It reads their stored values $\widehat{F}_i$.

Cache validity. A context is valid when each untouched sibling cache equals the optimum for its unchanged subtree. The function `refresh` constructs such a context from the original tree model, and Lean proves its validity. This assumption concerns old, unchanged sibling computations. It is not an assumption about the desired new root optimum.

Correctness of the actual update. For any edited subtree T' and valid context C, Lean proves

$$\operatorname{updateValue}(C, F(T')) = F(\operatorname{fill}(C, T')).$$

The proof inducts through the context. At each frame, the updated child contributes the new value, and each other child contributes its unchanged cached optimum. The frame recurrence is therefore exactly the full-tree recurrence.

The result is connected back to legal cuts: the updated value is no larger than the objective of any cut of the edited whole tree, and some cut attains it. The latter witness follows from the independently proved compiler theorem.

Unchanged context. Separate theorems show that a nonedited sibling subtree is unchanged by the child replacement, and its minimum value is consequently unchanged. A localized change of keep/error/overhead data can be represented by replacing just the corresponding subtree while leaving the surrounding model fixed.

This formalizes the dependency-local claim: recompute the edited subtree, then update the ancestor frames using old sibling caches. It does not assert that a real compiler has no nonlocal cache, rank, allocation, or device-scheduling interactions. Those interactions are outside the additive tree model.

B.4 The continuous allocation theorem

Source item 8.4, with an explicit positive budget

Let E be a finite nonempty edge set. Assume

$$s_e > 0, \qquad c_e > 0, \qquad \tau > 0,$$

and define $C = \sum_e c_e$. The optimization problem is

$$\min_{\varepsilon_e > 0} \sum_e c_e \log \frac{1}{\varepsilon_e} \qquad \text{subject to} \qquad \sum_e s_e \varepsilon_e = \tau.$$

Lean constructs the displayed candidate

$$\boxed{\varepsilon_e^* = \frac{\tau c_e}{s_e C}}$$

and proves strict positivity and the exact budget equality. It then proves global optimality and uniqueness for the actual logarithmic objective.

Global comparison. For any other feasible ε, set $r_e = \varepsilon_e / \varepsilon_e^* > 0$. The budget identities give

$$\sum_e c_e r_e = C.$$

Using the standard analytic inequality $\log r \le r - 1$ yields

$$\sum_e c_e \log r_e \le \sum_e c_e (r_e - 1) = 0.$$

Lean separately proves the exact objective-difference identity

$$J(\varepsilon) - J(\varepsilon^*) = -\sum_e c_e \log r_e.$$

Therefore $J(\varepsilon) \ge J(\varepsilon^*)$.

If the feasible vectors differ, at least one $r_e \ne 1$. At that coordinate the logarithm inequality is strict. Since $c_e > 0$, the finite weighted sum is strict, giving

$$\varepsilon \ne \varepsilon^* \quad \Longrightarrow \quad J(\varepsilon) > J(\varepsilon^*).$$

The final theorem characterizes every feasible global minimizer as exactly the constructed formula. No unproved stationary-point, convexity, or KKT optimality assertion is supplied as a hypothesis.

Why the hypothesis matters. Section A.5 shows that positive sensitivities and positive tolerances on a nonempty edge set force a positive budget. The theorem above states that condition explicitly and proves the unique global optimum.

This is a real-valued mathematical optimizer. It is not an executable floating-point implementation. Clipped allocation is treated in Sections D.5–D.6. The discrete precision program is treated in Section C.4.

B.5 Explicit storage and operation models

Source items 3.1, 3.2, 3.4, 3.6, 3.8–3.10, and 4.2

For a finite collection of rectangular blocks, the scalar addresses are actual elements of

$$\coprod_{e \in E} (\mathrm{Fin}(m_e) \times \mathrm{Fin}(n_e)).$$

The corresponding operation addresses include a right-hand-side index and one of two scalar-operation tags. Lean proves their cardinalities rather than merely defining a formula named “cost.”

Representation	Scalar storage	Modeled work for q right sides
Dense	n^2	$2qn^2$
Packet blocks	$\sum_e m_e n_e$	$2q\sum_e m_e n_e$
Equal diagonal blocks	nb	$2qnb$
BDLR	$\sum_i n_i^2 + 2nr$	$2q(\sum_i n_i^2 + 2nr)$
Equal-block BDLR	$n(b+2r)$	$2qn(b+2r)$
Sparse plus low rank	$z + 2nr$	$2q(z+2nr)$

For equal blocks, the layout condition is $n = |I|b$. Under nonzero denominator conditions, the dense-to-block reduction is n/b and the BDLR reduction is $n/(b+2r)$. The BDLR output thin product accumulates into the diagonal result under the declared model of two operations per coefficient.

Streaming. The explicit event type counts one block read, one source read, and a target read plus write for every edge. With scalar size s, its byte count is

$$B_{\text{stream}} = s\sum_e (m_e n_e + n_e q + 2m_e q).$$

No cross-edge cache reuse is assumed. Sparse index metadata and temporary workspace remain separate.

Capacity and roofline. Positive physical capacities and the inequalities $F \le PT$, $B \le WT$ give

$$T \ge \max\{F/P, B/W\}.$$

For positive bytes and elapsed time, the rate form is $F/T \le \min\{P, WF/B\}$. The dense memory bound is the exact equivalence $n^2 s \le M \iff n \le \sqrt{M/s}$ for nonnegative n, M and positive s.

Materialization. The declared dense product followed by one addition at each output entry has exactly $2n^2 r + n^2$ modeled events and n^2 output entries. The remainder is bounded by n^2 for every n, r, giving a concrete quadratic certificate for the manuscript's $O(n^2)$ term.

These theorems count a mathematical model. They do not verify CUDA instructions, wall time, memory system behavior, or a lower bound for every implementation.

B.6 Contracts, grouping, and amortization

Source items 2.9, 10.2, 10.4–10.6, and 11.3

Output conversion. A decoded run returns the actual pair

$$(\text{decode}(\text{compressed}(x)),\ t_{\text{run}}(x) + t_{\text{decode}}(\text{compressed}(x))).$$

Under the declared output equality, Lean proves that this returns the same explicit result and charges the conversion time. It also proves the downstream composition identity when compressed output is consumed directly. Omitting a positive decode cost strictly understates the modeled explicit-output time. This formalizes the protocol. It cannot certify the truth of measured times.

Shape grouping. Active shape classes are the image of the complete shape-signature map. Their count is at most the number of active blocks. The fiberwise sum over classes equals the original block sum, both for additive outputs and for modeled work. Thus grouping neither loses nor duplicates

contributions. The ability to process one class in one batched launch remains a backend capability premise.

Exact profitability. With setup s, baseline time t_b, candidate time t_c, and $t_c < t_b$, Lean proves

$$\boxed{s + Rt_c < Rt_b \quad \Longleftrightarrow \quad R > \frac{s}{t_b - t_c}.}$$

For $s \geq 0$ and natural-number reuse counts, the smallest profitable count is

$$\boxed{R_{\text{min}} = \left\lfloor \frac{s}{t_b - t_c} \right\rfloor + 1.}$$

It is proved both profitable and minimal. At equality there is only break-even. A checked example gives setup 6, baseline 5, candidate 3: three uses break even, and four are the first profitable count. Zero setup gives a first profitable count of one when there is a per-use advantage.

When the candidate is no faster per use, nonnegative setup and reuse cannot give strict profitability. Graph capture/replay is a direct specialization. For materialization, with nonnegative conversion cost and reuse, Lean proves the full equivalence: profitability requires both a lower explicit per-use time and reuse above the conversion threshold.

Fair matching. The benchmark signature has separate case, output-contract, correctness-reference, and timing-scope fields. Equality of all four fields is proved equivalent to signature equality, hence reflexive, symmetric, and transitive. Measured time is deliberately not a field in this equivalence. Matching metadata is not proof of measurement accuracy.

B.7 Place in the finite development

The integer-budget compiler and discrete precision program follow in Appendix C. Structured transforms and clipped allocation are developed in Appendix D, graph support and schedules in Appendix E, and optimal small-core recompression in Appendix F.

The accompanying source files preserve the compiler, regression and proof-development records.

C Product chains, Krylov spaces, and integer budgets

This appendix develops product-chain bounds, packet Krylov identities and exact integer-budget programs. Cost, error and candidate-set assumptions remain explicit.

C.1 Low-rank factors through a product chain

Source item 5.2

Let

$$A_j = D_j + U_j V_j^*, \qquad U_j, V_j \in \mathbb{C}^{n \times r_j},$$

with all D_j diagonal in one packet layout. Set

$$P_m = A_m \cdots A_1, \qquad D^{(m)} = D_m \cdots D_1.$$

The formalization constructs thin matrices L_m, R_m such that

$$\boxed{P_m = D^{(m)} + L_m R_m^*.}$$

Their column index type is a recursively constructed disjoint sum. Its cardinality is proved to equal $\sum_{j=1}^{m} r_j$.

Construction. Suppose $P_{m-1} = D^{(m-1)} + L_{m-1} R_{m-1}^*$. The new factors are

$$L_m = \begin{bmatrix} D_m L_{m-1} + U_m (V_m^* L_{m-1}) & U_m \end{bmatrix},$$
$$R_m = \begin{bmatrix} R_{m-1} & (D^{(m-1)})^* V_m \end{bmatrix}.$$

Substitution into the already checked two-factor product identity proves exactness. This is not a rank-only existence argument. The recursively defined factors are themselves audited.

Applying the ordinary matrix-rank inequality gives

$$\boxed{\operatorname{rank}(P_m - D^{(m)}) \le \sum_{j=1}^{m} r_j.}$$

The bound concerns the actual correction matrix, not just the number of allocated columns. The proof also shows that $D^{(m)}$ stays packet diagonal. The empty chain has identity base, empty column type, and zero correction. Individual $r_j = 0$ are permitted.

What is not completed here. This is an unrecompressed representation. Optimal small-core singular-value recompression, item 5.6, remains separate. The construction can accumulate redundant columns and is not a claim of minimal factor width.

C.1.1 Actual noncommutative products

The error module defines the left-accumulated product recursively, with $P_0 = I$ and $P_{j+1} = A_{j+1} P_j$. For a perturbed sequence $\widehat{A}_j$, it derives the discrepancy recursion

$$\widehat{P}_{j+1} - P_{j+1} = \widehat{A}_{j+1}(\widehat{P}_j - P_j) + (\widehat{A}_{j+1} - A_{j+1}) P_j.$$

The identity follows from the actual products. It is not supplied as an assumption to a norm estimate, and it does not commute the operators. Lean uses zero-based indices internally, so index j in source code corresponds to manuscript factor $j+1$.

C.2 Error propagation and recompression

Source items 5.8, 5.9, and 8.3

For $\widehat{A}_j = A_j + E_j$, the checked product-chain bound is

$$\boxed{\left\|\widehat{A}_m \cdots \widehat{A}_1 - A_m \cdots A_1\right\| \le \sum_{j=1}^{m} \left(\prod_{i=j+1}^{m} \left\|\widehat{A}_i\right\|\right) \|E_j\| \left(\prod_{i=1}^{j-1} \|A_i\|\right).}$$

Empty products are one. The proof first solves a scalar gain recurrence as a finite sum, then bounds the actual discrepancy recursion by it. A version with certified upper bounds $\delta_j \ge \|E_j\|$ is included. The product-norm argument uses a norm-one identity, as in operators on a nonzero normed space.

Post-product recompression is different. Define the implemented iterates by

$$\widetilde{P}_0 = I, \qquad \widetilde{P}_j = A_j \widetilde{P}_{j-1} + E_j.$$

Here E_j is a residual introduced after multiplication. Lean derives

$$\widetilde{P}_j - P_j = A_j(\widetilde{P}_{j-1} - P_{j-1}) + E_j$$

and proves

$$\boxed{\left\|\widetilde{P}_m - P_m\right\| \le \sum_{j=1}^{m} \left(\prod_{i=j+1}^{m} \|A_i\|\right) \delta_j, \quad \|E_j\| \le \delta_j.}$$

This theorem works in a normed ring without the extra norm-one condition. It includes the empty iteration. There is no exact-prefix factor in the local residual term, because the residual is already measured at the post-product output.

Packetwise mixed precision. At each stage let

$$A_j = \sum_e A_{j,e}, \qquad \widehat{A}_j = \sum_e (A_{j,e} + \Delta_{j,e}), \qquad \Delta_{j,e} = \Delta_{j,e} P_{j,a(e)}.$$

The previous packet certificate supplies the uniform operator bound

$$\left\|\widehat{A}_j - A_j\right\| \le \delta_j := \sum_e \|\Delta_{j,e}\| \left\|P_{j,a(e)}\right\|.$$

The new theorem substitutes these δ_j into the actual product-chain estimate. The resulting vector error is at most the operator certificate times $\|x\|$. A vector-specific packet bound is not silently reused as an operator norm.

These are deterministic implications from stated residual bounds. They do not establish the rounding behavior of a floating-point kernel. The floating-point matrix-product model remains one of the separately tracked classical inputs.

C.3 Exact and approximate packet Krylov spaces

Source items 7.2 and 7.3

Write

$$\mathcal{K}_m(A, v) = \operatorname{span}\{v, Av, \dots, A^{m-1}v\}.$$

For a complete finite projector family P_i, suppose A commutes with every P_i. Let $A_i = P_i A P_i$. Lean proves the actual orbit identity

$$A^j v = \sum_i A_i^j P_i v$$

and therefore

$$\boxed{\mathcal{K}_m(A, v) \subseteq \bigoplus_i \mathcal{K}_m(A_i, P_i v).}$$

The case $j = 0$ uses $\sum_i P_i = I$. The zeroth local power is the ambient identity, applied to $P_i v$, rather than an incorrectly substituted local projector power.

The direct sum is justified. Each local space is proved to lie in the actual range of P_i. Projecting a finite sum of local vectors selects its ith summand. Consequently a zero sum of local vectors has every summand zero. The proof does not assert equality between the global Krylov space and the full sum of local Krylov spaces.

For approximate invariance let $A = D + K$, where D is packet diagonal, and set

$$M = \max\{\|A\|, \|D\|\}.$$

For every positive integer j, the operator estimate is

$$\boxed{\left\|A^j - D^j\right\| \le j M^{j-1} \|K\|.}$$

The proof is noncommutative and uses actual powers. Its positive-index version works even in a trivial normed ring. No division by M is used, so $M = 0$ causes no exception.

Define the comparison space

$$\mathcal{L}_{j+1} = \bigoplus_i \mathcal{K}_{j+1}(P_i D P_i, P_i v).$$

Packet diagonality is first shown to imply commutation. The exact theorem then proves $D^j v \in \mathcal{L}_{j+1}$. Using that vector as a witness in the infimum distance gives

$$\boxed{\operatorname{dist}(A^j v, \mathcal{L}_{j+1}) \le j M^{j-1} \|K\| \|v\|.}$$

This statement uses Lean's actual metric infimum distance to the subspace. It does not assume that the comparison vector lies there. The block-Jacobi condition bound and the preconditioned conjugate-gradient corollary are not completed by these Krylov results.

C.4 Integer error budgets and discrete precision

Source item 8.7 and common minimum machinery

The finite budget programs use integer weights and exact ordered-field costs. They apply to rational costs for execution and to real costs for mathematical statements. Unreachable states are represented by `none`, not by a large finite sentinel.

For a predicate S on costs, the common minimum specification means:

$$\begin{aligned} &\texttt{none}: && \text{no cost satisfies } S,\\ &\texttt{some}(v): && S(v) \text{ and } v \le z \text{ whenever } S(z). \end{aligned}$$

Both attainment and minimality are included. Optional minimum and optional addition are proved to implement union and independent sum of feasible sets.

For exact-weight tables F, G, min-plus convolution is

$$(F \star G)(b) = \min_{0 \le k \le b} \{F(k) + G(b-k)\},$$

with an infeasible sum whenever either operand is infeasible. Its correctness theorem identifies every finite answer with an actual feasible pair of component weights and costs. Repeated convolution handles arbitrary finite lists of components.

Independent precision assignments. For every edge, a finite list contains its permitted pairs (w, c) of quantized error and cost. The legal assignment type chooses exactly one listed pair per edge. It is defined independently of the dynamic program. Costs and weights are then summed over that assignment.

If D is the already solved tail table, the next edge has exact-weight recurrence

$$F(b) = \min_{(w,c)\ \text{allowed},\ w \le b} \{D(b-w) + c\}.$$

The final answer is $\min_{0 \le b \le B} F(b)$. Lean proves that this is the exact minimum over legal assignments with total error at most B, or `none` exactly when no such assignment exists.

The subtraction guard matters. Natural subtraction truncates at zero. Without the condition $w \le b$, an option of weight one could be accepted at budget zero. The implemented program checks the condition before subtraction. Dedicated regressions also cover a zero-weight option, an empty option set, and the empty collection of edges. The last case has cost and error zero.

This result does not prove that an unquantized physical error model is accurately represented by integer weights. The formal optimum concerns the declared quantized model. Clipped continuous allocation, item 8.5, remains separate.

C.5 The quantized packet-tree compiler

Source item 9.8

The new program uses the previous block's actual finite `CandidateTree` and independent legal `Cut` type. An internal node has any nonempty finite family of children. A cut either keeps its node or chooses a legal cut in every child. A terminal node can only be kept.

Keeping node v costs κ_v and incurs integer error w_v. Splitting costs overhead σ_v in addition to the selected child cuts. The exact-weight recurrence is

$$F_v(b) = \min \begin{cases} \kappa_v & \text{if } b = w_v, \\ \sigma_v + \min\limits_{\sum_i b_i = b} \sum\limits_i F_{v_i}(b_i) & \text{if } v \text{ is internal.} \end{cases}$$

Nonexistent alternatives are infeasible. The child sum is implemented by the proved finite min-plus convolution, not by assuming an optimal allocation.

Exact semantics. For every tree and every integer weight b, Lean proves that $F_v(b)$ is a minimum of costs of independent legal cuts of exact weight b. Thus each finite answer has an attaining cut and is a lower bound for every other legal cut at that weight. Infeasibility is equivalent to the absence of such a cut.

The root scan

$$\boxed{\min_{0 \le b \le B} F_{\text{root}}(b)}$$

is therefore the exact budget-constrained optimum. Increasing the budget cannot increase a finite optimum. The theorem retains feasibility hypotheses where necessary rather than treating `none` as an ordinary real cost.

Why the budget program adds something. Consider the three admissible cost/error pairs

$$(0, 4), \qquad (3, 2), \qquad (4, 0).$$

At budget two the answer is cost three. The middle pair cannot minimize cost plus λ times error: comparison with the first pair would require $\lambda \ge 3/2$, while comparison with the third would require $\lambda \le 1/2$. The executable suite checks the budget answer on an actual unary candidate tree with these cuts. It is not obtained merely by varying the previous Lagrangian compiler's multiplier.

Output boundary. This budget implementation returns the minimum cost or `none`. Attainment is proved, but executable backtracking metadata for a selected cut is not yet returned. Universal packet discovery, overlapping decompositions, nonadditive cache costs, and arbitrary device scheduling remain outside the theorem.

C.6 Cached arrays and a work certificate

Source item 9.9 and implemented forms of 8.7 and 9.8

A recursive value equation alone need not be an efficient program. Repeated calls can recompute the same subtree table. The new implementation therefore stores each table as an array-backed `Vector` with exactly $B + 1$ optional entries.

Each child table is evaluated and cached before the parent merges it. A merge reads two existing tables and tabulates their convolution. The discrete precision program likewise computes its tail table once before filling the next edge's table. The final scan reads the stored root or final-edge table.

Entrywise implementation theorem. For every $b \le B$, Lean proves

$$\text{lookup}(\text{storedTree}(B, t), b) = F_t(b).$$

There is a parallel theorem for stored discrete precision. The proof establishes first that an output entry at b depends only on input entries at most b, then proceeds through cached convolution and the tree

recursion. Consequently the optimality, attainment, and infeasibility specification applies to the actual stored result.

Counted candidates. One full convolution table examines indices

$$(b, k), \qquad 0 \le b \le B, \quad 0 \le k \le b.$$

These form a concrete finite dependent-sum type. Its cardinality is proved to be

$$\sum_{b=0}^{B} (b+1) \le (B+1)^2.$$

For a nonempty finite tree, the number of child merges plus one equals the node count N. This identity is proved for arbitrary finite branching.

Let $W_B(t)$ be the declared unit-cost count of table-cell constructions and tested min-plus candidates. The model charges the empty child-combination table as well as the output cells and merge candidates. Lean proves

$$W_B(t) \le 2(B+1)N + \big((B+1) + (B+1)^2\big)(N-1)$$

and hence

$$\boxed{W_B(t) \le N(3(B+1) + (B+1)^2).}$$

The root minimum scan adds a linear pass. Thus the declared tabulation model is pseudo-polynomial in N and the numeric budget B.

Scope of this certificate. These are table and candidate counts, not a measured execution trace or a theorem about every instruction emitted by the compiler. Rational bit complexity, allocation overhead, memory traffic, and hardware timing are not included. The certificate is not polynomial in the binary input length of B.

C.7 Place in the finite development

The structured primitives and clipped-allocation theorem follow in Appendix D. Graph schedules and preconditioning certificates are developed in Appendix E. Appendix F gives the small-core optimality argument.

The accompanying source files preserve the compiler, regression and proof-development records.

D Structured transforms and clipped precision

This appendix proves the structured-transform identities and the global clipped-allocation theorem, including the maximal-budget endpoint.

D.1 Circulant Fourier diagonalization

Source item 4.3; module CirculantFourier

Let $n > 0$, with coordinates indexed by $\mathbb{Z}/n\mathbb{Z}$. Define the actual circulant by

$$C(c)_{jk} = c_{j-k}.$$

The formal Fourier matrix is

$$F_{jk} = \frac{1}{\sqrt{n}}\,\chi(-jk), \qquad \chi(a) = \exp\left(\frac{2\pi i a}{n}\right).$$

The standard character is not left abstract: a checked theorem identifies these entries with

$$\frac{1}{\sqrt{n}}\exp\left(-\frac{2\pi i\ \mathrm{val}(j)\,\mathrm{val}(k)}{n}\right).$$

The value representatives enter only this explicit exponential formula. All modular algebra uses the residue classes themselves.

Normalization and inversion. The proof identifies matrix application with the ordinary counting-measure discrete Fourier transform:

$$Fx = n^{-1/2}\,\mathrm{DFT}(x).$$

It separately identifies F^*x with the appropriately scaled inverse transform. Mathlib's checked Fourier inversion theorem and the proved scalar normalization yield both identities

$$\boxed{F^*F = I, \qquad FF^* = I.}$$

No unitarity assumption is inserted.

Convolution and reconstruction. An explicit bijective change of index proves

$$\mathrm{DFT}(C(c)x)_k = \mathrm{DFT}(c)_k\,\mathrm{DFT}(x)_k.$$

This gives the matrix intertwining relation $FC(c) = \mathrm{diag}(\mathrm{DFT}\,c)F$. Multiplication by the proved inverse reconstructs the circulant:

$$\boxed{C(c) = F^*\,\mathrm{diag}(\sqrt{n}\,Fc)F.}$$

The two-transform application formula is also checked for every input vector. The result includes $n = 1$ and arbitrary complex coefficients. Hermiticity is not required.

Claim boundary. This verifies the exact Fourier representation, not an $O(n \log n)$ implementation of the transform. The latter is an additional algorithmic factorization of the same linear map.

D.2 Toeplitz padding and column-major vectorization

Source items 4.4 and 4.5

Toeplitz embedding. For $n > 0$, define

$$T_{ij} = \begin{cases} c_{i-j}, & j \le i, \\ r_{j-i}, & i < j. \end{cases}$$

The diagonal is supplied by c_0, and the coordinate r_0 is unused. The constructed generator of length $2n$ is

$$g = (c_0, \dots, c_{n-1}, 0, r_{n-1}, \dots, r_1),$$

and the padding map is the actual finite-index sum eliminator that appends n zeros.

Lean first proves the upper-left block identity

$$C(g)_{ij} = T_{ij} \qquad (0 \le i, j < n).$$

For $j \le i$, finite modular subtraction has its ordinary value $i - j$. For $i < j$, it has wrapped value $2n + i - j$, whose reversed generator coordinate is $j - i$. Both branches are checked with the actual finite-index arithmetic.

Splitting the product sum into the original and padded halves then gives

$$\boxed{\left(C(g)(x, 0)^T\right)_{0:n} = Tx.}$$

The generator's first half and its middle zero are checked separately. Neither symmetry nor conjugation is involved.

Kronecker application. For $A \in \mathbb{C}^{m\times m}$, $B \in \mathbb{C}^{n\times n}$ and $X \in \mathbb{C}^{n\times m}$, Lean proves

$$\boxed{(A \otimes B)\,\mathrm{vec}(X) = \mathrm{vec}(BXA^T).}$$

The formal vectorization is explicitly column-major: its pair coordinate (j, i) stores X_{ij}. The right factor is the *ordinary transpose*, not the conjugate transpose. This distinction is essential over $\mathbb{C}$.

Finite types of multiplication/accumulation events and stored scalar addresses give

$$\boxed{2n^2m + 2nm^2 \text{ modeled operations}, \qquad n^2 + m^2 \text{ factor entries}.}$$

The explicit Kronecker matrix has n^2m^2 entries. As in the manuscript, the operation model assigns two scalar operations to each multiply-accumulate term.

D.3 Arbitrary tensor factors

Source item 4.6; module StructuredTensor

Let $A_0, \dots, A_{k-1}$ be square factors of order d. Tensor coordinates are represented by a nested product of k copies of $\{0, \dots, d-1\}$. The empty product is a singleton. Lean proves that the coordinate type has cardinality d^k.

The represented matrix is defined recursively using the actual Kronecker product:

$$M_0 = [1], \qquad M_{k+1} = A_0 \otimes M_k(A_1, \dots, A_k).$$

The algorithm is defined independently. On each slice with fixed first coordinate, it recursively contracts the trailing modes. It then applies A_0 to the resulting first-coordinate fibers:

$$y_{i,u} = \sum_{j=0}^{d-1} (A_0)_{ij} \ \mathrm{Apply}_k(A_1, \dots, A_k; x_{j,\cdot})_u.$$

Induction, the Kronecker entry formula, and finite-sum distributivity prove

$$\boxed{\mathrm{Apply}_k(A; x) = M_k(A)x.}$$

Thus correctness is not inferred merely from agreeing dimension or storage formulas.

Operation events. The event type for $k+1$ modes is a disjoint union of d copies of the trailing event type and the events for the final fiber contraction. Its cardinality obeys

$$W_0 = 0, \qquad W_{k+1} = dW_k + 2d^{k+2}.$$

Lean proves the closed form

$$\boxed{W_k = 2kd^{k+1}.}$$

The factor-address type has cardinality

$$\boxed{kd^2.}$$

These statements include $k = 0$ and $d = 0$. With no factors, the action is the identity on the singleton coordinate type and incurs zero modeled arithmetic. With $d = 0$ and at least one factor, the coordinate type is empty.

Implementation boundary. These are recursive mathematical contractions with exact complex arithmetic. The event model assumes each intermediate slice is computed once and reused. It is not an instrumented execution trace or a cost bound for every evaluator of the raw functional definition. The count excludes indexing, allocation, data movement, fused instruction effects, and the real-operation cost of a complex scalar operation. Those require a separately declared backend model.

D.4 Walsh butterfly and exact addition count

Source item 4.7; module WalshTransform

The two-point matrix is constructed as

$$H_2 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

and the full family is defined by $H_1 = [1]$ and

$$H_{2N} = H_2 \otimes H_N = \begin{pmatrix} H_N & H_N \\ H_N & -H_N \end{pmatrix}.$$

The two-point orthogonality identity is checked explicitly. Kronecker multiplication and induction then prove

$$\boxed{H_N H_N^T = NI, \qquad N = 2^k.}$$

The ordinary transpose is sufficient because all constructed entries are real, even though the scalar field is $\mathbb{C}$.

Actual butterfly. For the two halves x_0, x_1 of the input, the independently defined procedure returns

$$\mathrm{Walsh}_{2N}(x_0, x_1) = (\mathrm{Walsh}_N(x_0 + x_1), \mathrm{Walsh}_N(x_0 - x_1)).$$

Lean proves that this vector equals $H_{2N}x$. The argument expands the two first-coordinate cases and applies finite-sum distributivity. It does not assume that the recursive algorithm already represents the matrix.

Exact arithmetic count. Each pair of slices forms one sum and one difference at every trailing coordinate. The event type therefore gives

$$A_0 = 0, \qquad A_{k+1} = 2A_k + 2^{k+1}.$$

The closed form and its equivalent logarithmic expression are both checked:

$$\boxed{A_k = k2^k = N \log_2 N.}$$

The logarithm in the formal count is the natural-number binary logarithm, with its power-of-two identity proved by Mathlib. The case $N = 1$ has zero arithmetic events.

A further action theorem gives

$$H_N(H_N^T x) = Nx,$$

which identifies the inverse after division by the nonzero scalar N. This result concerns exact arithmetic, not floating-point error accumulation through a butterfly implementation.

D.5 Clipped precision: existence and multiplier uniqueness

Source item 8.5; module ClippedPrecision

Let E be a finite nonempty set and suppose

$$s_e > 0, \qquad c_e > 0, \qquad m_e > 0, \qquad 0 < \tau \le \sum_e s_e m_e.$$

The feasible set is

$$0 < \varepsilon_e \le m_e, \qquad \sum_e s_e \varepsilon_e = \tau,$$

and the objective is the same logarithmic objective used in item 8.4:

$$J(\varepsilon) = \sum_e c_e \log(1/\varepsilon_e).$$

Strictly positive caps are stated explicitly. A zero or negative cap cannot admit a positive tolerance at that coordinate.

Constructive parameterization. Write $t = 1/\lambda$ and set

$$u_e(t) = \min\{m_e, tc_e/s_e\}, \qquad \Phi(t) = \sum_e s_e u_e(t).$$

Lean proves that Φ is continuous and nondecreasing, with $\Phi(0) = 0$. At the finite positive scale

$$T = \sum_e \frac{m_e s_e}{c_e},$$

every coordinate is saturated, so $u(T) = m$ and $\Phi(T) = \sum_e s_e m_e$. The intermediate value theorem produces $t > 0$ with $\Phi(t) = \tau$. The multiplier is not assumed to exist.

Strictness below saturation. If $t < u$ and $\Phi(t)$ is below the maximum, at least one coordinate is unsaturated at t. That coordinate strictly increases, and every other coordinate is nondecreasing. Hence $\Phi(t) < \Phi(u)$. This proves uniqueness of the scale and, by reciprocation, the exact manuscript statement

$$\boxed{\exists!\lambda > 0 : \quad \sum_e s_e \min\left\{m_e, \frac{c_e}{\lambda s_e}\right\} = \tau}$$

when $0 < \tau < \sum_e s_e m_e$.

At the maximal budget, the minimizing vector remains unique but the multiplier need not be. The one-coordinate case $s = c = m = 1$ is checked: both $\lambda = 1$ and $\lambda = 1/2$ produce the same tolerance 1.

D.6 Clipped precision: global optimality

Source item 8.5, continued

Existence of a multiplier alone does not prove optimality. The formal proof supplies a global supporting inequality, rather than invoking an assumed Karush–Kuhn–Tucker optimality oracle.

Fix the feasible vector $u = u(t)$ obtained above and any feasible competitor ε. For each coordinate, Lean proves

$$\boxed{c_e\left(\frac{\varepsilon_e}{u_e} - 1\right) \le \frac{s_e}{t}(\varepsilon_e - u_e).}$$

When $u_e = tc_e/s_e$, this is equality. When $u_e = m_e$, the capped condition implies $s_e/t \le c_e/m_e$, while $\varepsilon_e - m_e \le 0$. Multiplying by this nonpositive difference gives the required inequality in the correct direction.

The equal-budget constraint then yields

$$\sum_e c_e\left(\frac{\varepsilon_e}{u_e} - 1\right) \le \frac{1}{t}\sum_e s_e(\varepsilon_e - u_e) = 0.$$

Applying the checked inequality $\log z \le z - 1$ for $z > 0$ gives

$$\sum_e c_e \log(\varepsilon_e/u_e) \le 0.$$

Since

$$J(\varepsilon) - J(u) = -\sum_e c_e \log(\varepsilon_e/u_e),$$

we obtain $J(u) \leq J(\varepsilon)$ for every feasible competitor.

If $\varepsilon \neq u$, one coordinate has ratio different from 1. The logarithmic inequality is strict there, and its positive weight preserves strictness in the sum. Consequently,

$$\boxed{\varepsilon \neq u \quad \Longrightarrow \quad J(u) < J(\varepsilon).}$$

This proves the unique global minimizing vector for every positive feasible budget, including the maximal endpoint.

Numerical boundary. Existence uses real continuity and the intermediate value theorem. This is a mathematical construction, not an executable floating-point multiplier search with a certified stopping tolerance. The companion exact-rational water-filling routine is an independent regression mirror and is not itself the compiled Lean construction.

D.7 Place in the finite development

Appendix E develops the remaining graph, schedule, counting and preconditioning constructions. Appendix F proves the global small-core recompression theorem from its stated factorization data.

The accompanying source files preserve the compiler, regression and proof-development records.

E Constructed graph schedules, support, and preconditioning

This appendix develops support bounds, graph schedules, block discovery and preconditioning certificates. Classical algorithmic inputs remain separate from the finite certificates proved here.

E.1 Constructing the optimal level schedule

Source items 6.6 and 10.3; module GraphSchedules

Let V be finite and let $u \to v$ mean that task v depends on task u. Assume there is no nonempty directed cycle. A topological order or valid level function is *not* supplied as an additional hypothesis.

For each vertex, define its strict ancestor set

$$\mathrm{Anc}(v) = \{u : \text{there is a positive-length path } u \rightsquigarrow v\}.$$

For every edge $u \to v$, the proof establishes

$$\mathrm{Anc}(u) \subsetneq \mathrm{Anc}(v).$$

The inclusion follows by appending the edge. It is strict because u is an ancestor of v but cannot be its own strict ancestor in an acyclic graph. Cardinality therefore decreases when following predecessors. This constructs a well-founded relation on which the level recursion is defined:

$$\boxed{\ell(v) = 1 + \max_{u \to v} \ell(u), \qquad \max \emptyset = 0.}$$

Validity and attainment. Lean proves $\ell(v) > 0$ and $\ell(u) < \ell(v)$ on every edge. A path of n edges from a to b satisfies

$$\ell(a) + n \le \ell(b).$$

Conversely, predecessor-max attainment and induction produce an actual path with $\ell(v) - 1$ edges ending at each vertex v. The result is an equality with a longest path, not merely an upper bound.

A valid schedule $s : V \to \mathbb{N}$ assigns positive stages and strictly increases on each edge. Induction proves the stronger pointwise statement

$$\ell(v) \le s(v) \quad \text{for every } v.$$

Consequently the constructed schedule achieves the least possible makespan,

$$\boxed{d = \max_{v \in V} \ell(v).}$$

For a nonempty graph, d equals the number of vertices on an attained longest path. Vertices of the same level have no dependency edge in either direction.

Empty graph and interpretation. When $V = \emptyset$, the checked depth is zero. The phrase "one plus the longest edge-path length" applies to nonempty graphs. These are ideal discrete scheduling statements. Weighted task costs, a finite processor budget, launch latency and communication are not part of this model. The definitions are mathematical constructions, not a certified hardware scheduler.

E.2 Forward substitution with an actual stage evaluator

Source item 6.5; module TriangularSolve

Use the graph and levels constructed on the previous page. A vertex v carries an arbitrary vector space X_v over a field. The spaces may have different dimensions. Let

$$D_v : X_v \xrightarrow{\sim} X_v, \qquad T_{vu} : X_u \longrightarrow X_v$$

be an invertible diagonal map and linear transfer maps. The operator being solved is defined by its actual block action:

$$(Ax)_v = D_v x_v + \sum_{u \to v} T_{vu} x_u.$$

No solution, solve equation or precomputed topological certificate is assumed.

Constructed solution. Well-founded recursion defines

$$\boxed{x_v = D_v^{-1}\left(b_v - \sum_{u \to v} T_{vu} x_u\right).}$$

Applying D_v proves the original equation at v. If another vector satisfies all equations, induction over predecessors makes each previously used coordinate identical, and invertibility of D_v forces agreement at v. Thus the construction gives existence and uniqueness, and the block operator is bijective.

Parallel stages. A second, independent definition is an explicit staged evaluator. Set $x^{(0)} = 0$ and

$$x_v^{(k+1)} = \begin{cases} D_v^{-1}\left(b_v - \sum_{u \to v} T_{vu} x_u^{(k)}\right), & \ell(v) = k+1, \\ x_v^{(k)}, & \ell(v) \neq k+1. \end{cases}$$

It reads the previous-stage vector, not partially updated coordinates. The invariant is

$$\ell(v) \leq k \quad \Longrightarrow \quad x_v^{(k)} = x_v.$$

Every predecessor of a level-$k+1$ vertex has level at most k, so the recurrence uses only coordinates already proved correct. At the canonical depth d this yields

$$\boxed{Ax^{(d)} = b.}$$

The local independence theorem separately proves that changing coordinates outside the strict earlier levels cannot change a vertex's local solve.

Scope. Diagonal invertibility is expressed by genuine linear equivalences. The task graph may include declared transfers whose values happen to be zero. Optimality refers to that declared dependency graph. Exact field arithmetic and exact local inverses are used. No floating-point stability or implementation-specific parallel speed is inferred.

E.3 Support of inverses and Schur elimination

Source items 6.7 and 6.8; modules InverseSupport and SchurSupport

Let (P_a) be a complete idempotent packet family in a finite-dimensional algebra. Define $a \rightsquigarrow b$ by an actual finite path through nonzero blocks $P_b A P_a$. **Zero-length paths are included**, so every packet reaches itself.

Fix the source packet a. In the regular representation, define the submodule

$$W_a = \{x : P_b x = 0 \text{ whenever } a \not\rightsquigarrow b\}.$$

It contains P_a. Completeness of the projectors expands each component of Ax into packet transfers. If a transfer into an unreachable packet were nonzero from a reachable packet, it would extend a path, a contradiction. Thus $AW_a \subseteq W_a$.

Suppose $BA = I$. Left multiplication by A is injective, including on W_a. Finite dimensionality makes that restricted map surjective. Given $x \in W_a$, choose $y \in W_a$ with $Ay = x$. Then $Bx = BAy = y \in W_a$. Applying this to P_a proves

$$\boxed{a \not\rightsquigarrow b \quad \Longrightarrow \quad P_b B P_a = 0.}$$

The matrix specialization takes B to Mathlib's actual nonsingular matrix inverse, with an invertible determinant. No inverse-sparsity hypothesis is inserted.

Hidden elimination. For the actual Schur complement

$$S = A_{RR} - A_{RH} A_{HH}^{-1} A_{HR},$$

the hidden inverse is expanded through the hidden projectors. A nonzero retained correction block requires indices j, k with nonzero entrance and exit blocks and a hidden path $j \rightsquigarrow k$. Therefore a nonzero block S_{ba} requires either a direct retained block, or

$$a \longrightarrow j \ \rightsquigarrow_H \ k \longrightarrow b.$$

The entrance and exit matrices may be rectangular. Retained and hidden coordinate sizes and packet systems are independently typed. The hidden matrix must be invertible. A zero-length hidden path permits entrance and exit through the same hidden packet.

Inclusion is not equality. Cancellation can remove a block permitted by a graph route. For example,

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix} \quad \text{has} \quad (A^{-1})_{13} = 0$$

despite a direct nonzero $(1, 3)$ block. The implementation proves support inclusion and the corresponding no-route zero certificate, not a converse.

E.4 Exact banded addresses and modeled work

Source item 4.1; module BandedCount

For p packets and half-bandwidth w, the actual address set is

$$\mathcal{B}_{p,w} = \{(i, j) \in \{0, \dots, p-1\}^2 : i \le j + w \text{ and } j \le i + w\}.$$

The predicate is the integer version of $|i-j| \le w$. The count is first defined as a double sum of indicators, then identified with the cardinality of this subtype. It is not defined by the target closed form.

Under $0 \le w < p$, the formal proof establishes

$$\boxed{N_{p,w} = |\mathcal{B}_{p,w}| = p(2w+1) - w(w+1).}$$

The proof uses finite prefix counting, the newly exposed boundary row and column when p increases, and the saturated initial band. An intermediate subtraction-free identity avoids relying on natural-number subtraction without the required inequality. The diagonal case $w = 0$ gives exactly p blocks, and the saturated case $w = p - 1$ gives p^2.

Stored scalars. With equal block width b, the storage-address type is

$$\mathcal{S} = \mathcal{B}_{p,w} \times \{0, \dots, b-1\}^2.$$

Its cardinality is the actual number of represented scalar entries:

$$\boxed{|\mathcal{S}| = b^2 N_{p,w}.}$$

Arithmetic events. For q right-hand sides, the declared event type adds a right-hand-side index and one of two operation roles, multiplication or accumulation:

$$\mathcal{O} = \{0,1\} \times \{0, \dots, q-1\} \times \mathcal{S}.$$

Hence

$$\boxed{|\mathcal{O}| = 2qb^2 N_{p,w}.}$$

These identities include zero right-hand-side count. The abstract storage formula also admits zero block width. To use the manuscript's substitution $p = n/b$, one must separately require $b > 0$ and $n = pb$.

Boundary. Two events per coefficient and right-hand side are a declared arithmetic convention. These counts do not identify the number of CUDA instructions, account for fused multiply-add lowering, price complex arithmetic in real operations, or include allocation, indexing, communication and launch overhead. They are also not a performance comparison with dense multiplication.

E.5 Exact residual certificates for supplied packets

Source item 9.2; module DiscoveryCertificate

Let (P_a) be a complete orthogonal projector system on a finite complex coordinate space. The projectors need not be coordinate masks. For an actual matrix A, define

$$\Pi(A) = \sum_a P_a A P_a, \qquad E = A - \Pi(A).$$

Reconstruction gives the exact off-diagonal residual

$$E = \sum_{b \ne a} P_b A P_a.$$

Hilbert–Schmidt orthogonality. For distinct ordered packet pairs $(b, a) \neq (d, c)$, adjoint multiplication and projector orthogonality give

$$\operatorname{tr}((P_b A P_a)^* P_d B P_c) = 0.$$

If $b \neq d$, the central projector product vanishes. Otherwise $a \neq c$, and cyclicity of trace brings $P_c P_a$ together. This is proved for arbitrary input matrices A, B.

Lean identifies the actual Frobenius norm with its trace expression,

$$\|M\|_{\mathrm{F}}^2 = \operatorname{Re}\operatorname{tr}(M^* M),$$

then expands the finite sum and removes each cross term. The result is

$$\boxed{\|A - \Pi(A)\|_{\mathrm{F}}^2 = \sum_{b \neq a} \|P_b A P_a\|_{\mathrm{F}}^2 .}$$

No Pythagorean equality for the target residual is assumed.

Operator norm. In a separate scoped matrix norm, the triangle inequality gives

$$\boxed{\|A - \Pi(A)\|_2 \leq \sum_{b \neq a} \|P_b A P_a\|_2 .}$$

Here $\|\cdot\|_2$ is the Euclidean induced operator norm, not the Frobenius norm. The formal declarations use distinct norm instances, preventing the two certificates from being conflated. Self-adjointness is used for Frobenius orthogonality. The sum estimate itself requires only the complete packet decomposition.

Discovery boundary. This result certifies the residual of a *supplied* decomposition. It does not construct useful projectors from an arbitrary matrix, prove that a searched decomposition is optimal, or guarantee that its application is profitable on a GPU. The simultaneous spectral-decomposition input remains separately recorded as classical.

E.6 Block-Jacobi normalization and the CG factor

Source items 7.4 and 7.6; module BlockJacobi

Work on a nonempty finite complex coordinate space with Euclidean operator norms. Assume D and $A = D + K$ are positive definite. Define

$$S = (\sqrt{D})^{-1}, \qquad B = SAS, \qquad E = SKS.$$

The square root is the actual positive matrix square root supplied by continuous functional calculus, and the inverse is the actual matrix inverse. Positive definiteness makes $\sqrt{D}$ a unit. Its square identity and inverse identities prove

$$SDS = I, \qquad B = I + E.$$

A direct inverse bound. If $C = (I + E)^{-1}$ and $\|E\|_2 \leq \eta < 1$, then $C = I - EC$. Consequently

$$(1 - \eta)\,\|C\|_2 \leq 1, \qquad \|I + E\|_2 \leq 1 + \eta.$$

The constructed normalization is invertible because S and A are. Combining the estimates gives the actual condition number bound

$$\boxed{\kappa_2(B) := \|B\|_2 \left\|B^{-1}\right\|_2 \leq \frac{1+\eta}{1-\eta}.}$$

This norm argument does not require a separately assumed Hermitian perturbation. Nonnegative η follows from the norm bound. Nonemptiness is explicit because the condition-number and norm-of-identity convention uses a nonzero coordinate space.

The preconditioning corollary. Define

$$q(\kappa) = \frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}.$$

Monotonicity of square root and positive denominators prove that q is monotone. Lean also proves $\kappa_2(B) \geq 1$, $q(\kappa) \geq 0$ for $\kappa \geq 1$, and $q(\kappa) < 1$. Thus

$$\boxed{q(\kappa_2(B)) \leq q\left(\frac{1+\eta}{1-\eta}\right).}$$

For $1 \leq \kappa$ and $e_0 \geq 0$, an explicit classical premise $e_m \leq 2q(\kappa)^m e_0$ and a certified upper bound $\kappa \leq \bar{\kappa}$ yield $e_m \leq 2q(\bar{\kappa})^m e_0$.

What is not claimed. The classical conjugate-gradient convergence theorem, item 7.5, is not newly formalized. The new corollary proves its factor comparison and bound substitution. It does not replace the original theorem's algorithm hypotheses with a new axiom or claim a floating-point CG convergence proof.

E.7 Place in the finite development

The global small-core recompression theorem is proved in Appendix F. The classical conjugate-gradient algorithm theorem, floating-point product model and simultaneous spectral decomposition remain separately supplied inputs.

The accompanying source files preserve the compiler, regression and proof-development records.

F Global small-core recompression from ordered thin SVD data

This appendix derives global small-core recompression from actual compact ranges and supplied ordered thin-SVD equations. Optimality is proved against arbitrary ambient competitors.

F.1 Compact factors from actual column spaces

Modules CompactRangeFactors and SmallCoreTransfer

Let

$$L \in \mathbb{C}^{m\times t}, \qquad R \in \mathbb{C}^{n\times t}, \qquad A = LR^*.$$

Use the ordinary Euclidean inner products on the coordinate spaces. Define

$$S_L = \operatorname{range}(L), \quad r_L = \dim S_L, \qquad S_R = \operatorname{range}(R), \quad r_R = \dim S_R.$$

The implementation constructs an orthonormal basis of each actual range subspace. Let Q_L and Q_R be the matrices of the corresponding isometric inclusions. Express the range-restricted input maps in these bases to obtain R_L, R_R.

The checked identities are

$$\boxed{Q_L^*Q_L = I, \quad L = Q_LR_L, \quad R_L = Q_L^*L,}$$

with the analogous identities on the right. The dimension theorem is not an input:

$$\boxed{r_L = \operatorname{rank} L, \qquad r_R = \operatorname{rank} R.}$$

The coordinate factors have full row rank. The construction therefore handles rank-deficient input factors without retaining artificial column directions.

Define the small core by actual multiplication,

$$G = R_LR_R^* \in \mathbb{C}^{r_L\times r_R}.$$

Finite matrix associativity and adjoint identities give

$$\boxed{A = Q_LGQ_R^*, \qquad \operatorname{rank} G = \operatorname{rank} A.}$$

The rank identity follows from both multiplication inequalities and the left inverse obtained by compression. It is not inferred from agreeing dimensions.

Zero factors and empty spaces. No positive-rank or nonempty-coordinate hypothesis is imposed. If a range is zero, its orthonormal basis has an empty index type. The factorization uses the resulting rectangular empty matrices. A separate theorem proves that the compact dimension is zero exactly when the original factor is zero.

Relation to QR. The argument only needs orthonormal columns and exact reconstruction. A compact QR factorization supplies these properties, but triangularity of its coordinate factor is irrelevant to the recompression theorem. The formal construction uses an exact orthonormal range basis. It does not claim Householder steps, pivot selection or floating-point stability. A supplied noncompact orthonormal factorization is also covered by the general transfer theorem, including extra zero singular directions.

F.2 Why a small-core optimum is a global optimum

Module SmallCoreNorms; arbitrary ambient competitors

For rectangular isometries Q, V define

$$\mathcal{L}(G) = QGV^*, \qquad \mathcal{C}(B) = Q^*BV, \qquad Q^*Q = I, \quad V^*V = I.$$

The following statements are proved for the actual matrix rank and actual matrix norms:

$$\mathcal{C}(\mathcal{L}(G)) = G, \qquad \operatorname{rank}\mathcal{L}(G) = \operatorname{rank} G, \qquad \operatorname{rank}\mathcal{C}(B) \le \operatorname{rank} B,$$

$$\boxed{\|\mathcal{L}(G)\|_\nu = \|G\|_\nu, \qquad \|\mathcal{C}(B)\|_\nu \le \|B\|_\nu, \quad \nu \in \{2, \mathrm{F}\}.}$$

For the spectral norm, the proof uses the Gram matrix identity

$$(QG)^*(QG) = G^*G$$

and the C^*-norm square identity, together with right-side adjoint symmetry. Compression follows from submultiplicativity and the isometry norm bound, including empty spaces.

For the Frobenius norm, trace cyclicity proves left and right isometric invariance. The proof also establishes the projection identity

$$\|B - QQ^*B\|_{\mathrm{F}}^2 = \|B\|_{\mathrm{F}}^2 - \|Q^*B\|_{\mathrm{F}}^2.$$

Nonnegativity of the left side gives left compression contractivity. The right version follows by adjoints. No norm-preservation or contractivity hypothesis is inserted.

Suppose G_k is a best rank-at-most-k approximation to G in either norm. Take an *arbitrary* ambient matrix B with rank $B \le k$. Compression is an admissible small-core competitor and

$$\begin{aligned}\|\mathcal{L}(G) - \mathcal{L}(G_k)\|_\nu &= \|G - G_k\|_\nu \\ &\le \|G - \mathcal{C}(B)\|_\nu \\ &= \|\mathcal{C}(\mathcal{L}(G) - B)\|_\nu \\ &\le \|\mathcal{L}(G) - B\|_\nu.\end{aligned}$$

The competitor B is not required to lie in the supplied row and column spaces. The next two pages discharge the intermediate small-core optimality obligation, rather than leaving it as a hypothesis in the final theorem.

F.3 Spectral optimality from a kernel witness

Modules DiagonalTruncation and SpectralOptimality

Let $\sigma_1 \ge \cdots \ge \sigma_d \ge 0$ and

$$D = \operatorname{diag}(\sigma_1, \dots, \sigma_d), \qquad D_k = \operatorname{diag}(\sigma_1, \dots, \sigma_{\min(k,d)}, 0, \dots, 0).$$

Lean uses indices beginning at zero, while the formulas on this page use the conventional one-based notation. The rank of D_k is proved to be at most k, even when retained singular values are zero.

For $k < d$, take any $d \times d$ matrix B of rank at most k. Restrict its domain to the first $k+1$ coordinates using the actual coordinate inclusion J. Since

$$\operatorname{rank}(BJ) \le \operatorname{rank} B \le k < k+1,$$

rank-nullity supplies a nonzero vector z with $BJz = 0$. The vector $y = Jz$ is nonzero, satisfies $By = 0$ and is supported in the first $k+1$ coordinates. The injection and the support property are checked separately.

Monotonicity of the diagonal entries gives

$$\|Dy\|^2 = \sum_{i=1}^{k+1} \sigma_i^2 |y_i|^2 \ge \sigma_{k+1}^2 \|y\|^2 .$$

Because $(D-B)y = Dy$, the operator-norm inequality implies

$$\sigma_{k+1} \|y\| \le \|(D-B)y\| \le \|D-B\|_2 \|y\| .$$

Cancellation of the strictly positive norm of y proves

$$\boxed{\sigma_{k+1} \le \|D-B\|_2 .}$$

The norm of the actual diagonal residual $D - D_k$ equals σ_{k+1}, so D_k attains the lower bound. If $k \ge d$, the residual is zero and optimality follows from norm nonnegativity.

No optimality oracle. The nonzero kernel vector, its coordinate support and the diagonal norm bound are all derived. No Eckart–Young inequality, best-rank property or singular-tail formula is assumed. The final rectangular SVD result follows by the isometric transfer proved on the preceding page.

F.4 Frobenius optimality from kernel weights

Modules KernelFrame and FrobeniusOptimality

For an arbitrary competitor B with $\operatorname{rank} B \le k$, construct an orthonormal matrix Q spanning its actual kernel. Then

$$BQ = 0, \qquad Q^*Q = I, \qquad q = \dim\ker B = d - \operatorname{rank} B.$$

Define the row weights

$$w_i = \sum_{j=1}^{q} |Q_{ij}|^2.$$

The proof derives

$$\boxed{0 \le w_i \le 1, \qquad \sum_i w_i = q \ge \max(d-k, 0).}$$

The upper bound uses contraction of Q^* on a coordinate vector. The weight sum follows from the trace of Q^*Q and rank-nullity.

For any nonnegative decreasing sequence a_i, weights with these properties satisfy

$$\sum_i a_i w_i \geq \sum_{i>k} a_i.$$

This finite weighted inequality is itself proved. For $k < d$, use $\mu = a_{k+1}$ and compare the summands to tail weights $v_i = 0$ for $i \leq k$ and $v_i = 1$ otherwise:

$$a_i v_i + \mu(w_i - v_i) \leq a_i w_i.$$

For a retained coordinate the inequality uses $a_i \geq \mu$ and $w_i \geq 0$. For a tail coordinate it uses $a_i \leq \mu$ and $w_i \leq 1$. Summation and $\sum w_i \geq \sum v_i$ give the result.

Set $a_i = \sigma_i^2$. Right compression cannot increase the Frobenius norm, and $BQ = 0$, hence

$$\begin{aligned} \|D - B\|_{\mathrm{F}}^2 &\geq \|(D - B)Q\|_{\mathrm{F}}^2 \\ &= \|DQ\|_{\mathrm{F}}^2 = \sum_i \sigma_i^2 w_i \geq \sum_{i>k} \sigma_i^2. \end{aligned}$$

Direct calculation of $D - D_k$ attains equality. Thus the best-rank Frobenius assertion is proved from kernel geometry and finite sums, independently of the spectral lower-bound proof. Repeated and zero singular values require no uniqueness claim.

F.5 Thin output factors and the final theorem

Modules CompactTruncation and SmallCoreRecompression

For the actual core $G = R_L R_R^*$, supply ordered thin SVD data

$$G = W \operatorname{diag}(\sigma) Z^*, \qquad W^*W = I, \qquad Z^*Z = I, \qquad \sigma_1 \geq \cdots \geq \sigma_d \geq 0.$$

These are precisely the fields of the formal SVD structure. It contains no rank-optimality or tail-error field. A derived theorem checks the Gram eigenvector equation

$$G^*GZ = Z \operatorname{diag}(\sigma_1^2, \ldots, \sigma_d^2).$$

Let $h = \min(d, k)$ and retain exactly the first h column indices. The rectangular square-root mask has entries

$$M_{ij} = \begin{cases} \sqrt{\sigma_j}, & i = j, \\ 0, & i \neq j, \end{cases} \qquad 1 \leq i \leq d, \quad 1 \leq j \leq h.$$

Lean proves its index cardinality and $MM^* = D_k$. Define

$$\boxed{L_k = Q_L W M, \qquad R_k = Q_R Z M.}$$

The product equals $Q_L W D_k Z^* Q_R^*$ and has rank at most k. The principal theorem proves, for every ambient B with rank $B \leq k$,

$$\boxed{\left\|LR^* - L_k R_k^*\right\|_\nu \leq \left\|LR^* - B\right\|_\nu, \quad \nu \in \{2, \mathrm{F}\}.}$$

It also gives the exact errors

$$\|LR^* - L_k R_k^*\|_2 = \begin{cases} \sigma_{k+1}, & k < d, \\ 0, & k \geq d, \end{cases} \qquad \|LR^* - L_k R_k^*\|_{\mathrm{F}} = \left(\sum_{i>k} \sigma_i^2 \right)^{1/2}.$$

Both the squared and square-root Frobenius formulas are checked. All these statements are combined in

`KomorebiPaperVIII.SmallCore.small_core_optimal_recompression`.

Endpoints. Rank zero produces the zero output, while $k \geq d$ reconstructs the original product. An empty SVD certificate is constructed for a zero core, and diagonal SVD certificates are constructed explicitly. Zero singular values are never inverted. At repeated singular values the result asserts optimality, not uniqueness of the minimizer.

F.6 Place in the finite development

The 56-item manuscript-proved register is covered under its stated hypotheses. General SVD existence, a numerical SVD algorithm, floating-point CG convergence and hardware speedups do not follow merely from this formal scope. The formal companion identifies the exact declaration map and recorded verification evidence.

The accompanying source files preserve the compiler, regression and proof-development records.

How to use this volume

Follow each small operator through its factors and formulas, then read the cited general argument in the traditional volume. The Lean companion records the separate finite formal contract.

Routes through the guide

Plates VIII.1 through VIII.32 identify worked pages independently of PDF pagination. Each source line names the corresponding general statement in the mathematical text. The integrated atlas uses the same plate labels.

Route	Mathematical question	Plates
Representations	Which exact data represent the required operator?	1–4, 27
Structured transforms	Which conventions preserve the same map?	5–8
Low-rank algebra	What remains exact after products and recompression?	9–13, 29
Support and solves	Which interactions can occur or cancel?	14–18, 30
Precision and compilation	Which finite costs and errors does the optimizer use?	19–23, 31–32
Performance contracts	Which one-time costs and outputs are compared?	24–26
Evidence	What is checked, proved, or still open?	2, 28

Keep the represented object visible

A dense array, factored operator, and execution plan may describe the same map while returning different objects. Representation savings are exact modeled counts. Measured speed requires a separate experiment with matching output and timing contracts.

Preservation and evidence

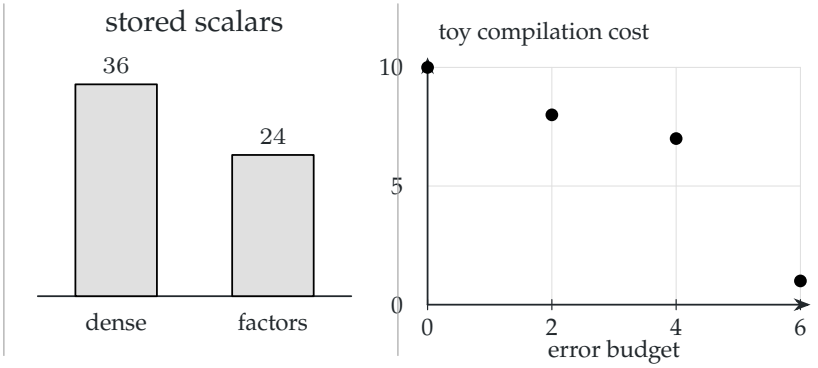
These plates illustrate the chapter's finite constructions. The accompanying models and checking code distinguish exact examples, symbolic calculations, bounded enumerations and rejected controls. Drawing geometry and model checks have separate scopes.

The finite formal correspondence contains 56 manuscript-proved items, 392 named declarations in 40 modules and 66 construction audits. Nineteen declarations are reused foundation results. The ordered-SVD hypotheses, four classical entries, recorded timing corpus and three broad research targets retain their separate scopes. These records do not claim a new Lean compiler execution.

Read this as: Choose a question, calculate its small model, and check the hypotheses, output contract, and evidence level of the corresponding general result.

Worked visual atlas

Plate VIII.1 / THREE VIEWS OF ONE COMPUTATION



Compute the representation first

Chapter VIII: Section 2, Section 3, Appendix F.

A dense array, a factored operator, and a compiled execution plan are different objects. They may denote the same linear map, but they need not store the same data, return the same output, or incur the same costs. This guide illustrates those distinctions with calculations.

A: 36 visible entries

4	2	1	1	1	1
2	4	1	1	1	1
1	1	4	2	1	1
1	1	2	4	1	1
1	1	1	1	4	2
1	1	1	1	2	4

Three models to carry through the paper

The first is a six-dimensional operator $A = D + uv^T$. Every entry of A is nonzero, yet three 2×2 diagonal blocks and two thin vectors suffice to apply it exactly. Plate VIII.3, Plate VIII.9, Plate VIII.10, and Plate VIII.27 reuse this operator or its factors.

The second starts with redundant factors L and R. Actual range coordinates reduce a 4×3 product to a 2×3 core. Plate VIII.11–Plate VIII.12 connect rank, singular tails, and the geometric reason a small-core optimum is also an ambient optimum.

The third is a seven-node candidate tree with exactly five prunings. Its budget optimum is not selected by any Lagrangian penalty. Plate VIII.21–Plate VIII.23 let readers inspect every feasible choice and every changed subproblem.

How to use the guide

A source line beneath each title identifies the relevant result in the mathematical text. The preserved examples use rational, Gaussian-rational, symbolic, and finite-enumeration arithmetic. Portable checks use exact rational and Gaussian-rational arithmetic. The retained SymPy records list the assertions and rejected controls separately. Smooth drawing coordinates illustrate stated formulas. They are not additional proof evidence.

> **Read this as:** An exact representation can remove work before a device is chosen. It does not by itself supply a fast kernel, a good approximation, or a fair timing comparison.

Plate VIII.2 / A READER'S ATLAS

The objects and their contracts

Chapter VIII: Definition 2.1, Definition 2.2, Definition 2.7, Section 8, Section 9, Section 11.

The same letter can refer to a mathematical operator or to a particular stored representation. Keep those levels separate when reading an algorithm or a benchmark row.

Symbol	Object	Question to ask
P_α	Coordinate projector	Which input or output coordinates does it select?
$A_{\beta\alpha}$	A block map	What are its source and target dimensions?
E	Active block addresses	Is this exact support, or only a structural upper bound?
$D + UV^*$	Factored operator	Is the desired output a vector, factors, or a dense array?
Q_L, G, Q_R	Range factors and core	Are the outer columns orthonormal, with exact reconstruction?
E_j	An error operator	Is it a factor perturbation or an additive error after a product?
s_e, ϵ_e	Sensitivity and tolerance	Is the budget input-dependent or uniform over unit inputs?
$(\kappa_v, \epsilon_v, \sigma_v)$	Candidate-tree data	Do costs, errors, and split overheads really add?
$F_v(b)$	A budget table	Does b mean exact weight, or an upper bound?
R	Reuse count	Which one-time costs have been included?

Conventions used in the examples

Matrices act on column vectors. A block $A_{\beta\alpha}$ goes from source α to target β. Products act from right to left. Real examples use transpose, while complex examples use adjoint unless a vectorization identity explicitly requires transpose. Column-major vectorization stacks the columns of a matrix.

An arithmetic count uses the modeled multiply/add convention. It is not a count of executed machine instructions. Scheduling and amortization examples use declared synthetic units, rather than measured GPU times. The source files preserve the recorded benchmark corpus.

Evidence levels

The theorem ledger records its stated finite formal scope. Exact checks validate these particular examples. A plot samples a formula. A recorded timing describes its case and machine. These evidence types have different scopes.

Read this as: Before interpreting a number, identify its object, norm, output contract, and timing scope. Most apparent contradictions disappear once those four fields are explicit.

Plate VIII.3 / THE RUNNING SIX-DIMENSIONAL OPERATOR

A dense-looking matrix, one scalar coupling

Chapter VIII: Theorem 2.3, Theorem 3.4.

Let D have three identical blocks $\begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}$ and put $u = v = \mathbf{1} \in \mathbb{Q}^6$. Then $A = D + uv^T$ has diagonal entries four, within-block off-diagonal entries two, and every cross-block entry one. All 36 entries are nonzero.

$$x = (1, -1, 2, 0, -2, 3)^T, \qquad v^T x = 3, \qquad Ax = Dx + 3u.$$

x		Dx		$u(v^T x)$		Ax
1		2		3		5
−1		−2		3		1
2		6		3		9
0	+	2	=	3	=	5
−2		−3		3		0
3		7		3		10

$v^T x = 3$ is shared by all six output coordinates.

What was avoided?

The global part does not require 36 independent coefficients. It depends on the input through one scalar, $v^T x$, which is broadcast through u. The diagonal part is computed by three separate local matrix products. Nothing is approximated and no channel is discarded.

The sixth output is $7 + 3 = 10$, while the fifth is $-3 + 3 = 0$. A zero result can arise through cancellation even when the corresponding row contains no zero coefficient. The output vector is therefore not a support map of the input matrix.

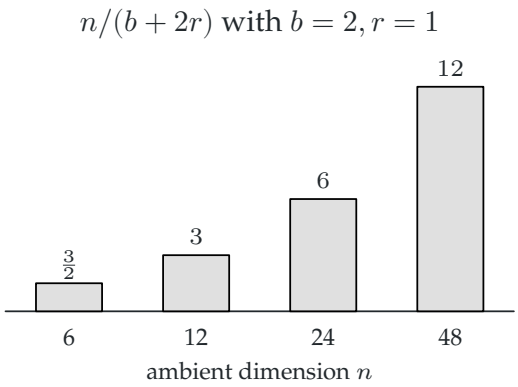
What has not been established?

This computation proves neither that the supplied factors are the cheapest representation nor that six small tasks outperform one dense kernel. For example, the repeated diagonal blocks and all-one vectors admit further special handling. The stated BDLR model deliberately treats the blocks as dense and the factors as stored vectors so that the paper's general formulas apply literally.

The checker constructs the complete matrix independently, multiplies it by x, and compares all six entries with the factored route. The same input returns in the product calculation on Plate VIII.27.

> **Read this as:** A matrix can have full entrywise support and still admit a small exact representation. Entry sparsity and algebraic compressibility are different properties.

Plate VIII.4 / ARITHMETIC, STORAGE, AND CAPACITY



Work removed is not time measured

Chapter VIII: Theorem 3.1, Corollary 3.2, Theorem 3.4, Corollary 3.9, Proposition 4.1.

For q right-hand sides, the paper models dense application by $2n^2q$ operations. A block-diagonal-plus-rank-r representation with equal block width b uses

$$F = 2qn(b + 2r), \qquad M = n(b + 2r) \text{ stored scalars.}$$

These formulas count the dense block products and two thin products. They follow the manuscript convention rather than adding every scalar accumulation or index operation.

Six-dimensional running operator

dense: 36 scalars, $72q$ work

BDLR: 24 scalars, $48q$ work

ratio: $3/2$, not a timing result

For the running example, $n = 6, b = 2, r = 1$. The model reduces storage from 36 to 24 scalars and application work from $72q$ to $48q$. For fixed b, r, the ratio $n/(b + 2r)$ grows with n. If the rank instead grows proportionally with dimension, that apparent advantage need not grow.

Memory is another constraint

With scalar size s, the representation alone requires sM bytes. Inputs, outputs, workspace, allocator overhead, and stored indices are additional. A matrix-only capacity inequality is not a complete device-memory fit test.

For a block band of p packets and half-bandwidth w, the exact active-block count is

$$p(2w + 1) - w(w + 1).$$

The subtraction removes overcounted edge diagonals. The checker enumerates all addresses for $1 \le p \le 6$ and every admissible w, including $w = 0$ and $w = p - 1$.

> **Read this as:** An arithmetic or storage ratio explains a representation advantage. Kernel launch cost, traffic, utilization, and conversion determine whether that advantage becomes a time advantage.

Plate VIII.5 / CIRCULANT MULTIPLICATION

Four coefficients, four exact frequencies

Chapter VIII: Theorem 4.3.

Take $c = (2, 1, 0, -1)^T$ and define $C(c)_{jk} = c_{j-k \bmod 4}$. The unitary Fourier matrix is $F_{jk} = \mathrm{i}^{-jk}/2$. Its normalization is visible in the exact diagonalization:

$$C(c) = F^* \operatorname{diag}(2Fc) F, \qquad 2Fc = (2, 2 - 2\mathrm{i}, 2, 2 + 2\mathrm{i})^T.$$

$C(c)$

2	−1	0	1
1	2	−1	0
0	1	2	−1
−1	0	1	2

$\sqrt{4}\,Fc$

2
$2 - 2i$
2
$2 + 2i$

$$F_{jk} = \tfrac{1}{2}\,\mathrm{i}^{-jk}$$

$$C = F^* \operatorname{diag}(\sqrt{4}Fc) F$$

$\sqrt{4} = 2$ is essential.

A unitary transform changes the normalization of the convolution eigenvalues.

Follow an actual input

For $x = (1, 2, -1, 0)^T$, dense multiplication gives $(0, 6, 0, -2)^T$. Transforming x, multiplying by the four displayed eigenvalues, and applying F^* gives exactly the same vector. Every entry belongs to $\mathbb{Q}(\mathrm{i})$, so the check needs no approximate trigonometric values.

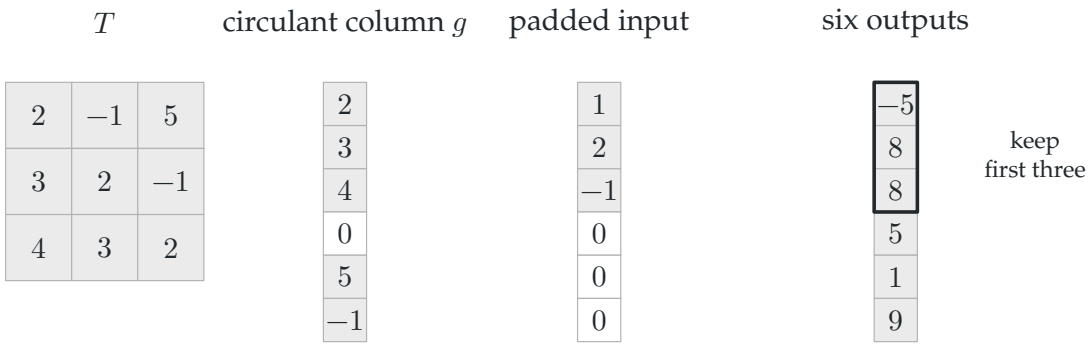
There is a common normalization trap. With an unnormalized discrete transform, the convolution multiplier has one convention. With the unitary transform used here, the eigenvalue vector is $\sqrt{n}\,Fc$, not Fc. Dropping the factor two reconstructs $C/2$ rather than C in this example. The invalid control deliberately tries that change and rejects it.

Where the fast algorithm enters

The identity specifies the represented operator. An FFT is an additional factorization that evaluates the transforms efficiently. The algebraic diagonalization does not certify a particular floating-point FFT, data layout, or launch policy. For a tiny four-point example, direct multiplication may be the simpler execution path even though the frequency representation is exact.

Read this as: Transform coordinates change both the storage pattern and the normalization conventions. Verify the inverse transform and convolution scale before interpreting a frequency-domain product.

Plate VIII.6 / TOEPLITZ EMBEDDING WITHOUT WRAPAROUND



Padding is part of the theorem

Chapter VIII: Corollary 4.4.

Consider

$$T = \begin{pmatrix} 2 & -1 & 5 \\ 3 & 2 & -1 \\ 4 & 3 & 2 \end{pmatrix}, \qquad x = (1, 2, -1)^T.$$

The diagonal pattern is Toeplitz, not circulant. To use a circular convolution, embed it into dimension six with first column $g = (2, 3, 4, 0, 5, -1)^T$ and pad the input with three zeros.

Padding is part of the operator identity, not optional workspace.

Read the wrapped indices

For output index $j < 3$, an input index $k \le j$ uses the first-column coefficient c_{j-k}. An input index $k > j$ wraps to the stored first-row coefficient r_{k-j}. The padded input positions contribute nothing. Keeping the first three outputs therefore gives

$$Tx = (-5, 8, 8)^T.$$

The remaining circular outputs are workspace consequences of the embedding, not additional components of Tx.

A concrete failure mode

Using only the first column $(2, 3, 4)$ as a three-dimensional circulant changes the upper-triangular coefficients. That is a different matrix. The checker compares its output with Tx and rejects the unpadded shortcut.

The middle zero in g is not a discarded Toeplitz coefficient: it separates the lower and reversed upper diagonals in the chosen $2n$ embedding. Other embeddings require their own index identities. It is not sufficient for an array merely to have the right length or to produce a plausible plot.

> **Read this as:** Zero padding prevents the wrong circular interactions. It is an algebraic part of the operator representation, not an optional performance tweak.

Plate VIII.7 / KRONECKER ACTION AND ARRAY ORDER

A transpose, not an adjoint

Chapter VIII: Theorem 4.5, Corollary 4.6.

With column-major vectorization, the tensor identity is

$$(A \otimes B)\,\mathrm{vec}(X) = \mathrm{vec}(BXA^T).$$

Here the transpose records index order, not a Hermitian inner product. Use the explicitly complex matrix $A = \begin{pmatrix} 1 & \mathrm{i} \\ 2 & -1 \end{pmatrix}$, together with $B = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$ and $X = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$.

X

1	2
3	4

$\mathrm{vec}(X)$

1
3
2
4

BXA^T

$5 + 8i$	2
$9 + 12i$	6

A^T not A^*

$$(A \otimes B)\,\mathrm{vec}(X) = \mathrm{vec}(BXA^T)$$

Check the coordinates

The stacked input is $(1, 3, 2, 4)^T$. Direct tensor multiplication agrees with stacking the columns of

$$BXA^T = \begin{pmatrix} 5 + 8\mathrm{i} & 2 \\ 9 + 12\mathrm{i} & 6 \end{pmatrix}.$$

Replacing A^T with A^* changes the signs of the imaginary terms. A real-only test would conceal that error, which is why the worked model uses an imaginary coefficient.

Why modewise contraction matters

For A of order m and B of order n, the explicit tensor matrix stores m^2n^2 entries. Its factors store $m^2 + n^2$. Applying through BXA^T costs $2n^2m + 2nm^2$ modeled operations, rather than forming the full tensor matrix first.

A different flattening convention has a different coordinate formula. The statement is not independent of how an array is reshaped. In a software implementation, shape, stride, and flattening order belong to the correctness contract as well as the cost model.

> **Read this as:** Tensor structure gives exact savings only when the address convention is preserved. A silent transpose, conjugation, or reshape change implements a different map.

Plate VIII.8 / WALSH RECURSION IN EIGHT COORDINATES

See every butterfly value

Chapter VIII: Theorem 4.7.

The unnormalized Walsh matrix satisfies $H_1 = [1]$ and

$$H_{2n} = \begin{pmatrix} H_n & H_n \\ H_n & -H_n \end{pmatrix}, \qquad H_n H_n^T = nI.$$

Apply the three add/subtract stages to $(1, 2, 3, 4, 5, 6, 7, 8)^T$. The full intermediate ledger is displayed below.

input	1	2	3	4	5	6	7	8
stage 1	3	-1	7	-1	11	-1	15	-1
stage 2	10	-2	-4	0	26	-2	-4	0
stage 3	36	-4	-8	0	-16	0	0	0

$8 \log_2 8 = 24$ additions/subtractions; $H_8 H_8^T = 8I$.

Arithmetic can be counted exactly

Each stage visits eight coordinates, producing one sum or difference per coordinate. Three stages therefore use exactly 24 additions or subtractions. No multiplication by a dense 8×8 matrix is necessary.

The result $(36, -4, -8, 0, -16, 0, 0, 0)^T$ still reconstructs the input: the inverse is $H_8^T/8$. Because the displayed transform is unnormalized, its squared output norm is eight times the squared input norm. The normalized transform $H_8/\sqrt{8}$ would instead be orthogonal.

What the zeros mean

The zero coefficients arise from exact cancellation among the input values. They do not imply that the transform's defining matrix is sparse. The butterfly structure, not the final coefficient support, explains the arithmetic reduction.

The checker verifies the recursion, orthogonality, dense-versus-butterfly output, and operation count for sizes one, two, four, eight, and sixteen. These bounded tests exercise the implementation and boundary cases. The general recursion theorem remains the manuscript's mathematical statement.

> **Read this as:** Factorization can turn a dense matrix into a short exact arithmetic circuit. Keep its normalization separate from its recursive evaluation rule.

Plate VIII.9 / CLOSED LOW-RANK PRODUCT ALGEBRA

The cross term has somewhere to go

Chapter VIII: Theorem 5.1, Corollary 5.2.

Let $A = D_A + u_a v_a^T$ be the running operator. Take $D_B = \mathrm{diag}(1,2,3,4,5,6)$, $u_b = (1,0,1,0,1,0)^T$, and $v_b = (0,1,0,1,0,1)^T$. Define $B = D_B + u_b v_b^T$.

$$U_C = [D_A u_b + u_a(v_a^T u_b)\ \ u_a], \qquad V_C = [v_b\ \ D_B^T v_a].$$

U_C

6	1
4	1
6	1
4	1
6	1
4	1

V_C

0	1
1	2
0	3
1	4
0	5
1	6

$$AB = D_A D_B + U_C V_C^T$$

$$U_A(V_A^T U_B)V_B^T$$

must be retained

Two input rank-one corrections produce at most rank two, not three.

Why there are only two columns

Expanding AB gives three correction terms, but two share the right factor v_b^T:

$$D_A u_b v_b^T + u_a(v_a^T u_b)v_b^T = (D_A u_b + u_a(v_a^T u_b))v_b^T.$$

The remaining term is $u_a v_a^T D_B$. Thus $AB = D_A D_B + U_C V_C^T$ with at most two correction directions. Counting the three expanded summands as independent ranks would overestimate this representation.

The scalar $v_a^T u_b$ is three. Removing the quadratic term would therefore remove $3u_a v_b^T$, which is nonzero. The checker compares the complete product to the factor construction and rejects a calculation that omits this contribution.

Before and after recompression

A rank bound on stored factors is not always the actual matrix rank. Repeated products may introduce dependent columns. Recompression can remove those dependencies exactly, or remove small singular directions approximately under an explicit error budget.

> **Read this as:** Closure of a representation class is an algebraic statement about all product terms. It is not permission to drop an interaction merely because it is second order in the factors.

Plate VIII.10 / WOODBURY WITH BOTH INVERTIBILITY CHECKS

A large inverse, a small denominator

Chapter VIII: Theorem 5.3, Corollary 5.4.

For the running operator, each diagonal block has inverse $\frac{1}{8}\begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}$. Hence $D^{-1}u = u/4$ and

$$S = 1 + u^T D^{-1} u = \frac{5}{2}.$$

The Woodbury identity reduces the entire inverse to

$$A^{-1} = D^{-1} - D^{-1} u S^{-1} u^T D^{-1} = D^{-1} - \frac{1}{40} u u^T.$$

one block of D^{-1}

$\frac{3}{8}$	$-\frac{1}{8}$
$-\frac{1}{8}$	$\frac{3}{8}$

$$D^{-1}u = \tfrac{1}{4}u$$

$$S = 1 + u^T D^{-1} u = \tfrac{5}{2}$$

$$A^{-1} = D^{-1} - \tfrac{1}{40} u u^T$$

$I - e_1 e_1^T$

0	0
0	1

invertible D
singular update

Two hypotheses, not one

Invertibility of D alone does not suffice. For $D = I_2$, $u = e_1$, and $v = -e_1$, the update is $\operatorname{diag}(0, 1)$. The small matrix S is zero, exactly where the correction formula would require an invalid division.

For the running model, the checker multiplies the proposed inverse by A in both orders and obtains the identity. It also checks the determinant relation $\det A = \det D \det S$. These tests verify the actual factors and sign of the correction, not just a numerical solve residual.

Conditioning survives the reduction

A small S can still be ill-conditioned. Reducing its dimension does not bound $\|S^{-1}\|$. The manuscript's inverse estimate keeps that term explicit, along with the norms of $D^{-1}u$ and $v^T D^{-1}$.

> **Read this as:** The hidden coupling has not vanished. Its solvability and sensitivity are concentrated in a smaller operator that still has to be invertible and numerically controlled.

Plate VIII.11 / ACTUAL RANGE COORDINATES

Stored width is not intrinsic rank

Chapter VIII: Theorem 5.6, Section F.1.

Choose the isometry

$$Q_L = \begin{pmatrix} 3/5 & 0 \\ 4/5 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad R_L = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad R_R = \begin{pmatrix} 3 & 0 & 2 \\ 0 & 2 & 0 \\ 1 & 0 & -1 \end{pmatrix}.$$

Set $L = Q_L R_L$ and $R = R_R$. The two equal columns of L do not create a third range direction. In contrast, R has rank three.

L: rank 2

$\frac{3}{5}$	0	$\frac{3}{5}$
$\frac{4}{5}$	0	$\frac{4}{5}$
0	1	0
0	0	0

R: rank 3

3	0	2
0	2	0
1	0	-1

G: 2×3

5	0	0
0	2	0

$$LR^T = Q_L G$$

The stored width is three; the left range has only two independent directions.

The actual core is

$$G = R_L R_R^T = \begin{pmatrix} 5 & 0 & 0 \\ 0 & 2 & 0 \end{pmatrix}, \qquad LR^T = Q_L G.$$

Its dimensions are the two actual input ranks, two and three. This is not inferred by merely discarding a column with a small norm. The range factor Q_L has orthonormal columns and reconstructs L exactly.

The preserved formal boundary

The small-core recompression construction in Appendix F constructs orthonormal bases of the actual column spaces. It then assumes exact ordered thin-SVD data for the core, as the manuscript instructs the reader to take an SVD. It does not assume an optimality or tail-error conclusion. Nor does it certify a floating-point QR or SVD implementation simply because those routines use similar notation.

This example has a diagonal rectangular core, so its singular directions are explicit. No iterative numerical factorization is needed to identify the two nonzero singular values, five and two.

> **Read this as:** Compactness is a statement about actual range spaces. The number of stored factor columns can exceed the dimensions that matter for recompression.

Plate VIII.12 / COMPRESSION, KERNEL WITNESSES, AND TAILS

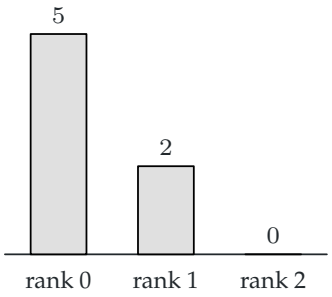
Why a core optimum is global

Chapter VIII: Theorem 5.6, Section F.2, Section F.3, Section F.4.

The product from the previous page is

$$A_0 = LR^T = \begin{pmatrix} 3 & 0 & 0 \\ 4 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Keeping only its first singular direction gives a rank-one approximation with spectral and Frobenius error exactly two. Keeping none gives errors five and $\sqrt{29}$, while keeping both gives zero.



LR^T

3	0	0
4	0	0
0	2	0
0	0	0

rank-one output

3	0	0
4	0	0
0	0	0
0	0	0

spectral error

Frobenius errors: $\sqrt{29},\ 2,\ 0$. The rank-one choice loses only the second mode.

Why an outside competitor cannot do better

For isometric outer factors, compression $C(B) = Q_L^* B Q_R$ cannot increase rank or either matrix norm. Every ambient rank-k competitor therefore supplies an admissible core competitor. The lifted core residual has exactly the core residual norm. These two facts transfer a core optimum to the entire ambient matrix space, not just to competitors already lying in the supplied ranges.

For a d-dimensional diagonal core and $0 \le k < d$, the spectral lower bound has a concrete witness. A rank-at-most-k competitor has a nonzero kernel vector in the first $k+1$ coordinates. On that vector the diagonal matrix acts with norm at least σ_{k+1} times the vector norm. The competitor cannot cancel that direction.

The Frobenius proof uses an orthonormal basis of the competitor's kernel. Its row weights lie in $[0, 1]$ and sum to the kernel dimension. Weighting the decreasing squared singular values forces at least the discarded tail. The two norm arguments are distinct. One is not a graph of the other.

> **Read this as:** Optimality is not inferred from the appearance of the singular-value plot. It follows from compression and a lower bound valid against every rank-bounded competitor.

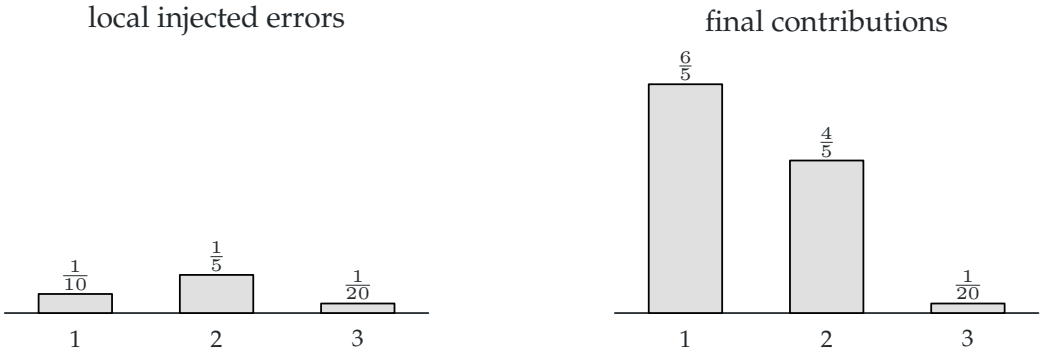


Plate VIII.13 / FACTOR PERTURBATION VERSUS RECOMPRESSION

Errors enter at different places

Chapter VIII: Theorem 5.8, Theorem 5.9.

Let the exact scalar factors be $(2, 3, 4)$ and start from $p_0 = 1$. If additive errors $(1/10, 1/5, 1/20)$ enter *after* each partial multiplication, then

$$\hat{p}_j = a_j \hat{p}_{j-1} + e_j, \qquad \hat{p}_3 - p_3 = 12e_1 + 4e_2 + e_3 = \frac{41}{20}.$$

$\hat{p}_j = a_j \hat{p}_{j-1} + e_j$, with $(a_1, a_2, a_3) = (2, 3, 4)$.

The same local numbers, a different model

If instead the factors themselves are perturbed, the computed product is $(4+e_3)(3+e_2)(2+e_1)$. Its error is $402/125$, not $41/20$. The factor-perturbation telescoping formula contains later factors that have already been perturbed, while the additive recompression formula contains the original later factors.

The visual comparison uses the additive model. The first error is multiplied by both remaining factors. The last error is not amplified at all. Summing only the local error magnitudes gives $7/20$, which is smaller than the actual final error and therefore not a valid bound here.

In a matrix chain

The corresponding formulas replace scalar magnitudes with operator norms and respect multiplication order. A bound can be conservative when contributions cancel, but it must not omit possible amplification. Singular-tail errors from a recompression step become useful only after they are inserted into the correct global error model.

> **Read this as:** An error tolerance needs an entry point. A bound for perturbing factors and a bound for compressing partial products are not interchangeable.

Plate VIII.14 / SUPPORT IS AN INCLUSION

Two routes can cancel exactly

Chapter VIII: Theorem 2.5, Theorem 6.1, Corollary 6.3.

Let K have transfers $0 \to 1$, $0 \to 2$, $1 \to 3$, and $2 \to 3$, with coefficients $1, 1, 1, -1$. There are two length-two routes from packet zero to packet three, but their contributions sum to zero.

K

0	0	0	0
1	0	0	0
1	0	0	0
0	1	-1	0

path counts at length two

0	0	0	0
0	0	0	0
0	0	0	0
2	0	0	0

$$1 + (-1) = 0$$

$$K^2 = 0$$

Structural support is an upper bound. It does not encode destructive cancellation.

$$(K^2)_{30} = K_{31}K_{10} + K_{32}K_{20} = 1 - 1 = 0, \qquad K^2 = 0.$$

The matrix of path counts sees the two possibilities and forgets the signs. It therefore predicts possible support but not actual support. Replacing the inclusion $\operatorname{supp}(AB) \subseteq \operatorname{supp}(A) \circ \operatorname{supp}(B)$ by equality would be wrong even in this four-dimensional model.

What an acyclic graph does guarantee

If the longest strict directed path has h edges, then no term of K^{h+1} can survive. Thus $K^{h+1} = 0$. This is an upper bound on the nilpotence index, not an assertion that $K^h \neq 0$. Here the graph has paths of length two, while coefficient cancellation already gives $K^2 = 0$.

A structurally permitted block may also vanish because a product of rectangular maps is zero before any sum is taken. A support graph cannot distinguish that mechanism from cancellation among separate routes. The actual block coefficients are therefore part of a proof-bearing operator representation.

> **Read this as:** Use graph reachability to exclude impossible transfers. Use the algebra to determine which permitted transfers actually survive.

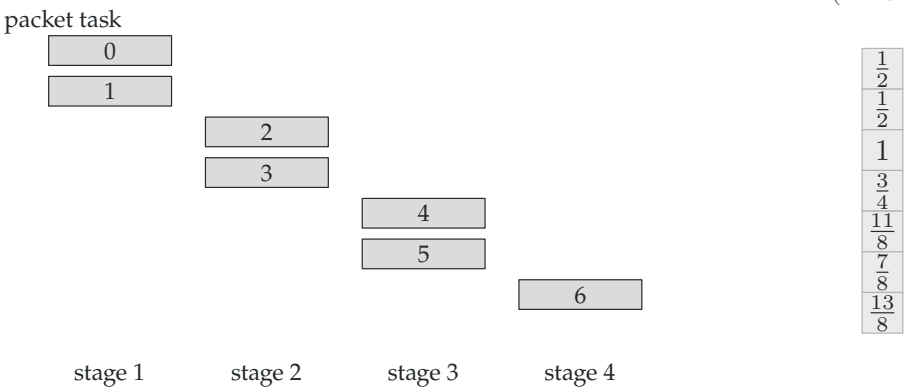

Plate VIII.15 / TOPOLOGICAL LEVELS WITH EXACT OUTPUTS

A solve has a dependency clock

Chapter VIII: Theorem 6.5, Corollary 6.6, Theorem 10.3.

For seven scalar packets, put two on the diagonal and -1 on each declared incoming edge. The edges are $0 \to 2$, $1 \to 2$, $1 \to 3$, $2 \to 4$, $3 \to 4$, $3 \to 5$, $4 \to 6$, and $5 \to 6$. Solve $(2I + K)x = \mathbf{1}$.

$$x = (2I + K)^{-1}\mathbf{1}$$

Read the stages as dependencies

Packets zero and one are ready first. Packets two and three use those values. Packets four and five then become available, followed by packet six. For instance,

$$x_4 = \frac{1 + x_2 + x_3}{2} = \frac{11}{8}, \qquad x_6 = \frac{1 + x_4 + x_5}{2} = \frac{13}{8}.$$

All entries in the displayed solution are checked by multiplying the original triangular matrix by the resulting vector.

When is four a minimum?

There are four vertices on a longest dependency path. Under the paper's unit-duration, unlimited-concurrency model, four stages are both necessary and attainable. If only one execution slot is available, seven tasks require seven slots of work. If task durations differ, the relevant critical path is weighted.

The theorem is not a universal GPU scheduling result. Transfers, synchronization, contention, and nonunit task costs change the model. The exact benefit here is that independent rows in one level need not wait for one another's mathematical results.

Read this as: A topological schedule separates dependencies from resources. Its optimal depth is conditional on the task-duration and concurrency model that defines a stage.

Plate VIII.16 / SCHUR FILL AND ITS CANCELLATION

Elimination creates new interactions

Chapter VIII: Theorem 6.7, Proposition 6.8.

Retain the first two coordinates of

$$A = \begin{pmatrix} 2 & 0 & 1 \\ 0 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}.$$

The third coordinate is hidden. Its invertible block is $[2]$, so eliminating it produces

$$S = A_{RR} - A_{RH}A_{HH}^{-1}A_{HR} = \begin{pmatrix} 3/2 & -1/2 \\ -1/2 & 3/2 \end{pmatrix}.$$

A before elimination

2	0	1
0	2	1
1	1	2

$S = A_{RR} - A_{RH}A_{HH}^{-1}A_{HR}$

$\frac{3}{2}$	$-\frac{1}{2}$
$-\frac{1}{2}$	$\frac{3}{2}$

cancelling variant

$\frac{3}{2}$	0
0	$\frac{3}{2}$

A hidden route creates $-1/2$; adding $+1/2$ in the original block cancels it.

The hidden route has a sign

The retained coordinates had no direct coupling, yet both touch the hidden coordinate. The resulting correction couples them by $-1/2$. This is fill: a new active retained block produced by an eliminated route.

Now change both original retained off-diagonal entries to $+1/2$. The same hidden correction cancels them, leaving the diagonal matrix $\frac{3}{2}I$. Thus a structural route can create or remove visible coupling depending on the direct coefficient already present.

A stronger inverse statement

For an invertible finite packet matrix, inverse support lies in the directed transitive closure. A reachable-coordinate subspace is invariant under the matrix. Injectivity of its restriction implies surjectivity in finite dimension, so the inverse preserves it as well. This proof uses finite-dimensional invertibility, not a convergent geometric series.

The checker verifies both Schur complements and, in each invertible example, equality between S^{-1} and the retained block of A^{-1}.

> **Read this as:** Removing coordinates does not remove their influence. It changes the retained operator, with possible fill, cancellation, and new conditioning constraints.

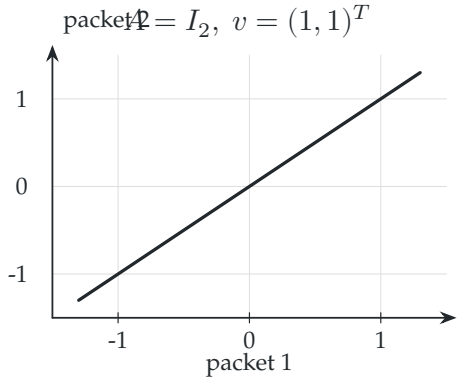

Plate VIII.17 / A STRICT KRYLOV INCLUSION

Invariant does not mean independently addressable

Chapter VIII: Proposition 7.2, Theorem 7.3.

Take $A = I_2$, split into the two coordinate packets, and start with $v = (1, 1)^T$. Every packet is invariant. Nevertheless every polynomial applies the *same* scalar to both coordinates:

$$p(A)v = p(1)(1, 1)^T, \qquad \dim \mathcal{K}_m(A, v) = 1 \quad (m \geq 1).$$

$$p(A)v = p(1)(1, 1)^T$$

$$\dim \mathcal{K}_m(A, v) = 1$$

Independent local spans have dimension 2.

The direct sum of the two local Krylov spans is all of $\mathbb{Q}^2$. It permits independent coefficients in the two packets. The global Krylov space does not. This is why the manuscript states an inclusion, not an unconditional equality.

What breaks the linkage?

With $A = \mathrm{diag}(1, 2)$, the vectors v and $Av = (1, 2)^T$ are independent. Two polynomial samples now distinguish the packet labels. Alternatively, allowing the packet projectors as extra address operators separates the coordinates even when $A = I_2$. Both changes enlarge the addressing power, but in different ways.

When invariance is only approximate

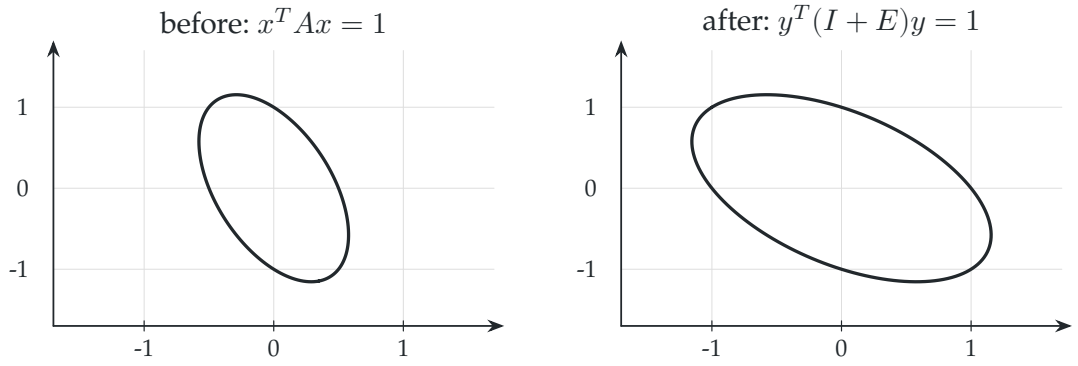
If $A = D + K$ with D packet diagonal, then

$$\|A^j - D^j\| \leq jM^{j-1}\|K\|, \qquad M = \max\{\|A\|, \|D\|\}.$$

This controls departure from the decoupled iterate. It is not a claim that the dimension or numerical conditioning of a Krylov basis varies continuously. Near dependence can remain difficult even when the operator error is small.

> **Read this as:** A single global polynomial can lock otherwise invariant packets together. Independence of subspaces is not the same as independence of the allowed actions.

Plate VIII.18 / BLOCK JACOBI AS A GEOMETRIC CHANGE



Measure coupling after normalization

Chapter VIII: Theorem 7.4, Corollary 7.6, Classical input 7.5.

Let

$$A = \begin{pmatrix} 4 & 1 \\ 1 & 1 \end{pmatrix}, \quad D = \operatorname{diag}(4, 1), \quad B = D^{-1/2} = \operatorname{diag}(1/2, 1).$$

Then $BAB = I + E = \begin{pmatrix} 1 & 1/2 \\ 1/2 & 1 \end{pmatrix}$. Its exact eigenvalues are $1/2$ and $3/2$, giving condition number three.

Exact normalized eigenvalues: $1/2, 3/2$. Hence $\kappa_2 = 3$.

The unit circles of the energy norms

The left ellipse is $x^T Ax = 1$. Writing $x = By$ gives the right ellipse $y^T(BAB)y = 1$. The drawing samples these explicitly defined curves. The norm and eigenvalue equalities are checked symbolically.

Here $\|E\|_2 = 1/2$. The manuscript's general inequality

$$\kappa_2(D^{-1/2}AD^{-1/2}) \le \frac{1+\eta}{1-\eta}, \qquad \|E\|_2 \le \eta < 1,$$

is attained. The raw off-diagonal entry is one. Its meaningful size is one-half only after normalization by the diagonal energy scales.

Keep the convergence input separate

The condition bound can be inserted into a conjugate-gradient convergence estimate under that method's positive-definite assumptions. The CG estimate is one of the separately tracked classical inputs. The algebraic normalization theorem does not certify every stopping rule, floating-point iteration, or arbitrary preconditioner.

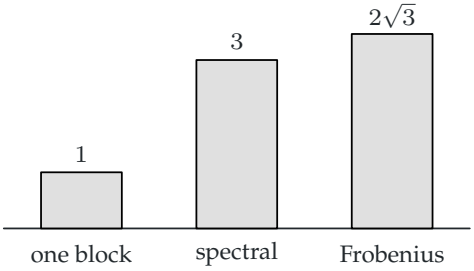
> **Read this as:** A small raw coupling is not scale-invariant. Normalize against the diagonal blocks before deciding whether the coupling is weak enough for a condition bound.

Plate VIII.19 / DISCOVERY AND PERTURBATION CERTIFICATES

Twelve small blocks, one coherent error

Chapter VIII: Theorem 8.1, Proposition 9.2.

Split $\mathbb{Q}^4$ into scalar packets and let



$$A = I + E, \qquad E = \frac{1}{100}(\mathbf{1}\mathbf{1}^T - I).$$

Dropping every off-diagonal block leaves I. Each discarded entry is only $1/100$, but the total error is not bounded by that single-entry size.

$100E$: twelve omitted entries

0	1	1	1
1	0	1	1
1	1	0	1
1	1	1	0

error norms, in units of $1/100$

$\|E\|_F^2 = 12/10^4$, while $E\mathbf{1} = (3/100)\mathbf{1}$.

Two norms answer different questions

There are twelve omitted entries, so $\|E\|_F^2 = 12/10^4$. The all-one vector is an eigenvector with eigenvalue $3/100$, while the three orthogonal directions have eigenvalue $-1/100$. Hence $\|E\|_2 = 3/100$.

For orthogonal coordinate blocks, the squared Frobenius norms add exactly. Operator norms instead require a suitable bound or further spectral information. The maximum omitted block norm is generally insufficient.

Input sensitivity is additional information

The packet perturbation estimate is

$$\|(\widehat{A} - A)x\| \le \sum_e \|E_e\| \, \|P_{\alpha(e)}x\|.$$

It can be much tighter for an input that scarcely occupies an affected source packet. To obtain a uniform operator bound, the input dependence must be bounded uniformly over unit vectors. A certificate for one input is not automatically a certificate for every right-hand side.

These are a posteriori checks for supplied projectors. They do not discover the best packet system or prove that a thresholding heuristic is globally optimal.

> **Read this as:** A proposed compression needs a residual certificate in the requested norm and input scope. Small individual blocks can align into a larger collective error.

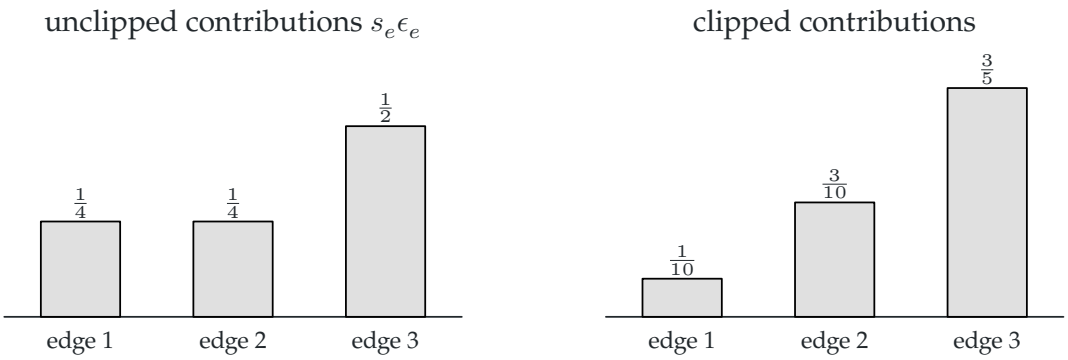


Plate VIII.20 / CONTINUOUS AND CLIPPED PRECISION

Spend error where it is cheapest

Chapter VIII: Theorem 8.4, Theorem 8.5.

Take sensitivities $s = (1, 2, 4)$, cost coefficients $c = (1, 1, 2)$, and budget $\tau = 1$. Minimizing $\sum_e c_e \log(1/\epsilon_e)$ subject to $\sum_e s_e \epsilon_e = 1$ gives

$$\epsilon_e = \frac{c_e}{4s_e}, \qquad \epsilon = (1/4, 1/8, 1/8).$$

Both allocations spend exactly one unit of error budget.

The budget is weighted

The three contributions to the error allowance are $(1/4, 1/4, 1/2)$. Equal cost coefficients give equal weighted contributions, not equal tolerances. The third edge has twice the cost coefficient of the second, which offsets its doubled sensitivity in this example.

Now impose upper tolerances $m = (1/10, 1/2, 1/2)$. The first edge must stop at its tighter cap. With multiplier $\lambda = 10/3$, the clipped solution is

$$\epsilon_e = \min\{m_e, c_e/(\lambda s_e)\}, \qquad \epsilon = (1/10, 3/20, 3/20).$$

Its weighted contributions are $(1/10, 3/10, 3/5)$ and still sum to one. The checker verifies the active cap, the multiplier equations, and the budget exactly.

From tolerance to a real data type

The continuous objective is a model. Actual kernels offer discrete precisions and may use different accumulation types. A tolerance below one does not identify a particular hardware format. The finite option program on the next page is the correct next step once admissible costs and error bounds have been supplied.

> **Read this as:** Precision allocation is an optimization over certified sensitivities and costs. It does not infer error bounds from a data-type name alone.

Plate VIII.21 / THREE EDGES, TWENTY-SEVEN ASSIGNMENTS

An exact budget is not a greedy choice

Chapter VIII: Theorem 8.7, Remark 8.8.

Each edge has three allowed $(\text{integer weight}, \text{cost})$ options:

$$1 : (0,7), (2,3), (4,1),$$
$$2 : (0,6), (1,4), (3,1),$$
$$3 : (0,9), (2,5), (5,1).$$

There are exactly $3^3 = 27$ full assignments. The table stores the minimum cost at each *exact* weight. Columns zero through eight are displayed.

	0	1	2	3	4	5	6	7	8
edges 0	0	∞	∞	∞	∞	∞	∞	∞	∞
edges 1	7	∞	3	∞	1	∞	∞	∞	∞
edges 2	13	11	9	7	7	4	∞	2	∞
edges 3	22	20	18	16	14	12	12	9	8

Columns are exact weights; the budget optimum is the minimum across allowed columns.

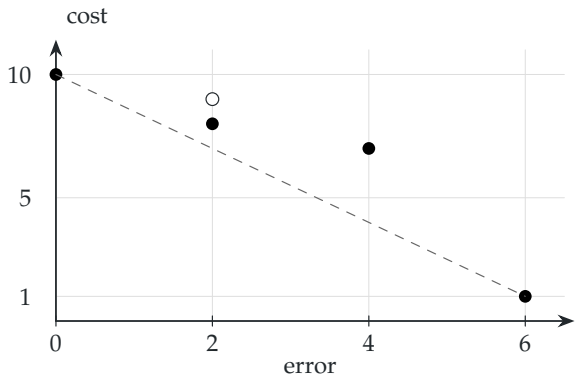
Read the final row correctly

At budget four, minimize across columns zero through four. The optimum costs 14: choose weights $(2, 0, 2)$ with costs $(3, 6, 5)$. The zero-weight choice on edge two is its first, more expensive option. A locally cheap choice can consume too much of the shared budget.

The checker compares the recurrence with complete enumeration for every budget from zero through twelve. Infeasible states remain $+\infty$. They are not zero-cost states.

Quantization must be conservative

Suppose real errors are $3/50$ and $2/25$, and one integer unit represents $1/10$. Rounding down gives two zero weights, even though the true sum is $7/50 > 1/10$. Rounding up gives a certified upper envelope instead. The budget method is exact for its integers. It cannot repair unsafe integers supplied by a preprocessing step.



> **Read this as:** The table optimizes the declared option set exactly. Accuracy depends separately on the validity and conservativeness of the option weights.

Plate VIII.22 / FIVE PRUNINGS, ONE NONCONVEX FRONTIER

A penalty can miss the budget optimum

Chapter VIII: Theorem 9.4, Corollary 9.7, Theorem 9.8.

A root r has children a, b, each with two terminal children. Keeping r costs one with error six. Splitting it adds overhead one. Keeping either a or b costs three with error two. Splitting a costs four with zero error, and splitting b costs five with zero error.

Budget $B = 2$: cost 8

Penalty optimum: root or full split

$8 + 2\lambda \le 1 + 6\lambda$
and $8 + 2\lambda \le 10$
cannot both hold.

The five complete prunings have $(\text{cost}, \text{error})$ pairs

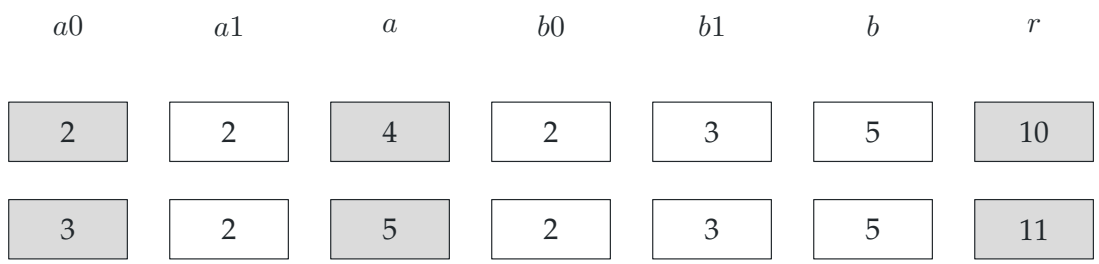
$$(1, 6),\ (7, 4),\ (9, 2),\ (8, 2),\ (10, 0).$$

At budget two the unique cheapest pruning is $\{a_0, a_1, b\}$, costing eight. It is Pareto optimal, but never minimizes cost $+\lambda$ err for any $\lambda \ge 0$.

See the incompatible inequalities

To beat the root, that pruning would require $8 + 2\lambda \le 1 + 6\lambda$, hence $\lambda \ge 7/4$. To beat the full split, it would require $8 + 2\lambda \le 10$, hence $\lambda \le 1$. No multiplier meets both conditions.

The exact budget recurrence retains the point because it enumerates admissible weight allocations. A sweep of Lagrangian parameters sees only supported frontier points. The two compiler formulations are therefore genuinely different, even on this tiny tree.



> **Read this as:** A penalty parameter is not a universal substitute for an explicit budget. Discrete, nonconvex frontiers can contain useful optima that no penalty selects.

Plate VIII.23 / LOCAL DEPENDENCIES AND STRICT MARGINS

Recompile the changed part, not everything

Chapter VIII: Theorem 9.11, Theorem 9.12.

Use the same tree with $\lambda = 2$. Increase only the leaf cost at a_0 from two to three. The exact subtree values change at a_0, its parent a, and the root r. Every value in the b subtree remains untouched.

Top: old values. Bottom: new values. Only a0, a, and r change.

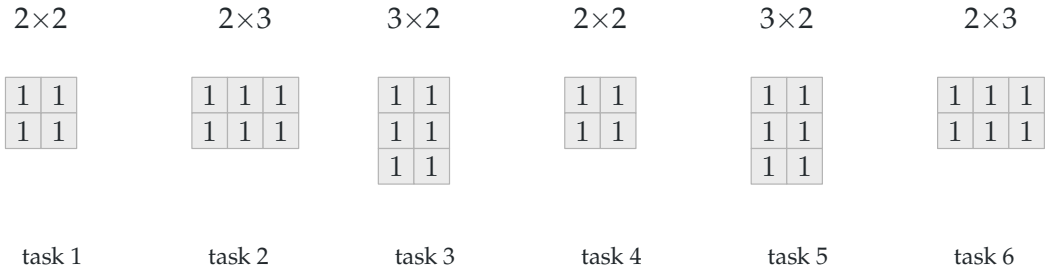
Why the update is local

A dynamic-programming value depends only on the local keep/split data and its children's values. A changed leaf can therefore affect its ancestors but not a disjoint sibling subtree. Recomputing the dependency closure yields the same global optimum as a fresh traversal. In this example, the root value increases from ten to eleven.

Strict gaps protect decisions

Before the update, the root keep score is 13 and its split score is 10, giving gap three. If each score changes by less than $3/2$, their strict ordering is retained. Allowing exactly $3/2$ in both directions can produce a tie, so the strict inequality in the stability statement matters.

The bound applies to the completed scores after child subproblems have been evaluated. Bounds on raw leaf perturbations must first be propagated to those scores. Shared caches, overlapping subproblems, or global rank constraints can introduce dependencies outside a tree and invalidate this simple locality argument.



> **Read this as:** Local recompilation is exact because the model has local dependencies. The locality is a mathematical hypothesis, not an automatic property of every compiler optimization.

Plate VIII.24 / A LAUNCH MODEL IS NOT A BANDWIDTH MODEL

Batch shapes, account for traffic

Chapter VIII: Proposition 3.6, Theorem 3.8, Proposition 10.2.

Six independent blocks have the displayed dimensions. When right-hand-side count, scalar type, accumulation type, and kernel contract also agree within each class, they can be grouped into three batches. That reduces the modeled launch count from six to three without changing their arithmetic.

Three shape classes, six independent tasks.

Grouping does not remove arithmetic, data transfer, or shared-output dependencies.

Independence must be real

The batching statement assumes compatible backend support and independent block tasks. If several blocks accumulate into one target, the reduction or accumulation policy is additional work. Equal matrix dimensions alone do not remove that dependency. Different accumulation types also define different shape classes under the paper's convention.

Count the data separately

For three diagonal 2×2 blocks, eight-byte scalars, and q right-hand sides, the stated one-pass model moves

$$B_{\text{stream}} = 8 \cdot 3(4 + 2q + 4q) = 96 + 144q \text{ bytes.}$$

It gives 240 bytes at $q = 1$ and 672 bytes at $q = 4$. It deliberately assumes no reuse across edges. A cache-aware implementation may have another traffic model, but it must state one.

Given operation capacity P and bandwidth W, $T \geq \max(F/P, B/W)$ is a lower bound, not an achieved runtime. Launch overhead, imperfect overlap, and utilization can make the actual time much larger.

Read this as: Grouping can remove launches while leaving the same products and data movement. Arithmetic, traffic, and scheduling are related constraints, not one interchangeable cost.

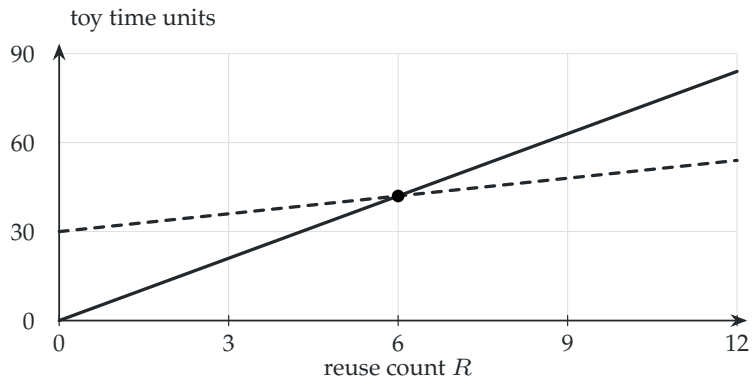


Plate VIII.25 / SETUP AND REUSE IN ONE LINEAR MODEL

The first win comes after the tie

Chapter VIII: Theorem 10.4, Corollary 10.5, Corollary 10.6.

Suppose the baseline costs seven units per use. A candidate costs 30 units to set up and two per use. These are synthetic constants chosen to expose the exact threshold:

$$T_b(R) = 7R, \qquad T_c(R) = 30 + 2R.$$

solid: $7R$

dashed: $30 + 2R$

tie at 6
first win at 7

At $R = 6$, both cost 42. The candidate becomes strictly faster at $R = 7$, where it costs 44 instead of 49. The minimum profitable integer reuse count is

$$\left\lfloor \frac{30}{7-2} \right\rfloor + 1 = 7.$$

Replacing the floor-plus-one rule with a ceiling would be wrong when the ratio is already an integer and strict improvement is required.

Which costs belong to setup?

Discovery, compilation, host/device transfer, graph capture, and factor preparation can have different reuse lifetimes. If a matrix changes but its shape does not, a captured schedule might remain reusable while its numerical factors do not. A single setup number is meaningful only after those lifetimes are fixed.

Materialization has the opposite tradeoff: pay once for an explicit representation, then use a potentially faster dense downstream operation. It pays off only when the explicit per-use cost is lower and the reuse count exceeds the corresponding conversion threshold.

> **Read this as:** A faster steady-state kernel can lose end-to-end. State the reuse regime and count the tie separately from the first strict win.

Plate VIII.26 / A BENCHMARK ROW IS A CONTRACT

Same output before comparing times

Chapter VIII: Proposition 2.9, Section 11, Section 12.

Consider four synthetic timing rows for a product. Row B returns factors, while row A returns an explicit matrix. A ratio $12/2 = 6$ does not compare two implementations of the same returned object. Adding the decoding cost changes the candidate to row C.

row	output	scope	time
A	explicit matrix	materialization included	12
B	low-rank factors	factor product only	2
C	explicit matrix	factor product + decode	14
D	explicit matrix	different input precision	1

Synthetic times: A versus C is contract-aligned. A versus B is not a sixfold speedup.

What a fair match retains

The input values, dimensions, layout, source precision, correctness reference, returned output, and timing scope must agree. Row D changes the input precision. That can be a useful accuracy tradeoff, but it is not the same case merely because the output has the same shape.

If a downstream task consumes factors directly, row B has a valid compressed-output contract. It should be compared with another method that supplies that downstream result, not forced to materialize an unused array. Fairness does not mean every algorithm must use the same internal representation.

How the original measurements are treated here

The accompanying benchmark study records the CPU/GPU corpus. Regenerating its figures redraws the saved observations. It does not rerun the device, establish current hardware performance or turn logically avoided work into physically executed floating-point operations. These figures add no new timing measurements.

Exact representation gains, device gains, kernel gains, and amortization gains can be isolated only through appropriately matched rows. A total ratio that mixes them is still an observation, but not a decomposition theorem.

> **Read this as:** A timing number without its case and scope is incomplete data. Preserve the mathematical output contract before claiming a speedup.

Plate VIII.27 / FACTORS, APPLICATION, AND AN INDEPENDENT REFERENCE

Close the loop on the running example

Chapter VIII: Theorem 2.3, Theorem 3.4, Theorem 5.1.

Return to the two operators from Plate VIII.9. The exact product representation has diagonal part $D_A D_B$ and two-column correction factors U_C, V_C. Apply it to the original $x = (1, -1, 2, 0, -2, 3)^T$.

$$V_C^T x = (2, 13)^T, \qquad (AB)x = D_A D_B x + U_C(V_C^T x).$$

$V_C^T x$	$D_A D_B x$	$U_C(V_C^T x)$	$(AB)x$
2	1	25	26
13	−5	21	16
	18	25	43
	6	21	27
	−12	25	13
	44	21	65

Two intermediate scalars and six output coordinates, with an exact dense reference.

A complete reader calculation

The local contribution is $(1, -5, 18, 6, -12, 44)^T$. The correction is $(25, 21, 25, 21, 25, 21)^T$. Their sum is

$$(26, 16, 43, 27, 13, 65)^T.$$

The checker forms the dense matrices A and B independently, multiplies them, applies the product to x, and compares all six components. The dense array is a validation reference, not a requirement of the factored application route.

Choose what happens next

For another input, reuse the factors. For a required explicit matrix, pay materialization. For a long product chain, track rank growth and decide whether recompression is useful. If approximation is introduced, transport its error through the later operators rather than reporting only a local singular tail.

This small example does not predict a speedup: at dimension six, implementation overhead can dominate. Its purpose is to make the semantics auditable. The same identity can then be used inside a larger, separately benchmarked workload.

> **Read this as:** The full route is: represent the exact operator, retain every interaction, return the requested object, and validate against an independent reference. Performance is a further experiment.

Plate VIII.28 / FORMAL, EXACT, NUMERICAL, AND EMPIRICAL EVIDENCE

What the evidence certifies

Chapter VIII: Sections 13–14; accompanying benchmark and verification records.

The formal companion covers 56 finite manuscript-proved items through 392 supporting theorem declarations in 40 modules. Nineteen declarations are reused foundation results. The 66 construction audits are counted separately. Compiler records and source identities are provided with the formal companion.

Evidence	Its precise use here
Saved Lean records	Preserve the exact hypotheses and declared finite formalization boundary.
Exact model checks	Reproduce the guide's displayed matrices, identities, integer models, and finite optima. They are not extracted Lean proofs.
Vector drawings	Display explicit arrays, schedules, and sampled geometric formulas. Pixel accuracy is not algebraic certification.
Separate software checks	The verification report records actual runs, tolerances, failures, and unavailable gates. These are separate from this guide's exact arithmetic.
Recorded GPU corpus	Remains a record of the supplied original cases and environment. It is not a new measurement.

The recompression distinction

The recompression theorem derives best-rank and singular-tail conclusions from ordered thin-SVD equations rather than an assumed optimality certificate. It does not establish general SVD existence, certify a floating-point QR/SVD algorithm or identify every result with a canonical singular-values API. These are separate statements.

The four classical entries remain visible

The manuscript separately tracks Eckart–Young–Mirsky, the conjugate-gradient energy estimate, the floating-point product model, and simultaneous spectral decomposition. The strengthened ordered-SVD proof does not silently promote all associated existence and numerical-algorithm claims.

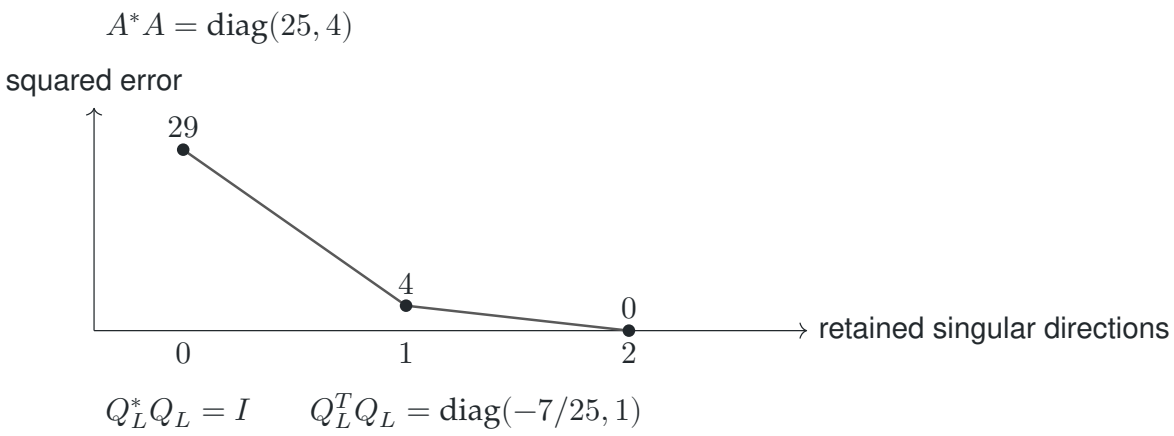
Limits of exact compilation

The optimizer needs a finite candidate tree with additive data. Nonlocal cache effects, overlapping decompositions, global rank coupling, and unrestricted discovery can destroy its optimal substructure. No new generic dense-matrix exponent or universal accelerator claim follows from this guide.

> **Read this as:** This guide explains the chapter's finite concepts through reproducible examples and preserved source evidence. It changes exposition, not the formal theorem contract.

Plate VIII.29 / THE INNER PRODUCT IS PART OF THE CONTRACT

A complex range needs an adjoint



Chapter VIII: Theorem 5.6, Section F.1, Section F.2.

The earlier compact example is real. Over $\mathbb{C}$, an isometry means $Q^*Q = I$, with conjugation. Take the exact Gaussian-rational factors

$$Q_L = \begin{pmatrix} 3/5 & 0 \\ 4\mathrm{i}/5 & 0 \\ 0 & 1 \end{pmatrix}, \qquad Q_R = \begin{pmatrix} 1 & 0 \\ 0 & \mathrm{i} \end{pmatrix}, \qquad G = \operatorname{diag}(5, 2).$$

Their product is a genuinely complex rectangular operator:

$$A = Q_L G Q_R^* = \begin{pmatrix} 3 & 0 \\ 4\mathrm{i} & 0 \\ 0 & -2\mathrm{i} \end{pmatrix}, \qquad A^*A = \operatorname{diag}(25, 4).$$

The small calculation exposes a wrong convention

The first column of Q_L has Hermitian squared length $9/25 + 16/25 = 1$. Its bilinear square without conjugation is $9/25 - 16/25 = -7/25$. Thus $Q_L^TQ_L$ is not the identity. The portable negative control replaces the adjoint by transpose and rejects the resulting isometry claim.

Keeping the first diagonal entry of G gives A_1 with its second column zero. The residual has squared Frobenius norm four and Gram matrix $\operatorname{diag}(0, 4)$, hence spectral norm two. Both errors agree with the discarded core singular value. Every displayed arithmetic operation occurs in $\mathbb{Q}(\mathrm{i})$.

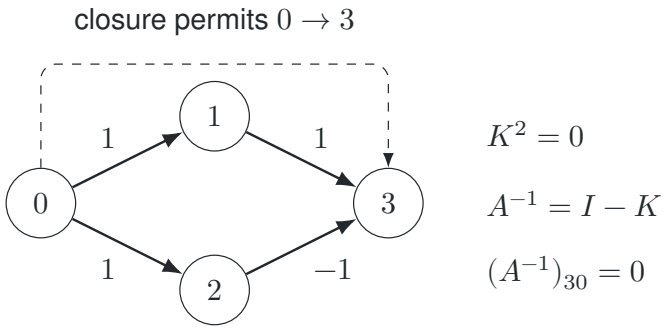
What the finite check establishes

It checks both isometries, the reconstructed ambient matrix, its Gram matrix, and the explicit rank-one residual. Global best-rank optimality still comes from the manuscript's compression and lower-bound proof. This two-column calculation is a worked instance of that argument. No existence theorem or numerical SVD routine is executed.

> **Read this as:** Conjugation preserves the complex Euclidean norm. A transpose is correct in the vectorization identity on Plate VIII.7, but an adjoint is required for an isometric range lift.

Plate VIII.30 / A FINITE INVERSE WITH A CANCELLED ROUTE

Inverse reachability is still an inclusion



Chapter VIII: Theorem 6.7, Theorem 6.1, Corollary 6.3.

Reuse the signed diamond from Plate VIII.14, now as a complete operator:

$$A = I + K = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & -1 & 1 \end{pmatrix}.$$

The two routes from coordinate zero to coordinate three cancel, so $K^2 = 0$. Consequently

$$A^{-1} = I - K = \begin{pmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & -1 & 1 & 1 \end{pmatrix}.$$

What the closure permits

The directed transitive closure includes $0 \to 3$, because it records existence of a route rather than the signed sum of its coefficients. Nevertheless $(A^{-1})_{30} = 0$. Reachability is therefore an upper envelope for inverse support, just as it is for product support.

The portable checker computes the inverse independently by rational row elimination, compares it with $I - K$, constructs Boolean reachability, and checks every inverse entry outside that closure. It separately rejects the assertion that every reachable transfer is nonzero.

Why the general proof is broader

This example happens to have a terminating Neumann polynomial. The general finite-dimensional theorem does not require nilpotence or a small norm. For a fixed source coordinate, its reachable-coordinate subspace is invariant under A. If A is invertible, the restricted map is injective. Equal finite domain and codomain dimensions make it surjective, so the inverse preserves the same subspace.

The finite-dimensional and invertibility hypotheses matter. In an infinite-dimensional space, an injective restriction can fail to be onto. A singular matrix does not have an inverse whose support can be tested at all.

> **Read this as:** The inverse can never transmit outside the reachable subspace under the theorem's hypotheses. Inside that subspace, coefficient cancellation can still remove a structurally permitted interaction.

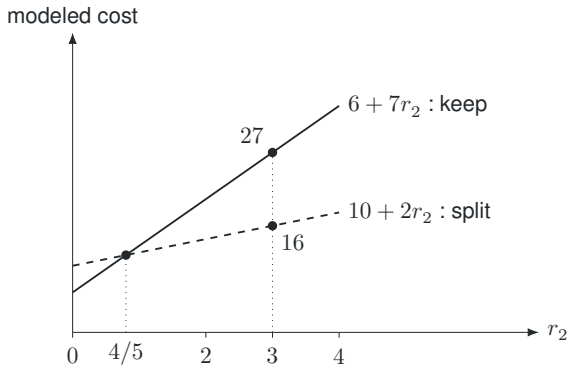


Plate VIII.31 / SHARED COMPILATION HAS ITS OWN OBJECTIVE

One tree can serve a weighted family

Chapter VIII: Corollary 9.5, Theorem 9.4.

Use a tree with one root and two terminal children. There are exactly two admissible prunings: keep the root, or split into both children. All declared errors and the split overhead are zero. Their additive total costs are:

Cost component	Keep	Split
Setup paid once	4	2
Operator 1, per use	2	8
Operator 2, per use	7	2

With reuse weights $(r_1, r_2) = (1, 3)$, the aggregated objectives are

$$J_{\text{keep}} = 4 + 2 + 3 \cdot 7 = 27, \qquad J_{\text{split}} = 2 + 8 + 3 \cdot 2 = 16.$$

The exact shared optimum is split. Operator 1 alone prefers keep on its per-use costs, while operator 2 prefers split. Choosing independently and trying to combine those decisions would not solve the declared one-pruning problem.

A hand-computable decision threshold

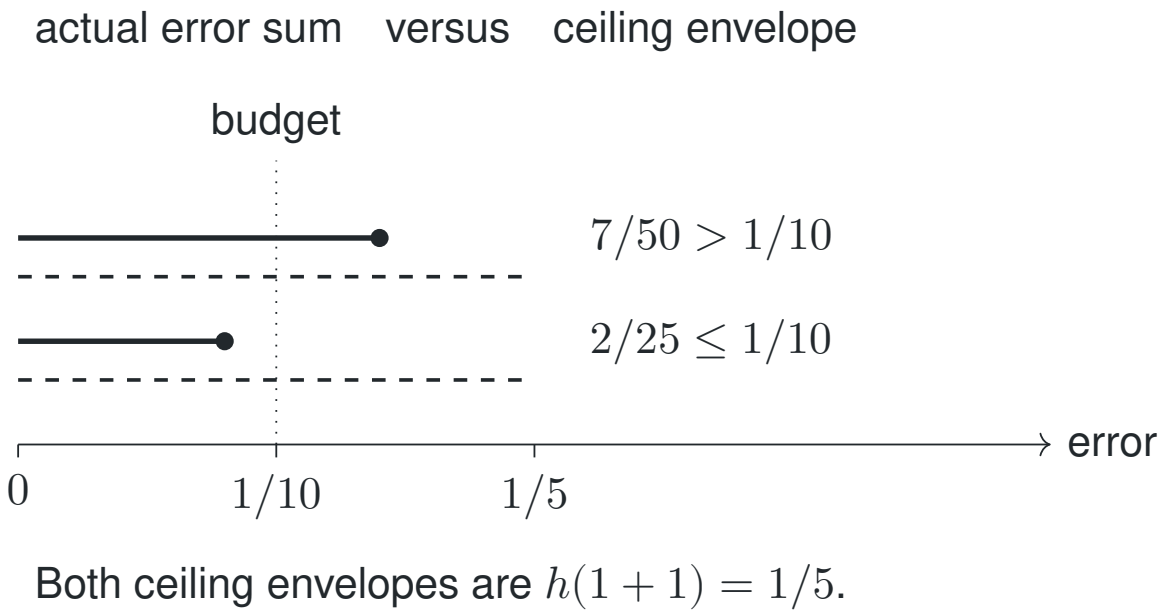
Fix $r_1 = 1$ and vary $r_2 = r \geq 0$. Keeping costs $6 + 7r$ and splitting costs $10 + 2r$. Splitting is strictly cheaper when $r > 4/5$. Its first integer reuse win is $r = 1$. The checker evaluates both admissible choices for integers zero through four and checks the displayed totals at three.

Where the common-tree proof applies

The family corollary aggregates local keep costs and errors, then uses the same exact subtree recurrence. In this example, each row denotes the sum of the selected local leaf terms. It does not conceal a nonlocal discount. A setup shared by distant unrelated nodes, overlapping candidates, or a global resource constraint would need an enlarged state or a different model.

Read this as: Reuse weights change the objective before compilation. Shared optimality is exact for the supplied common tree and additive family costs, rather than for an unspecified set of future workloads.

Plate VIII.32 / QUANTIZATION AND THE SIZE OF THE BUDGET TABLE



Safe integers can still be conservative

Chapter VIII: Theorem 8.7, Theorem 9.8, Corollary 9.9.

Let one integer unit represent $h = 1/10$ of certified error. For an individual nonnegative error e, choosing

$$w = \lceil e/h \rceil \qquad \text{ensures} \qquad e \le hw.$$

Thus integer feasibility $\sum w \le B$ implies the real bound $\sum e \le hB$. This implication is checked before applying the exact option or tree recurrence.

A false certificate and a conservative rejection

For errors $(3/50, 2/25)$, rounding down assigns weights $(0, 0)$ although their real sum is $7/50 > 1/10$. Rounding up gives $(1, 1)$ and correctly excludes the assignment from budget one.

Now change the errors to $(3/50, 1/50)$. Their sum is $2/25 \le 1/10$, but separate ceilings still give $(1, 1)$. The integer model rejects an assignment that is feasible for the real-valued problem. Conservative rounding protects soundness. It need not preserve every optimum of the unquantized problem.

Why the complexity is pseudo polynomial

For a declared integer budget B, a table has $B + 1$ possible exact-weight states. A direct merge checks at most $(B + 1)^2$ state pairs. At $B = 255$, this means 256 states and 65,536 candidate pairs at a merge, even though the budget fits in eight binary digits.

With a bounded number of children, the paper's direct tree implementation therefore has quadratic budget dependence at each node. Polynomial dependence on the numerical value of B does not mean polynomial dependence on the binary input length. These are counts of declared states and pairs, not measured runtimes or claims that every state is reachable.

Read this as: The dynamic program is exact for its integer data. Conservative conversion and the numerical size of the budget are separate obligations that determine its accuracy and practical scale.

CHAPTER IX

Euler Congruences

Completion, factorial strengthening, and sharp dyadic geometry

The arithmetic sequence begins with congruence identities and the hypotheses needed to extend them.

Euler congruences are developed through completion, factorial strengthening and dyadic geometry. The accompanying guides connect exact statements, bounded examples and formal coverage.

IN THIS CHAPTER

Mathematical text 931

Visual studies 1145

Formal companion 2220

Sources and references 2687

Scope

The arithmetic, dyadic and lifting results have distinct hypotheses. General Euler-tail simplicity and the broader native and polyphase extensions remain open.

The next chapter organizes residual seeds and conditional system completion from supplied arithmetic data.

Abstract

We prove Nishibuchi's generalized Euler congruence conjecture in its full stated parameter range and develop sharper arithmetic consequences. For every prime-power packet width, a charged Hurwitz differential operator transfers integral difference estimates through the reciprocal generating series. In the dyadic case this gives mixed finite-difference bounds at every row, without a starting threshold. For the four addresses of width four, a divided-power argument adds the factorial gain $v_2(k!)$, determines every repeated-step valuation in addresses zero and one, and gives a stronger address-two estimate with exact values at all power-of-two orders. The corresponding first differences yield least periods and bijective isometric continuations onto explicit dyadic residue classes. We also determine exact Taylor radii for three addresses. The manuscript retains the complete earlier arithmetic, lifting, deformation, and analytic-regularity development, with detailed mathematical appendices. A separate appendix states the precise remaining simplicity problem for ordinary Euler tails. Formal coverage is explicit: the external conjecture and several four-address results have inherited Lean verification. The new factorial, mixed-step, all-rank, and radius arguments are written proofs with recorded audits and exact computational checks, and await dedicated Lean formalization.

Principal results

The original external problem is Nishibuchi's Conjecture 3.9 for generalized Euler numbers. Its full parameter range is resolved. If p is prime, m is positive with $m \mid p-1$ or $m = 2$, $0 \le j < mp$, and $q = \operatorname{lcm}(2, p-1)$, then the original Euler coefficients are p-adically integral and

$$E^{(mp,j)}_{mpn+qp^r} \equiv E^{(mp,j)}_{mpn} \pmod{p^r} \qquad (r \ge 1,\ n \ge r).$$

The chapter states the generating function and the conversion between ordinary degree and packet row before using this formula. The normalized coefficient is $C_{N,j}(n)$ and the original coefficient is $E^{(N,j)}_{Nn} = j!C_{N,j}(n)$. The constant coefficient of the original series is $j!$.

The strongest common-step conclusion in width four is compact. For $n \ge 0$ and $k, H \ge 1$,

$$\sum_{i=0}^{k} (-1)^{k-i} \binom{k}{i} E^{(4,j)}_{4(n+iH)} \equiv 0 \pmod{2^{\,v_2(k!)+kv_2(H)+A_j(k)}},$$

where

$$A_0(k) = A_1(k) = k, \qquad A_2(k) = \max\{k+4,\ 2k + \lfloor k/2 \rfloor + 1\}, \qquad A_3(k) = k+2.$$

There is no starting-row threshold. The exponent is exact in addresses zero and one for every order and positive step. It is exact in address two at every power-of-two order. The proof chapters also give mixed-step forms, the cancellation criterion in addresses zero and one, and exact first-displacement laws.

Result	Scope	Evidence
Nishibuchi Conjecture 3.9	Every parameter in the original statement, with explicit $n \geq r$	Inherited Lean proof
Width-four all-row common-step bound, first differences, least periods and isometry	Every address, row and positive displacement	Inherited Lean proof
General prime-power inverse transfer and mixed steps	Every prime-power width, with signed steps for odd primes	Written proof and audit
Factorial gains and exact higher-order families	Four width-four addresses, with stated sharpness scopes	Written proof and audit
Taylor radii and broader dyadic first differences	Exact radii in addresses $0, 1, 2$ and stated all-rank cases	Written proof and audit
Ordinary Euler tail simplicity	Partial families and an explicit remaining discriminant problem	Open in full generality

The arithmetic development leads to polynomial lifting, deformation and analytic regularity. The appendices give the detailed continuation arguments and the recovered foundational treatment. Where an earlier formulation is retained for comparison, its hypotheses and proof status remain explicit. The formal companion supplies the exact source map and distinguishes source review from compiler execution. The visual studies supply finite examples and diagrams derived from the theorems.

Recorded proof reviews are internal reviews. Formal proof coverage and the scope of each mathematical result are stated separately.

1 Scope and conventions

The central objects are sequences and polynomial equations equipped with arithmetic coordinates. Residue projectors select addresses in a sequence, finite differences measure compatibility between nearby addresses, and valuation bounds control the passage from finite precision to a p-adic limit. These constructions provide a common language for the Euler packet results and the later lifting results. Each theorem nevertheless retains its own coefficient ring, topology and nonsingularity hypotheses.

The arithmetic framework is developed together with its completed extensions. The stated external Nishibuchi conjecture is proved in its full specified parameter range. The dyadic refinements and polynomial deformation theorems give stronger conclusions under the hypotheses stated with each result. The native conjectures retain their original identifiers, 13.2 and 13.3, when discussed as research questions, although the section numbering of this consolidated manuscript is new.

Throughout, $\mathbb{N} = \{0, 1, 2, \ldots\}$. When p is prime, $\mathbb{Z}_p$ denotes the p-adic integers and $\mathbb{Q}_p$ their fraction field. We normalize $v_p(p) = 1$. For a rational or p-adic quantity, a displayed lower valuation bound is understood with the mathematical convention $v_p(0) = +\infty$. The corresponding formal predicates are zero-safe: the quantity is zero or its valuation meets the stated bound. An exact finite valuation assertion requires a nonzero quantity, and this is stated where used. Congruence in $\mathbb{Z}_p$ means ideal divisibility. Thus

$$x \equiv y \pmod{p^r} \quad \Longleftrightarrow \quad x - y \in p^r \mathbb{Z}_p.$$

For vectors, ideal membership and congruence are coordinatewise.

Write $\Delta_u f(n) = f(n+u) - f(n)$ and use Δ_u^k for its k-fold iterate. Euler coefficients indexed by ordinary degree and by packet row are distinguished explicitly. A packet displacement by u rows is a degree displacement by Nu in a packet of width N.

The main text presents theorem statements and their arguments. Accompanying source maps identify the Lean declarations and archived files that support them. The formal companion identifies the scope of each recorded build. The 91-check polynomial record covers the polynomial development. Separate records support the arithmetic results. The inherited formal development is retained without adding Lean declarations. The strengthening chapters add written proofs and clearly mark their formalization boundary. No historical-priority claim is made. The analytic inverse-function results used in Section 11 come from Mathlib.

2 Arithmetic packets and coefficient transport

We work with sequences, formal power series, and finite recurrence states. Residue selectors isolate coefficients in a chosen congruence class, while triangular transport expresses the same object in new coordinates. A valuation filtration determines how many coordinates are needed at a given precision. Together, these operations provide a common framework for the Euler congruences and the finite lifting constructions developed later.

The original arithmetic seed notation

$$\mathcal{S} = (A, a_0, \mathcal{O}, \mathcal{R}, \{P_{N,j}\}, w, \tau_p)$$

records a coefficient ring or module, a seed, allowed operators, relations, residue selectors, a depth weight, and a topology. This notation describes the ingredients of the construction. A category of seed presentations and a notion of equivalence still require separate definitions. We therefore state each theorem for a concrete object. Section 12 discusses the additional structure needed for the original native conjectures.

The Lean declarations cited in this section have namespace prefix `KomorebiPaperIX`. Their exact modules and source hashes are recorded in the accompanying statement map. All belong to the preserved baseline formalization. This section brings their statements and proofs together.

2.1 Residue selectors and exact reconstruction

Let R be a commutative ring, $a : \mathbb{N} \to R$, $N \geq 1$, and $0 \leq j < N$. Define

$$(P_{N,j}a)(n) = \begin{cases} a(n), & n \equiv j \pmod{N}, \\ 0, & \text{otherwise.} \end{cases}$$

This definition keeps the original index set. The compressed subsequence $a(Nq + j)$, used below for recurrence packets, is a different representation of the selected coefficients.

Theorem 2.1 (Residue reconstruction)**.** *The selectors satisfy*

$$P_{N,j}^2 = P_{N,j}, \qquad P_{N,i}P_{N,j} = 0 \quad (i \neq j), \qquad \sum_{j=0}^{N-1} P_{N,j} = I.$$

If $N \mid M$ and $M > 0$, then

$$P_{N,j}a = \sum_{\substack{0 \leq r < M \\ r \equiv j \pmod{N}}} P_{M,r}a.$$

The same identities hold coefficientwise for formal power series.

Proof. At each index n, exactly one standard residue label equals n mod N. Consequently a repeated selector changes nothing, two different selectors have zero composite, and the sum retains $a(n)$ exactly once. If $N \mid M$, reducing n mod M modulo N gives n mod N. This proves the refinement identity at every coefficient. Equality of all coefficients proves the formal-series versions. □

Formal correspondence. `ResiduePackets.packet_idempotent`, `ResiduePackets.packet_orthogonal`, `ResiduePackets.packet_reconstruction`, and `ResiduePackets.packet_refinement`. The series variants have the prefix `series_packet` in the same module. The algebraic statements need no convergence hypothesis.

2.2 Formal exponential coordinates and Hurwitz multiplication

Over a characteristic-zero field K, put

$$\mathcal{E}(a) = \sum_{n\ge 0} \frac{a_n}{n!} t^n, \qquad \mathcal{D}(A)_n = n![t^n]A.$$

These inverse maps between sequences and $K[[t]]$ provide *formal* exponential coordinates. No analytic convergence is needed for the coefficient identities below.

Theorem 2.2 (Constructed unit-triangular coordinates)**.** *Let $h : \mathbb{N} \to K$ satisfy $h_0 = 1$, write $H = \mathcal{E}(h)$ and $H^{-1} = \mathcal{E}(k)$, and define*

$$U_H a = \mathcal{D}(H\mathcal{E}(a)).$$

Then U_H is an equivalence, with inverse $U_H^{-1}a = \mathcal{D}(H^{-1}\mathcal{E}(a))$. Its coefficient formulas are

$$(U_H a)_n = \sum_{r=0}^{n} \binom{n}{r} h_r a_{n-r}, \qquad (U_H^{-1} a)_n = \sum_{r=0}^{n} \binom{n}{r} k_r a_{n-r}.$$

The resulting triangular matrix has diagonal entries 1*. The transported selectors*

$$\widehat{P}_{N,j} = U_H P_{N,j} U_H^{-1}$$

are idempotent and pairwise orthogonal, and their sum is the identity.

Proof. The factorials are nonzero in K, so encoding and decoding cancel coefficientwise. The constant coefficient of H is 1. Hence its formal power-series inverse exists. Multiplication by H and H^{-1} gives the two inverse laws. The ordinary product coefficient formula, multiplied by $n!$, gives the displayed binomial sums. In row n, the coefficient of a_n is $h_0 = 1$ and coefficients of a_q with $q > n$ vanish. Conjugating the identities of Theorem 2.1 by the constructed equivalence proves the transported projector identities. □

Formal correspondence. `EGF.decode_encode`, `EGF.encode_decode`, `EGF.egf_product`, `EGF.coordinateEquiv`, `EGF.coordinate_forward`, `EGF.coordinate_inverse`, and `EGF.transported_reconstruction`, together with the idempotence and orthogonality declarations in `EGFCoordinates`.

In characteristic p, factorial division is unavailable in general, but the coefficient operation remains meaningful over every commutative ring:

$$(f \star g)_n = \sum_{r=0}^{n} \binom{n}{r} f_r g_{n-r}, \qquad (D^d f)_n = f_{n+d}, \qquad \mathbf{1}_n = \begin{cases} 1, & n = 0, \\ 0, & n > 0. \end{cases}$$

Here $\star$ is Hurwitz multiplication. The symbol D^d denotes a coefficient shift, which agrees with formal differentiation after characteristic-zero encoding.

Theorem 2.3 (Hurwitz product rules)**.** *For $d \ge 0$,*

$$D^d(f \star g) = \sum_{r=0}^{d} \binom{d}{r} (D^r f) \star (D^{d-r} g).$$

If R has prime characteristic p, then

$$D^p(f \star g) = f \star D^p g + D^p f \star g.$$

Over a field, if $g_0 = 1$, a sequence b is constructed recursively with $b \star g = \mathbf{1}$. If also $D^p g = Dg$ in characteristic p, then $D^p b = Db$.

Proof. Pascal's identity proves the first product rule, and induction proves the higher rule. The intermediate binomial coefficients $\binom{p}{r}$ vanish in characteristic p. For the inverse, solve row n using the coefficient of b_n, which is $g_0 = 1$:

$$b_n = \mathbf{1}_n - \sum_{r<n} \binom{n}{r} b_r g_{n-r}.$$

Subtract the first and pth product rules for $b \star g = \mathbf{1}$. The assumed identity for g leaves $(D^p b - Db) \star g = 0$. A second triangular induction shows that convolution with a sequence having constant coefficient 1 has trivial kernel. □

Formal correspondence. `Hurwitz.shift_convolution`, `Hurwitz.prime_shift_convolution`, `Hurwitz.convolution_left_eq_zero`, `HurwitzInverse.inverse_convolution`, and `HurwitzInverse.inverse_prime_difference`. Working directly with coefficient sequences avoids the undefined expression $1/n!$ in $\mathbb{F}_p$ when $p \mid n!$.

2.3 Triangular inversion and a finite precision filtration

Theorem 2.4 (Forward substitution and denominator clearing)**.** *Let T_{nq} be coefficients over a field with $T_{nn} \neq 0$ for every n. For any sequence b, define*

$$a_n = \frac{b_n - \sum_{q<n} T_{nq} a_q}{T_{nn}}.$$

This constructs the unique solution of $\sum_{q=0}^{n} T_{nq} a_q = b_n$ for all n. If T_{nq} and b_n are integers and the solution is taken over $\mathbb{Q}$, then

$$\left(\prod_{r=0}^{n} T_{rr} \right) a_n \in \mathbb{Z}.$$

Proof. The recursion uses only smaller indices, and substitution verifies each row. If a second solution agrees through row $n-1$, subtracting row n and cancelling T_{nn} proves equality at n. For integrality, use induction and promote every earlier clearing product to $\prod_{r<n} T_{rr}$. Multiplication by the additional factor T_{nn} cancels the only new division. □

Formal correspondence. `Triangular.solve_row`, `Triangular.solve_unique`, and `Triangular.solve_denominator_integral`. The clearing product bounds the denominator. The unscaled solution can still be nonintegral.

To isolate the filtration argument, let p be any element of a commutative ring and let $w : \mathbb{N} \to \mathbb{N} \cup \{\infty\}$. Set $p^{[r]} = p^r$ for finite r and $p^{[\infty]} = 0$. The latter notation means the coefficient vanishes.

Theorem 2.5 (Filtered finite reconstruction)**.** *For every $n, L \in \mathbb{N}$ and sequences c, S in that ring,*

$$\sum_{r=0}^{n} \binom{n}{r} c_r p^{[w(r)]} S_{n-r} \equiv \sum_{\substack{0 \le r \le n \\ w(r) < L}} \binom{n}{r} c_r p^{[w(r)]} S_{n-r} \pmod{p^L}.$$

Here congruence means divisibility of the difference by p^L in the coefficient ring. In $\mathbb{Z}_p$, it means membership in $p^L \mathbb{Z}_p$.

Proof. The difference of the two sums consists exactly of terms with $w(r) \ge L$. Every such term is divisible by p^L, including the zero terms with infinite weight. Their finite sum has the same divisibility. □

Formal correspondence. `Filtered.filtered_triangular_reconstruction` and `Filtered.padic_filtered_reconstruction`. For weights $2r$, retaining $r \le M$ gives the bound p^{2M+2} through `Filtered.even_weight_tail`. A sharper kernel weight can improve this bound, as in the classical dyadic reconstruction later in the chapter. Each coefficient row is finite, so no hypothesis $w(r) \to \infty$ is needed here.

2.4 Finite Mahler coordinates and weighted differences

For $f : \mathbb{N} \to R$, define the step-h forward difference and its iterates by

$$\Delta_h f(n) = f(n+h) - f(n), \qquad \Delta_h^0 f = f,$$

and put $c_r(f) = \Delta_1^r f(0)$. Thus the coefficients are determined by the differences of f.

Theorem 2.6 (Finite Newton–Mahler identities)**.** *For every $n, s, h \in \mathbb{N}$,*

$$\begin{aligned} f(n) &= \sum_{r=0}^{n} c_r(f) \binom{n}{r}, \\ c_r(\Delta_1^s f) &= c_{s+r}(f), \\ \Delta_1^s f(n) &= \sum_{j=0}^{n} c_{s+j}(f) \binom{n}{j}, \\ \Delta_h^s f(n) &= \sum_{j=0}^{s} (-1)^{s-j} \binom{s}{j} f(n+jh). \end{aligned}$$

The finite interpolant $I_N f(n) = \sum_{r=0}^{N} c_r(f) \binom{n}{r}$ agrees with f for $n \le N$. It has the same order-s unit-step difference at n whenever $n + s \le N$. For arbitrary coefficients $c_0, \dots, c_N$, the corresponding binomial interpolant has exactly those coefficients and zero coefficients above N.

Proof. Write $E_h f(n) = f(n+h)$ for the shift operator. The unit shift is $I + \Delta_1$. Expanding its nth power and evaluating at zero gives reconstruction. Composing difference operators gives the coefficient shift and applying reconstruction to $\Delta_1^s f$ gives the third identity. The binomial expansion of $(E_h - I)^s$ gives the explicit stencil. Binomial coefficients vanish when their lower index exceeds n, which proves the interpolation claim. Equality of every point of the stencil proves equality of differences. Repeated finite differences of $\binom{n}{r}$ at zero give the exact coefficient extraction. □

Formal correspondence. `Mahler.finite_mahler_reconstruction`, `Mahler.coefficient_difference`, `Mahler.difference_from_coefficients`, `Mahler.difference_explicit`, `Mahler.finite_sample_difference`, and `Mahler.coefficient_interpolant`. Finite samples determine the stencils contained in the sample interval. A universal tail estimate requires additional information.

For $x \in \mathbb{Z}_p$, extend the valuation to zero by setting

$$\operatorname{ord}_p(x) = \begin{cases} v_p(x), & x \neq 0, \\ \infty, & x = 0. \end{cases}$$

Thus $L \leq \operatorname{ord}_p(x)$ is equivalent to $x \in p^L\mathbb{Z}_p$.

Theorem 2.7 (Weighted difference bound)**.** *Let $f : \mathbb{N} \to \mathbb{Z}_p$ and let $w : \mathbb{N} \to \mathbb{N} \cup \{\infty\}$ satisfy $w(s+j) \leq \operatorname{ord}_p(c_{s+j}(f))$ for $0 \leq j \leq n$. Then*

$$\operatorname{ord}_p(\Delta_1^s f(n)) \geq \min_{0 \leq j \leq n} \left\{ w(s+j) + v_p\binom{n}{j} \right\}.$$

Proof. Apply the nonarchimedean inequality to the finite coefficient formula in Theorem 2.6. For $0 \leq j \leq n$, the integer $\binom{n}{j}$ is positive. The order of its product with $c_{s+j}(f)$ is the sum of the two orders, including the case where that coefficient is zero. □

Formal correspondence. `PadicBounds.nat_le_order_iff`, `PadicBounds.weighted_difference_bound`, and `PadicBounds.weighted_difference_divisibility`. An expansion on all of $\mathbb{Z}_p$ requires a convergence theorem in addition to these finite algebraic identities and bounds.

2.5 Unit modes and the dyadic distinction

Theorem 2.8 (Differences of unit modes)**.** *Over every commutative ring,*

$$\Delta_h^s(u^n) = u^n(u^h - 1)^s.$$

For any prime p, units $u_i \in \mathbb{Z}_p^\times$, coefficients $a_i \in \mathbb{Z}_p$, and a finite index set I, the sequence $f(n) = \sum_{i \in I} a_i u_i^n$ satisfies

$$\Delta_{p-1}^s f(n) \in p^s\mathbb{Z}_p \qquad (n, s \in \mathbb{N}).$$

Proof. Induction gives the geometric identity. Reduction of a unit to $\mathbb{F}_p^\times$ gives $u_i^{p-1} = 1$ modulo p. Taking s powers supplies p^s in each summand. The difference operator is linear over finite sums. □

Formal correspondence. `UnitModes.geometric_difference`, `UnitModes.unit_fermat_divisibility`, and `UnitModes.finite_unit_modes_divisibility`. The result includes $p = 2$, where the displayed step is 1. Its scope here is finite sums of modes.

Theorem 2.9 (Finite unit coordinates)**.** *Let p be prime, $L \geq 0$, and $a \in (\mathbb{Z}/p^{L+1}\mathbb{Z})^\times$. Define*

$$\omega_L(a) = a^{p^L}, \qquad \langle a \rangle_L = a\omega_L(a)^{-1}.$$

Then

$$a = \omega_L(a)\langle a \rangle_L, \qquad \omega_L(a)^{p-1} = 1, \qquad \langle a \rangle_L \equiv 1 \pmod{p}.$$

The two factors are uniquely determined by these properties and are compatible with reduction to lower precision. For $a \in (\mathbb{Z}/2^{L+2}\mathbb{Z})^\times$, there is instead a unique decomposition

$$a = \epsilon(a)\langle a\rangle_4, \qquad \epsilon(a) \in \{1,-1\}, \qquad \langle a\rangle_4 \equiv 1 \pmod 4.$$

Proof. The unit-group exponent $p^L(p-1)$ gives the root identity for ω_L. Its residue is that of a, so the remaining factor has residue 1. If two $(p-1)$st roots have equal residue, raising them to p^L makes them equal modulo p^{L+1}, while each root is fixed by this exponent. This proves uniqueness and then compatibility under reduction. In the dyadic construction, an odd residue is exactly 1 or -1 modulo 4. Choose that sign and multiply a by it to obtain the principal factor. The two signs remain distinct modulo 4, which proves uniqueness. □

Formal correspondence. `FiniteUnits.finite_unit_decomposition`, `FiniteUnits.decomposition_unique`, `UnitRefinement.omega_compatible`, `UnitRefinement.principal_compatible`, and `DyadicUnits.dyadic_unit_decomposition` with `DyadicUnits.decomposition_unique`. The finite $p = 2$ version of the first construction has trivial root-of-unity factor. The separate modulo-4 construction retains the sign that reduction modulo 2 cannot detect.

2.6 Recurrence packets and finite arithmetic synchronization

Theorem 2.10 (Companion jumps and packet recurrences)**.** *Let C be a $d \times d$ matrix over a commutative ring and $x_n = C^n x_0$. For $N, j, k \in \mathbb{N}$, put $b_k = x_{Nk+j}$. Then*

$$b_k = C^j (C^N)^k x_0, \qquad b_{k+1} = C^N b_k.$$

If $\chi_{C^N}(X) = X^d + \sum_{r<d} q_r X^r$, then

$$b_{k+d} = -\sum_{r=0}^{d-1} q_r b_{k+r}.$$

Every coordinate and every linear scalar observable satisfies the same recurrence. No invertibility or diagonalization hypothesis is required.

Proof. The jump identity follows from the power law for one matrix. Apply the Cayley–Hamilton identity $\chi_{C^N}(C^N) = 0$ to the state b_k. The leading coefficient is 1, so the final state can be isolated. A linear observable preserves the resulting finite sum. □

Formal correspondence. `Companion.companion_jump`, `Companion.packet_charpoly_recurrence`, and `Companion.packet_observable_recurrence`. The source-sequence versions derive the packet recurrence from the relation $x_{n+1} = Cx_n$. For the Fibonacci matrix $C = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, its jump trace is the Lucas number L_N and its determinant is $(-1)^N$. Thus

$$F_{N(k+2)+j} = L_N F_{N(k+1)+j} - (-1)^N F_{Nk+j}.$$

This specialization is `FibonacciPackets.fibonacci_packet_recurrence`. It is derived from the Fibonacci state.

Theorem 2.11 (Dyadic–odd packet factorization)**.** *Let $a \geq 0$ and let M be a positive odd integer. The Chinese remainder map is a ring isomorphism*

$$\mathbb{Z}/(2^a M)\mathbb{Z} \simeq \mathbb{Z}/2^a\mathbb{Z} \times \mathbb{Z}/M\mathbb{Z}.$$

For $0 \leq r < 2^a M$ and any coefficient sequence f,

$$P_{2^a M, r} f = P_{2^a, r \bmod 2^a}\, P_{M, r \bmod M} f.$$

The same identity holds for formal-series coefficient selectors.

Proof. The two moduli are coprime. An index has the prescribed combined residue exactly when it has both component residues. Applying this equivalence to the indicator defining each selector proves the formula. □

Formal correspondence. `CRTPackets.addressEquiv`, `CRTPackets.residue_equivalence`, `CRTPackets.packet_factorization`, and `CRTPackets.series_packet_factorization`. This theorem synchronizes finite arithmetic addresses. The passage from a family of p-adic objects to a global integer object is a separate question, discussed in Section 12.3.

2.7 Polyphase notation retained from the recovered manuscript

The recovered Annals text develops a broader polyphase vocabulary. We explain it through elementary identities with explicit algebraic derivations. These identities have not been separately formalized in Lean for this consolidation. For a sequence a and $M \geq 1$, let $a_r^{[M]}(q) = a_{Mq+r}$ for $0 \leq r < M$. If $A(z) = \sum_n a_n z^n$ and $A_r(w) = \sum_q a_{Mq+r} w^q$ are ordinary generating functions, then unique quotient and remainder give

$$A(z) = \sum_{r=0}^{M-1} z^r A_r(z^M), \qquad \left(a_r^{[M]}\right)_s^{[N]} = a_{r+Ms}^{[MN]}.$$

For ordinary Cauchy multiplication, the phase-r product has a term without a carry and a term with one carry:

$$C_r(w) = \sum_{u+v=r} A_u(w)B_v(w) + w \sum_{u+v=r+M} A_u(w)B_v(w), \qquad 0 \leq u, v < M.$$

Adding the two phase addresses gives the formula. It describes ordinary Cauchy multiplication. Hurwitz convolution has its own binomial weights.

For $M \geq 1$ and $s, r, k \in \mathbb{N}$, define the affine Mahler kernel by

$$\Theta_{M,s}(r,k) = [z^r](1+z)^s\left((1+z)^M - 1\right)^k = \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} \binom{Mj+s}{r}.$$

It vanishes unless $k \leq r \leq Mk + s$. For a finite binomial expansion $f(n) = \sum_{r=0}^{D} c_r \binom{n}{r}$, the kth Newton coefficient of $g(q) = f(Mq + s)$ is therefore

$$c_k(g) = \sum_{r=k}^{\min(D, Mk+s)} c_r \Theta_{M,s}(r,k).$$

Indeed, insert the finite stencil for $\Delta_1^k g(0)$ and interchange its two finite sums. Coefficient extraction of the binomial expansion of $((1+z)^M - 1)^k$ gives the kernel. In the binary zero-address case,

$$\Theta_{2,0}(k+j,k) = 2^{k-j}\binom{k}{j} \qquad (0 \leq j \leq k),$$

since $(2z + z^2)^k = z^k(2+z)^k$. Exact valuations for the general kernel remain to be determined. The recovered infinite analytic extensions and stronger historical identities lie beyond these finite derivations. Their status is discussed in Section 12.5.

3 Congruential Euler packets and their arithmetic

Two related constructions run through this section. The congruential Euler family is indexed by a modulus N and an address j. Its exceptional dyadic member has $N = 4$ and four addresses. The classical signed Euler numbers arise from $N = 2$, $j = 0$. Keeping these indices visible distinguishes the four-packet period theorems from the classical edge truncations.

3.1 Original coefficients, normalized packets, and precision

Definition 3.1 (Congruential Euler coefficients)**.** For $N \geq 1$ and $0 \leq j < N$, define rational coefficients by the formal identity

$$\sum_{d\geq 0} E_d^{(N,j)} \frac{t^d}{d!} = \left(\sum_{n\geq 0} \frac{t^{Nn}}{(Nn+j)!}\right)^{-1}. \tag{3.1}$$

The reciprocal exists because its denominator has constant coefficient $1/j! \neq 0$. Set

$$U_{N,j}(n) = E_{Nn}^{(N,j)}, \qquad C_{N,j}(n) = \frac{U_{N,j}(n)}{j!}.$$

Thus $C_{N,j}(0) = 1$ and $U_{N,j}(0) = j!$. All coefficients outside the multiples of N vanish.

The normalized source and its inverse are

$$K_{N,j}(t) = j! \sum_{n\geq 0} \frac{t^{Nn}}{(Nn+j)!}, \qquad \mathcal{P}_{N,j}(t) = \sum_{n\geq 0} C_{N,j}(n) \frac{t^{Nn}}{(Nn)!}. \tag{3.2}$$

Their product is one. Clearing factorials in its coefficient of t^{Nn} gives the triangular system

$$\sum_{q=0}^{n} \binom{Nn+j}{Nq} C_{N,j}(q) = \delta_{n0}. \tag{3.3}$$

In particular, for $n > 0$,

$$C_{N,j}(n) = -\binom{Nn+j}{Nn}^{-1} \sum_{q=0}^{n-1} \binom{Nn+j}{Nq} C_{N,j}(q).$$

The diagonal binomial coefficient is positive, so this recurrence determines the sequence uniquely. The Lean construction begins with this recurrence and derives the reciprocal identity from it. The resulting sequence is then identified with the degree-indexed coefficients of (3.1), so both descriptions refer to the same family.

The relevant declarations are `KomorebiPaperIX.Congruential.triangular_inverse`, `KomorebiPaperIX.Congruential.packet_is_actual_inverse`, and `KomorebiPaperIX.NishibuchiCompletion.generalizedEuler_at_packet`. The cleared identity with the original positive-address exponential section is `KomorebiPaperIX.NishibuchiCompletion.original_generating_identity`.

Proposition 3.2 (A denominator bound for every address)**.** *For $N \geq 1$, $0 \leq j < N$, and $n \in \mathbb{N}$, set*

$$D_{N,j}(n) = \prod_{r=1}^{n} \binom{Nr+j}{Nr}, \qquad D_{N,j}(0) = 1.$$

Then $D_{N,j}(n)C_{N,j}(n) \in \mathbb{Z}$.

Proof. Proceed by induction in the recurrence (3.3). For every $q < n$, the product $D_{N,j}(q)$ divides $D_{N,j}(n-1)$. Multiplying the recurrence by $D_{N,j}(n-1)$ therefore makes every previous term integral. The diagonal factor completes the product $D_{N,j}(n)$, proving the claim. At $n = 0$, both factors are one. This gives a uniform denominator bound without requiring integrality of the normalized coefficients themselves. The Lean statements are `KomorebiPaperIX.Congruential.clearing_product` and `KomorebiPaperIX.Congruential.universal_denominator_clearing`. □

Example 3.3 (The Bernoulli boundary address)**.** At $N = 2$, the address $j = 1$ gives a second classical family. Define the Bernoulli numbers by

$$B(z) = \frac{z}{e^z - 1} = \sum_{r \geq 0} B_r \frac{z^r}{r!}, \qquad B_0 = 1, \quad B_1 = -\frac{1}{2}.$$

All quotients here are regular formal series. The identity

$$2B(z) - B(2z) = \frac{z}{\sinh z} = \sum_{n \geq 0} C_{2,1}(n) \frac{z^{2n}}{(2n)!}$$

follows by putting the two fractions on a common denominator and using (3.1). Comparing even coefficients yields

$$C_{2,1}(n) = (2 - 2^{2n}) B_{2n} \qquad (n \in \mathbb{N}).$$

This classical derivation restores the boundary example from the original manuscript. No dedicated Lean bridge for this Bernoulli specialization was identified in the preserved sources.

Definition 3.4 (Differences and valuation conventions)**.** For a sequence f and $h, k, n \in \mathbb{N}$, put

$$\Delta_h f(n) = f(n+h) - f(n), \qquad \Delta_h^0 f(n) = f(n), \qquad \Delta_h^{k+1} f(n) = \Delta_h^k f(n+h) - \Delta_h^k f(n).$$

We use the extended valuation $v_p(0) = +\infty$ in mathematical statements. Thus $v_p(x) \geq L$, including negative integers L, means $x = 0$ or the ordinary valuation of the nonzero rational x is at least L. For integral coefficients and $L \geq 0$, it is equivalent to $x \in p^L \mathbb{Z}_p$. In expressions involving a step multiplier we write $\nu_p(u) = v_p(u)$ for $u > 0$ and set $\nu_p(0) = 0$. This finite convention makes the displayed exponents meaningful at step zero, where all positive-order differences vanish.

The valuation convention at zero is encoded by `KomorebiPaperIX.GlobalEulerBoundary.precision`. For p-adic congruences, divisibility is interpreted in $\mathbb{Z}_p$. Statements over other coefficient rings specify the ring explicitly. Field divisibility in $\mathbb{Q}_p$ alone does not encode precision.

3.2 The standard address window and its common reduction

The addresses below the prime have unit diagonal coefficients. In this window the normalized packets are integral, and their reductions agree at every row.

Proposition 3.5 (Lucas reduction and address independence)**.** *Let p be prime, $m > 0$, and $N = mp$. For $0 \leq j < p$ and $n, q \in \mathbb{N}$,*

$$\binom{mpn + j}{mpq} \equiv \binom{mn}{mq} \pmod{p}.$$

Every $C_{mp,j}(n)$ belongs to $\mathbb{Z}_p$. Its reduction is the unique sequence $\overline{C}_m : \mathbb{N} \to \mathbb{F}_p$ satisfying

$$\sum_{q=0}^{n} \binom{mn}{mq} \overline{C}_m(q) = \delta_{n0} \quad \text{in } \mathbb{F}_p.$$

Consequently, for any two addresses $0 \le j, k < p$,

$$C_{mp,j}(n) \equiv C_{mp,k}(n) \pmod{p} \qquad (n \in \mathbb{N}).$$

Proof. Lucas reduction separates the lowest base-p digits, which are j and zero in the upper and lower arguments. Their binomial contribution is one, leaving the displayed reduced row. On the diagonal the reduced coefficient is one. The recurrence (3.3) therefore constructs an integral packet by successive division by units in $\mathbb{Z}_p$. After reduction, every address satisfies the same triangular system over $\mathbb{F}_p$. Its diagonal entries are one, so its solution is unique. This proves both the common reduction and the congruence between addresses. The row reduction is `KomorebiPaperIX.StandardWindow.lucas_row_reduction`. The integral identification and the two reduction statements are `KomorebiPaperIX.WindowIndependence.standard_window_integral`, `KomorebiPaperIX.WindowIndependence.coeffPadic_coe`, `KomorebiPaperIX.WindowIndependence.residue_independence`, and `KomorebiPaperIX.WindowIndependence.two_window_addresses_congruent`. □

3.3 The full Nishibuchi statement and its starting bound

Theorem 3.6 (Nishibuchi congruence)**.** *Let p be prime, let $m > 0$, and suppose that $m \mid p-1$ or $m = 2$. Put $N = mp$ and $q = \operatorname{lcm}(2, p-1)$. For every $0 \le j < N$, all $U_{N,j}(n)$ belong to $\mathbb{Z}_p$. For $r \ge 1$ and $n \ge r$,*

$$E^{(N,j)}_{Nn+qp^r} \equiv E^{(N,j)}_{Nn} \pmod{p^r}. \tag{3.4}$$

Thus the positive sufficient starting index $n_0 = r$ works uniformly. If $m \mid p-1$, the stronger sufficient condition $r \le mn$ is valid.

This theorem covers the full parameter range and displacement of Conjecture 3.9 in Nishibuchi's cited statement. The corresponding Lean theorem is KomorebiPaperIX.NishibuchiCompletion.conjecture_3_9. The stronger divisor-branch threshold is `KomorebiPaperIX.NishibuchiCompletion.divisor_period`. The starting index is sufficient uniformly, although it need not be the earliest one for a given tuple of parameters.

We first prove the difference estimates on the divisor branch, then derive the period from a finite Newton expansion.

Theorem 3.7 (All-address differences on the divisor branch)**.** *Let p be prime, $m > 0$, $m \mid p-1$, $N = mp$, and $0 \le j < N$. Write $h = (p-1)/m$. For every $u, k, n \in \mathbb{N}$,*

$$U_{N,j}(n) \in \mathbb{Z}_p, \tag{3.5}$$

$$\Delta^k_{uh} U_{N,j}(n) \in p^{\min(k,mn)} \mathbb{Z}_p, \tag{3.6}$$

$$v_p\big(\Delta^k_{uh} C_{N,j}(n)\big) \ge \min(k, mn) - v_p(j!). \tag{3.7}$$

The factorial correction is part of the normalized statement, including addresses $j \ge p$.

Proof. Work in the Hurwitz integral ring of formal series

$$\mathcal{H}_p = \left\{ F \in \mathbb{Q}_p[[t]] : d![t^d]F \in \mathbb{Z}_p \text{ for every } d \right\}.$$

For $D = d/dt$, let $B_p = (D^{p^2} - D^p)/p$. Call F flat if $B_p^s F \in \mathcal{H}_p$ for every $s \geq 0$. We will prove that $j!\mathcal{P}_{N,j}$ is flat at every address. The main difficulty is to include the addresses at which the usual unit-pivot argument fails.

Set

$$H_c(t) = \sum_{n \geq 0} \frac{t^{Nn+c}}{(Nn+c)!}, \qquad A_c(t) = \sum_{n \geq 0} \frac{t^{Nn}}{(Nn+c)!}, \qquad R_c(t) = \frac{A_{c-1}(t)}{A_c(t)} \quad (1 \leq c < N).$$

The denominator of this last quotient has nonzero constant coefficient. The section identities give

$$R_c H_c = t H_{c-1}, \qquad R_c(0) = c, \qquad j!\mathcal{P}_{N,j} = \mathcal{P}_{N,0} \prod_{c=1}^{j} R_c.$$

Cancellation of consecutive source sections proves the product identity and ties the ratios directly to the family under study.

At the singular addresses $c = ap$, $1 \leq a < m$, use the weighted ring

$$\mathcal{W}_p = \left\{ \sum_{d \geq 0} a_d T^d : p^{\lfloor d/p \rfloor} a_d \in \mathbb{Z}_p \right\}.$$

The key estimate is $R_{ap}(\log(1+T)) \in \mathcal{W}_p$. Its arithmetic input comes from the cyclic group ring $\mathbb{Z}[\mathbb{Z}/N\mathbb{Z}]$. For its canonical element x and $I = (p, x^{p-1} - 1)$, the relation $(x^{p-1})^p = 1$ implies $I^p \subseteq (p)I$. Induction yields $I^q \subseteq (p^{v_p(q!)})$. Grouping the falling factorial $(x)_d = \prod_{i=0}^{d-1}(x-i)$ into consecutive blocks of length p then gives an integral residue-coordinate factor $p^{v_p(\lfloor d/p \rfloor !)}$. The identity

$$v_p(d!) = \lfloor d/p \rfloor + v_p(\lfloor d/p \rfloor !)$$

accounts for precisely the weight in $\mathcal{W}_p$ after dividing by $d!$. Comparison of the section and group-ring recurrences identifies these coordinates with the logarithmically substituted section.

To pass from the section to the singular ratio, factor out its initial zero: for $c = ap$, the section has the form

$$H_c(\log(1+T)) = \frac{T^c}{c!} V(T), \qquad V(0) = 1, \qquad V \in \mathcal{W}_p.$$

The weight of $c!$ compensates for the coefficient shift by c. The weighted ring is closed under inversion of series with constant coefficient one and under $L_T = \log(1+T)(1+T)d/dT$. With $\ell(T) = \log(1+T)/T$, interpreted by coefficient shifting, differentiation of the displayed factorization gives

$$R_c(\log(1+T)) = c(1+T)\ell(T) + (L_T V)V^{-1}.$$

Since $p\ell(T) \in \mathcal{W}_p$ and $p \mid c$, both terms are weighted. This is the singular estimate `KomorebiPaperIX.SingularRatioAmice.paper_singular_amice_estimate`.

To deduce flatness from the weighted estimate, use $\Theta = (1+T)d/dT$. Both Θ and $(\Theta^{p^2} - \Theta^p)/p$ preserve $\mathcal{W}_p$. For the first operator, its coefficient formula is $(d+1)a_{d+1} + da_d$. Whenever the floor

weight rises, the factor $d+1$ provides the missing p. For the second operator, the proof uses its full Leibniz correction and the scalar congruence $p^2 \mid b^{p^2} - b^p$. Weighted monomials factor as

$$a_d T^d = (p^{\lfloor d/p \rfloor} a_d)(T^p/p)^{\lfloor d/p \rfloor} T^{d \bmod p}.$$

The operator preserves these monomials and hence finite weighted polynomials. Each fixed output coefficient depends on only finitely many input coefficients, which extends the result to the formal series. Substitution $T = e^t - 1$ intertwines D with Θ and maps $\mathcal{W}_p$ into $\mathcal{H}_p$, because

$$d![t^d]F(e^t - 1) = [T^0]\Theta^d F.$$

It follows that the singular ratios are flat. This transfer is proved in `KomorebiPaperIX.WeightedDworkTransfer.singular_ratio_flat`.

At a nonsingular address $2 \le c < N$ with $p \nmid c$, differentiation of the section identities gives

$$tR_c' = R_c(1 + R_{c-1} - R_c).$$

Writing $q = R_{c-1} - (c-1)$ and $y = R_c - c$, this becomes

$$(tD + c)y = cq + yq - y^2.$$

On degrees divisible by p, the inverse of $tD + c$ divides the degree-d coefficient by the unit $d + c$. Starting with $y_0 = 0$, form

$$y_{s+1} = (tD + c)^{-1}(cq + y_s q - y_s^2).$$

Flatness and support are preserved. Indeed, put $E_c = tD + c$ and $C_p = pD^{p^2} - D^p$. The commutator is $[B_p, E_c] = C_p$, and iteration gives

$$B_p^r E_c y = E_c B_p^r y + r C_p B_p^{r-1} y.$$

For the inverse equation $E_c y = f$, induction on r makes the correction term Hurwitz-integral. Both operators preserve support in degrees divisible by p. On that support the degree multiplier $d + c$ is a unit, so integrality of $E_c B_p^r y$ implies integrality of $B_p^r y$. Thus the inverse preserves full flatness, as well as support. Since the difference of two right sides factors as $(z - y)(q - z - y)$ and its second factor has zero constant term, agreement with the solution gains one coefficient at each iteration. Consequently $[t^d]y_s = [t^d]y$ for $d \le s$. Every coefficient of $B_p^r y$ can therefore be read from a sufficiently long finite iterate. The argument is entirely formal. This is the content of `KomorebiPaperIX.RiccatiFlatPropagation.riccati_solution_flat`.

The standard window supplies the initial ratio R_1. The weighted estimate handles $p \mid c$, and Riccati propagation handles $p \nmid c$. Flatness is closed under products, so the exact factorization establishes flatness of $j!\mathcal{P}_{N,j}$. Extracting its supported Hurwitz coefficients and applying the proved saturation and step-multiple lemmas yields (3.5)–(3.6).

Here is the coefficient extraction explicitly. If $a_d = d![t^d]F$, then

$$d![t^d]B_p^k F = p^{-k}\Delta_{p(p-1)}^k a_{d+pk}.$$

For $F = j!\mathcal{P}_{N,j}$ and $k \le mn$, take $d = mpn - pk$. Support in multiples of mp turns this into $p^{-k}\Delta_h^k U_{N,j}(n)$, so flatness gives divisibility by p^k. For $k > mn$, expand Δ_h^{k-mn} applied to $\Delta_h^{mn} U_{N,j}(n)$. Every shifted

row is at least n, so each summand is divisible by p^{mn}. Finally $\Delta_{uh} = ((I + \Delta_h)^u - I)$, whose kth power for $u > 0$ is an integral combination of powers of Δ_h of order at least k. The case $u = 0$ gives zero for $k > 0$, and order zero is the original integral coefficient. This proves the bound for all u and k. Finally $\Delta_{uh}^k U_{N,j} = j!\Delta_{uh}^k C_{N,j}$ gives (3.7), with the zero case retained. The resulting statements are `KomorebiPaperIX.AllResidueEuler.all_residue_flat`, `KomorebiPaperIX.AllResidueEuler.global_unnormalized_bound`, and `KomorebiPaperIX.AllResidueEuler.global_normalized_precision`. □

Example 3.8 (Why the factorial loss is necessary)**.** Take $p = 3$, $m = 2$, $N = 6$, and $j = 3$. The recurrence gives

$$C_{6,3}(1) = -\frac{1}{84}, \qquad C_{6,3}(2) = \frac{703}{5460}, \qquad C_{6,3}(2) - C_{6,3}(1) = \frac{64}{455}.$$

The last difference has 3-adic valuation zero. Here $h = 1$, so at $n = 1$ the order-one bound without factorial loss would require valuation at least one. The corrected normalized bound is sharp, since

$$v_3\big(C_{6,3}(2) - C_{6,3}(1)\big) = 0 = 1 - v_3(3!).$$

Multiplication by 3! gives

$$U_{6,3}(2) - U_{6,3}(1) = \frac{384}{455}, \qquad v_3\big(U_{6,3}(2) - U_{6,3}(1)\big) = 1,$$

consistent with the unnormalized theorem. Thus the factorial correction is already necessary at a single step in the all-address parameter range. These exact values and the refutation of a universal bound without loss are formalized in `KomorebiPaperIX.Normalization.normalized_first`, `KomorebiPaperIX.Normalization.normalized_second`, `KomorebiPaperIX.Normalization.normalized_difference`, `KomorebiPaperIX.Normalization.difference_valuation`, `KomorebiPaperIX.Normalization.factorial_loss_is_sharp`, `KomorebiPaperIX.Normalization.unnormalized_difference`, `KomorebiPaperIX.Normalization.unnormalized_difference_valuation`, and `KomorebiPaperIX.Normalization.universal_no_loss_refuted`.

Corollary 3.9 (A common period in the standard window)**.** *Let p be prime, $m > 0$, $m \mid p - 1$, and $0 \le j < p$. Put $h = (p-1)/m$. For every $n \ge 1$ and $u \in \mathbb{N}$,*

$$\overline{C}_m(n + uh) = \overline{C}_m(n), \qquad C_{mp,j}(n + uh) \equiv C_{mp,j}(n) \pmod{p}.$$

Thus h is a sufficient period from row one, common to all addresses in the standard window. It need not be the least period.

Proof. Since $j < p$, the factorial $j!$ is a unit in $\mathbb{Z}_p$. Also $mn \ge 1$. The order-one case of Theorem 3.7 therefore gives valuation at least one for the normalized difference at every step uh. This proves the congruence, and Proposition 3.5 identifies its reduction with the equality for $\overline{C}_m$. The preserved Lean development also proves this period directly from the Hurwitz inverse in characteristic p: `KomorebiPaperIX.WindowPeriod.uniform_standard_window_period`, `KomorebiPaperIX.WindowPeriod.multiple_period`, and `KomorebiPaperIX.WindowPeriod.standard_window_period_divisibility`. □

Lemma 3.10 (Prime-power period from finite differences)**.** *Let R be a commutative ring, p a prime, $f : \mathbb{N} \to R$, $h, n \in \mathbb{N}$, and $r \ge 1$. If*

$$p^{\min(k,r)} \mid \Delta_h^k f(n) \quad \text{for every } k \in \mathbb{N},$$

then $p^r \mid f(n + p^{r-1}h) - f(n)$.

Proof. The finite Newton expansion gives

$$f(n+p^{r-1}h)-f(n)=\sum_{k=1}^{p^{r-1}}\binom{p^{r-1}}{k}\Delta_h^k f(n).$$

Terms with $k\geq r$ have the required factor from the difference. For $1\leq k<r$, the identity

$$k\binom{p^{r-1}}{k}=p^{r-1}\binom{p^{r-1}-1}{k-1}$$

and $v_p(k)<k$ imply $p^r\mid\binom{p^{r-1}}{k}p^k$ in $\mathbb{Z}$. Mapping that integer divisibility to R proves the claim term by term. The argument includes $r=1$. The declaration is `KomorebiPaperIX.PeriodFromDifferences.prime_power_period`. □

Proof of Theorem 3.6. On the divisor branch, $m\mid q$ and the packet step q/m is an integer multiple of $h=(p-1)/m$. If $r\leq mn$, Theorem 3.7 supplies the hypotheses of Lemma 3.10. Its packet displacement is $p^{r-1}q/m$, which converts to the original degree as follows:

$$mp\left(n+p^{r-1}\frac{q}{m}\right)=mpn+qp^r.$$

The choice $n\geq r$ implies $mn\geq r$ because $m\geq 1$.

For an odd prime, $2\mid p-1$, so the option $m=2$ introduces no further case. The sole remaining branch is $p=2,m=2,N=4$. The all-row theorem proved next gives $2^k\mid\Delta_1^k C_{4,j}(n)$ at every row and address. After multiplying by $j!$, Lemma 3.10 gives packet period 2^{r-1} and degree displacement $4\cdot 2^{r-1}=2^{r+1}=qp^r$. It also gives integrality. Hence the complete statement follows. The formal degree conversion is `KomorebiPaperIX.NishibuchiCompletion.original_degree_shift`. The all-parameter degree theorem is `KomorebiPaperIX.NishibuchiCompletion.full_period_degree`. □

3.4 All-row dyadic differences and displacement amplification

For the remainder of the four-packet discussion abbreviate $C_j=C_{4,j}$ and $U_j=U_{4,j}$. Removing the original row cap requires an unshifted coefficient operator.

Theorem 3.11 (All-row dyadic higher differences)**.** *For $0\leq j<4$ and all $u,k,n\in\mathbb{N}$,*

$$C_j(n)\in\mathbb{Z}_2, \tag{3.8}$$

$$\Delta_u^k C_j(n)\in 2^{k(1+\nu_2(u))}\mathbb{Z}_2, \tag{3.9}$$

$$\Delta_u^k U_j(n)\in 2^{k(1+\nu_2(u))+v_2(j!)}\mathbb{Z}_2. \tag{3.10}$$

There is no restriction $k\leq n$ and no minimum with the row n.

Proof. The Hurwitz coefficients of the normalized source $K_{4,j}$ at degrees $4n$ are

$$g_j(n)=\binom{4n+j}{4n}^{-1}.$$

Their explicit expressions are

$$g_0(n) = 1, \qquad g_1(n) = \frac{1}{4n+1},$$
$$g_2(n) = \frac{1}{(4n+1)(2n+1)}, \quad g_3(n) = \frac{3}{(4n+1)(2n+1)(4n+3)}.$$

Every denominator is odd. An affine sequence with even slope satisfies $2^k \mid \Delta_1^k f(n)$ for every k, n. The exact product identity

$$\Delta_1^s(fg)(n) = \sum_{i=0}^{s} \binom{s}{i} \Delta_1^i f(n) \Delta_1^{s-i} g(n+i)$$

proves closure of this property under products. Applying the formula with the factors interchanged to $fg = 1$ isolates $f(n+s)\Delta_1^s g(n)$. Multiplication by $f(n+s)^{-1}$ and induction then prove closure under pointwise unit inverses. Thus all four g_j have the property. The explicit formulas and difference bounds are formalized in `KomorebiPaperIX.DyadicFourKernel.source_coe` and `KomorebiPaperIX.DyadicFourKernel.source_kummer`.

For an integer charge c, put

$$A_c = \frac{D^4 - c}{2}.$$

A series is flat of charge c when applying any power A_c^s to it gives an element of $\mathcal{H}_2$. The required product formula is

$$A_{c+d}(FG) = (A_c F)G + F(A_d G) + 2F'G''' + 3F''G'' + 2F'''G'. \tag{3.11}$$

All middle coefficients are integral. Derivatives preserve $\mathcal{H}_2$ and commute with A_c. Induction on the number of iterations in (3.11) proves that multiplication adds charges. If $FG = 1$, the same formula yields

$$A_{-c}G = -G^2 A_c F - G(2F'G''' + 3F''G'' + 2F'''G').$$

Induction, starting from the independently established integrality of the reciprocal G, proves that inversion negates the charge. Finally $A_{c+2} = A_c - 1$, so increasing a charge by two preserves flatness. These are `KomorebiPaperIX.ChargedDworkClosure.B_mul`, `KomorebiPaperIX.ChargedDworkClosure.flat_inverse`, and `KomorebiPaperIX.ChargedDworkClosure.flat_charge_shift`.

Packing g_j into degrees divisible by four gives $K_{4,j}$. Its source property is precisely charge-one flatness. Inversion gives charge -1, and the charge shift restores charge one for the reciprocal $\mathcal{P}_{4,j}$. If $\mathrm{dec}(F)(d) = d![t^d]F$, the exact coefficient identity is

$$\mathrm{dec}(A_1^s F)(d) = 2^{-s}\Delta_4^s \,\mathrm{dec}(F)(d).$$

At $d = 4n$, packing turns the right side into $2^{-s}\Delta_1^s C_j(n)$. This extraction requires no negative degree and therefore holds at every n, including zero. It proves the unit-step bound `KomorebiPaperIX.DyadicFourAllRows.base_step_bound`.

To incorporate $v_2(u)$, expand a displacement using finite Newton coefficients. For any prime p, $u > 0$, and $1 \le a \le u$,

$$p^{v_p(u)+1} \mid \binom{u}{a} p^a,$$

as follows from $a\binom{u}{a} = u\binom{u-1}{a-1}$ and $v_p(a) < a$. Repeated displacement, retaining the remaining base-difference order at each induction step, gives a factor $p^{k(1+v_p(u))}$ from k displacements. This induction is formalized in `KomorebiPaperIX.StepAmplification.repeated_precision`. Applying it with $p = 2$ proves (3.9). Multiplication by $j!$ proves (3.10). Zero step and zero order follow from their definitions. The final statements are `KomorebiPaperIX.DyadicFourFinalStrengthening.normalized_step_bound` and `KomorebiPaperIX.DyadicFourFinalStrengthening.unnormalized_step_bound`. □

Corollary 3.12 (Step-sensitive divisor-branch bound)**.** *Under the hypotheses of Theorem 3.7, for all $u, k, n \in \mathbb{N}$,*

$$\Delta^k_{u(p-1)/m} U_{mp,j}(n) \in p^{\min(k(1+v_p(u)),mn)}\mathbb{Z}_p.$$

For $C_{mp,j}$ the corresponding valuation lower bound is $\min(k(1+v_p(u)), mn) - v_p(j!)$.

Proof. Apply the same repeated-displacement theorem with the fixed cap mn to (3.6). The argument preserves this cap and improves the contribution from the order of the difference. Division by the fixed factorial gives the rational valuation statement, with the zero case included. These are `KomorebiPaperIX.AllResidueStepAmplification.unnormalized_precision` and `KomorebiPaperIX.AllResidueStepAmplification.normalized_precision`. □

Corollary 3.13 (Dyadic periods from row zero)**.** *For $0 \le j < 4$, $r \ge 1$, and $n \ge 0$,*

$$U_j(n + 2^{r-1}) \equiv U_j(n) \pmod{2^r}.$$

For $j = 2, 3$ and $r \ge 2$, 2^{r-2} is also a sufficient packet period. The respective original degree displacements are 2^{r+1} and 2^r.

Proof. Use Lemma 3.10 and the unit-step case of Theorem 3.11. At $j = 2, 3$ the factorial contributes an additional power of two. The original degree versions are `KomorebiPaperIX.DyadicFourFinalStrengthening.all_rows_period_degree` and `KomorebiPaperIX.DyadicFourFinalStrengthening.all_rows_half_period_degree`. The next theorem sharpens these sufficient periods to a complete classification. □

3.5 Exact displacement valuations and least packet periods

Lemma 3.14 (Finite Newton dominance)**.** *Let $f : \mathbb{N} \to \mathbb{Q}$ and write $a_k = \Delta^k_1 f(0)$. Suppose that $c \in \mathbb{N}$, $a_1 \ne 0$, $v_2(a_1) = c$, and*

$$v_2(a_k) \ge c + 1 + \lfloor \log_2 k \rfloor \qquad (k \ge 2).$$

Then for every $n \ge 0$ and $T > 0$,

$$f(n+T) - f(n) \ne 0, \qquad v_2\big(f(n+T) - f(n)\big) = v_2(T) + c.$$

Proof. Finite Newton reconstruction at an arbitrary row gives

$$\Delta^k_1 f(n) = \sum_{i=0}^{n} \binom{n}{i} a_{k+i}.$$

The monotonicity of $\lfloor \log_2 k \rfloor$ therefore preserves the higher-coefficient bound after translation. In addition, $\Delta_1 f(n) - a_1 \in 2^{c+1}\mathbb{Z}_2$, so the first difference is nonzero of exact valuation c.

Now expand the displacement:

$$f(n+T)-f(n)=T\Delta_1 f(n)+\sum_{k=2}^{T}\binom{T}{k}\Delta_1^k f(n).$$

For $1\le k\le T$, the binomial denominator identity implies

$$v_2\binom{T}{k}\ge v_2(T)-v_2(k)\ge v_2(T)-\lfloor\log_2 k\rfloor.$$

Every term of the remaining sum consequently has valuation at least $v_2(T)+c+1$. Its sum cannot cancel the leading term, which has exact valuation $v_2(T)+c$. This proves nonvanishing and the claimed valuation using only finite sums. The general theorem is `KomorebiPaperIX.NewtonDominance.exact_displacement`. □

Theorem 3.15 (Exact four-packet displacement law)**.** *Set*

$$(c_0,c_1,c_2,c_3)=(1,1,4,2),\qquad (d_0,d_1,d_2,d_3)=(1,1,5,3).$$

For $0\le j<4$, $n\ge 0$, and every positive integer T,

$$\begin{aligned} C_j(n+T)-C_j(n)&\neq 0, & v_2\big(C_j(n+T)-C_j(n)\big)&=v_2(T)+c_j,\\ U_j(n+T)-U_j(n)&\neq 0, & v_2\big(U_j(n+T)-U_j(n)\big)&=v_2(T)+d_j.\end{aligned}$$

Proof. The first Newton coefficients, derived from (3.3), are

$$a_{0,1}=-2,\quad a_{1,1}=-\frac{6}{5},\quad a_{2,1}=-\frac{16}{15},\quad a_{3,1}=-\frac{36}{35}.$$

Their exact valuations are c_j. Theorem 3.11 gives $v_2(a_{j,k})\ge k$ for all orders. To obtain the stronger logarithmic envelope required by Lemma 3.14, only a finite initial segment needs improvement. The recurrence proves the following exact valuations:

Address j	Further orders k	$v_2(a_{j,k})$ in that order
0	2	3
1	2	3
2	2, 3, 4, 5, 6	6, 9, 13, 16, 22
3	2, 3, 4	8, 8, 15

For all subsequent k, the elementary inequality $c_j+1+\lfloor\log_2 k\rfloor\le k$ completes the envelope. The entries follow by exact rational computation from the defining recurrence, and their valuations are proved in Lean. Together with the inequality for all subsequent orders, they establish the bound at every order. The uniform envelope is `KomorebiPaperIX.DyadicFourPrefix.tail_precision`.

Apply Lemma 3.14 to C_j. Multiplication by the nonzero factorial $j!$ adds $v_2(j!)$ and preserves nonzeroness. Hence $d_j=c_j+v_2(j!)$, giving the four valuation gains for the original coefficients. The declarations are `KomorebiPaperIX.DyadicFourLeastPeriods.normalized_exact_displacement` and `KomorebiPaperIX.DyadicFourLeastPeriods.exact_displacement`. □

Corollary 3.16 (All positive periods and their least element)**.** *For $r \in \mathbb{N}$ and $0 \le j < 4$, a positive integer T is a packet period of U_j modulo 2^r if and only if*

$$2^{\max(0,r-d_j)} \mid T.$$

Here a packet period means $U_j(n+T) \equiv U_j(n) \pmod{2^r}$ for every $n \ge 0$. Consequently the least positive packet periods are

j	0	1	2	3
least period	$2^{\max(0,r-1)}$	$2^{\max(0,r-1)}$	$2^{\max(0,r-5)}$	$2^{\max(0,r-3)}$.

Proof. By the exact displacement law, the congruence at any row is equivalent to $v_2(T) + d_j \ge r$. This is exactly the displayed integer divisibility criterion. Its least positive solution is the indicated power of two, which also covers $r = 0$ and $r \le d_j$. The all-period and least-element statements are `KomorebiPaperIX.DyadicFourLeastPeriods.period_iff_dvd` and `KomorebiPaperIX.DyadicFourLeastPeriods.least_packet_period`. □

For example, $U_2(n) \equiv 2 \pmod{32}$ and $U_3(n) \equiv 6 \pmod{8}$ for every row. At precision 2^{10} the least packet periods are $512, 512, 32, 128$. A packet displacement T has original degree displacement $4T$, as proved by `KomorebiPaperIX.DyadicFourLeastPeriods.original_degree_exact_displacement`. Minimality here concerns packet shifts. Shifts of the full degree-indexed sequence, including its zero coefficients off the packet support, require a separate analysis. The new strengthening chapters determine all repeated-step higher differences in addresses zero and one and a power-of-two-order family in address two. The full exact classification of arbitrary higher-order differences is also a separate question from the first-displacement law.

3.6 Classical odd-length coordinates and their congruence ladder

The classical signed Euler numbers have generating function $\operatorname{sech} t = \sum_{n\ge 0} E_{2n} t^{2n}/(2n)!$. They are the $N = 2$, $j = 0$ member of (3.1). The coordinate theorem reconstructs them from finite alternating sums of odd powers.

Definition 3.17 (Odd-length source and inverse coefficients)**.** For a positive odd integer p, define

$$S_d(p) = \sum_{a=0}^{p-1} (-1)^a (2a+1)^d.$$

Let γ_m be the integral Hurwitz coefficients of sech^2:

$$\operatorname{sech}^2 t = \sum_{m\ge 0} \gamma_m \frac{t^{2m}}{(2m)!}, \qquad \gamma_m = \sum_{b=0}^{2m} \binom{2m}{b} E_b E_{2m-b},$$

where $E_b = 0$ for odd b. Then $\gamma_0 = 1$. Define

$$T^{\mathrm{odd}}_{p,M}(n) = \sum_{m=0}^{\min(M,n)} \binom{2n}{2m} \gamma_m p^{2m} S_{2(n-m)}(p).$$

Here p need only be odd. Primality is needed only to interpret the result as a prime-adic congruence ladder.

The source and inverse coefficients are `KomorebiPaperIX.OddPower.source` and `KomorebiPaperIX.EulerCoefficients.inverseEven`. The truncation is `KomorebiPaperIX.OddEuler.truncation`.

The same inverse coefficients can be written in the signed zigzag notation of the original manuscript. Define Z_r by

$$\sec t + \tan t = \sum_{r\ge 0} Z_r \frac{t^r}{r!}.$$

Then

$$\gamma_m = (-1)^m Z_{2m+1} \qquad (m \in \mathbb{N}). \tag{3.12}$$

Indeed, the odd coefficients come from $\tan t$, whose derivative is $\sec^2 t$. Changing the sign of the squared variable in the even series for $\operatorname{sech}^2 t$ gives $\sec^2 t$, so its degree-$2m$ Hurwitz coefficient is $(-1)^m\gamma_m$. Differentiation identifies this coefficient with Z_{2m+1}, proving the formula. The Lean bridge is `KomorebiPaperIX.Zigzag.inverse_is_signed_zigzag`. It uses the formal generating-function definition of the zigzag numbers.

Theorem 3.18 (Classical odd-length reconstruction)**.** *For every positive odd integer p and every $n \in \mathbb{N}$,*

$$E_{2n} = \sum_{m=0}^{n} \binom{2n}{2m} \gamma_m p^{2m} S_{2(n-m)}(p).$$

Equivalently, $E_{2n} = \sum_{q=0}^{n} V_{nq} S_{2q}(p)$ for the lower triangular matrix

$$V_{nq} = \binom{2n}{2q} \gamma_{n-q} p^{2(n-q)} \quad (q \le n), \qquad V_{nq} = 0 \quad (q > n).$$

It has $V_{nn} = 1$ and $p^{2(n-q)} \mid V_{nq}$ when $q \le n$.

Proof. The exponential generating series of the source is the finite sum

$$\mathcal{S}_p(t) = \sum_{a=0}^{p-1} (-1)^a e^{(2a+1)t}.$$

Multiplication by $\cosh t$ telescopes. Since p is odd,

$$\mathcal{S}_p(t) = \frac{1 + e^{2pt}}{2} \operatorname{sech} t.$$

Taking its even part gives

$$\sum_{n\ge 0} S_{2n}(p) \frac{t^{2n}}{(2n)!} = \cosh^2(pt) \operatorname{sech} t.$$

Multiplication by the reciprocal $\operatorname{sech}^2(pt)$ yields $\operatorname{sech} t$. The EGF product rule now gives the reconstruction coefficient by coefficient. Replacing m by $n - q$ produces the displayed lower triangular row. Its diagonal and weights follow from $\gamma_0 = 1$ and the explicit factor $p^{2(n-q)}$. The source-series identity is `KomorebiPaperIX.OddPower.odd_source_even_egf`. The reconstruction and row statement are `KomorebiPaperIX.OddEuler.odd_euler_reconstruction` and `KomorebiPaperIX.OddEuler.row_action`. □

Corollary 3.19 (Odd-prime truncation ladder)**.** *For every positive odd integer p and all $M, n \in \mathbb{N}$,*

$$p^{2M+2} \mid E_{2n} - T^{\mathrm{odd}}_{p,M}(n) \quad \text{in } \mathbb{Z}.$$

If $M \geq n$, the truncation equals E_{2n} exactly. In particular, for an odd prime p this is a congruence modulo p^{2M+2} in $\mathbb{Z}_p$.

Proof. Every omitted summand has $m \geq M+1$, hence contains the integer factor p^{2m} divisible by p^{2M+2}. All its other factors are integral. The finite sum of these omitted terms proves the assertion, with the empty-tail case giving exact equality. These are `KomorebiPaperIX.OddEuler.odd_euler_supercongruence` and `KomorebiPaperIX.OddEuler.full_depth_exact`. □

The reconstruction and its truncation bound already hold over the integers. For the dyadic construction we use a different source. Its original bound of 2^{2M+2} follows from integral reciprocal coefficients, and the next subsection sharpens that bound to the optimal uniform exponent $4M+3$.

3.7 The optimal classical dyadic edge tower

Return now to the classical signed Euler numbers

$$\operatorname{sech} t = \frac{1}{\cosh t} = \sum_{n\geq 0} E_{2n} \frac{t^{2n}}{(2n)!}.$$

Thus $E_{2n} = E_{2n}^{(2,0)}$ in the convention (3.1). In particular $E_0 = 1$, $E_2 = -1$, and $E_4 = 5$. The following construction concerns these $N = 2$ coefficients, not $C_{4,0}$.

Definition 3.20 (Dyadic truncation)**.** Define β_m by the formal unit-series identity

$$\sum_{m\geq 0} \beta_m z^{2m} = \Big(\frac{z}{\sinh z}\Big)^2, \qquad \beta_0 = 1,$$

where the quotient means the inverse of the unit series $(\sinh z/z)^2$. Define

$$A(n) = \frac{3^{2n+2}-1}{4(2n+1)(2n+2)}, \qquad S_m(n) = \beta_m 2^{2m} \frac{(2n)!}{(2n-2m)!} A(n-m) \quad (0 \leq m \leq n),$$

and

$$T_M(n) = \sum_{m=0}^{\min(M,n)} S_m(n) \qquad (M, n \in \mathbb{N}). \tag{3.13}$$

These definitions correspond to `KomorebiPaperIX.Dyadic.beta`, `KomorebiPaperIX.Dyadic.sourceEven`, and `KomorebiPaperIX.DyadicReconstruction.truncation`. The formal summand uses a falling factorial, and `KomorebiPaperIX.DyadicReconstruction.falling_factorial_fraction` proves its equality with the quotient displayed above.

Lemma 3.21 (Exact reconstruction and source integrality)**.** *For every $n \in \mathbb{N}$,*

$$E_{2n} = \sum_{m=0}^{n} S_m(n).$$

Every β_m is 2-adically integral and every $A(n)$ is a nonzero 2-adic unit. If $M \geq n$, then $T_M(n) = E_{2n}$.

Proof. The ordinary kernel coefficients of $(\sinh z/z)^2$, in z^2, are

$$\frac{2^{2m+1}}{(2m+2)!}.$$

Legendre's strict factorial bound $v_2((2m+2)!) < 2m+2$ makes them integral. Their constant coefficient is one. The coefficient recurrence for its reciprocal therefore proves integrality of every β_m. For the source factor, lifting the exponent at the even power $2n+2$ gives

$$v_2(3^{2n+2}-1) = 2 + v_2(2n+2).$$

Its denominator has the same valuation, since $2n+1$ is odd. Thus $A(n)$ is a nonzero unit.

Its exponential generating function is

$$\mathcal{A}(t) = \sum_{n\geq 0} A(n)\frac{t^{2n}}{(2n)!} = \frac{\cosh(3t)-\cosh t}{4t^2}.$$

The quotients by powers of t are well defined because the required initial coefficients vanish. The hyperbolic identity

$$\mathcal{A}(t)\cosh t = \left(\frac{\sinh(2t)}{2t}\right)^2$$

then gives the exact formal-series product

$$\left(\sum_{m\geq 0}\beta_m(2t)^{2m}\right)\mathcal{A}(t) = \operatorname{sech} t.$$

Taking the factorial-scaled coefficient of t^{2n} produces the stated finite sum. Full depth leaves no omitted terms. The relevant declarations are `KomorebiPaperIX.Dyadic.beta_integral`, `KomorebiPaperIX.Dyadic.source_valuation`, `KomorebiPaperIX.DyadicSeries.dyadic_reconstruction_series`, and `KomorebiPaperIX.DyadicReconstruction.dyadic_reconstruction`. □

Lemma 3.22 (Exact weighted inverse coefficient)**.** *Let $\kappa_m = \beta_m 2^{2m}(2m)!$. For every $m \geq 1$,*

$$\kappa_m = -2^{4m}(2m-1)B_{2m} \neq 0, \qquad v_2(\kappa_m) = 4m-1,$$

where B_{2m} is the usual even Bernoulli number.

Proof. Let $Q(z) = z\coth z$, the regular formal series with constant coefficient one. The elementary differential identity

$$\left(\frac{z}{\sinh z}\right)^2 = Q(z) - zQ'(z)$$

and the Bernoulli expansion

$$Q(z) = 1 + \sum_{m\geq 1}\frac{2^{2m}B_{2m}}{(2m)!}z^{2m}$$

give $\beta_m = -2^{2m}(2m-1)B_{2m}/(2m)!$. Multiplication by $2^{2m}(2m)!$ proves the identity for κ_m. The Bernoulli denominator theorem gives $v_2(B_{2m}) = -1$ for $m > 0$: its denominator contains each prime q with $(q-1) \mid 2m$ exactly once, including 2[3]. Since $2m-1$ is odd, the valuation is exactly $4m-1$. This also proves nonvanishing. In Lean, the hyperbolic identity is proved after clearing removable zeros.

The library Bernoulli theorem then determines the valuation of κ_m. The declarations are `KomorebiPaperIX.DyadicSharpTower.kappa_bernoulli` and `KomorebiPaperIX.DyadicSharpTower.kappa_valuation`. □

Theorem 3.23 (Optimal uniform dyadic tower). *For all $M, n \in \mathbb{N}$,*

$$E_{2n} - T_M(n) \in 2^{4M+3}\mathbb{Z}_2. \tag{3.14}$$

At the first omitted row $n = M + 1$, the error is nonzero and

$$v_2\big(E_{2M+2} - T_M(M+1)\big) = 4M + 3.$$

Thus the exponent $4M + 3$ cannot be increased uniformly in the Euler row.

Proof. Rewrite the summand exactly as

$$S_m(n) = \kappa_m \binom{2n}{2m} A(n-m).$$

For $m > M$, its first factor is divisible by 2^{4m-1}, the binomial coefficient is integral, and $A(n-m)$ is a unit. Hence every omitted summand is divisible by 2^{4M+3}. Summing the finite tail proves (3.14). If $M \geq n$, the tail is empty and the statement includes the resulting zero error.

At $n = M + 1$ there is exactly one omitted summand. Here $\binom{2n}{2n} = 1$ and $A(0) = 1$, so the error is κ_{M+1}. Lemma 3.22 gives its exact valuation $4M + 3$ and nonvanishing. The statements are `KomorebiPaperIX.DyadicSharpTower.dyadic_supercongruence_sharp`, `KomorebiPaperIX.DyadicSharpTower.first_omitted_error`, and `KomorebiPaperIX.DyadicSharpTower.first_omitted_error_valuation`. □

Proposition 3.24 (Row-dependent summand weights). *For $1 \leq m \leq n$, the summand is nonzero and*

$$v_2(S_m(n)) = 4m - 1 + v_2\binom{2n}{2m}.$$

More generally, if $L \in \mathbb{N}$ satisfies

$$L \leq 4m - 1 + v_2\binom{2n}{2m} \qquad \text{for every } M < m \leq n,$$

then $E_{2n} - T_M(n) \in 2^L\mathbb{Z}_2$.

Proof. Use the same factorization of $S_m(n)$, the nonzero binomial coefficient for $m \leq n$, the exact valuation of κ_m, and the unit property of $A(n-m)$. The tail conclusion follows by addition in $2^L\mathbb{Z}_2$. These are `KomorebiPaperIX.DyadicSharpTower.summand_valuation` and `KomorebiPaperIX.DyadicSharpTower.dyadic_supercongruence_row_weight`. □

The minimum summand weight bounds the tail valuation from below, but cancellation may raise that valuation. Appendix A gives a later exact factorization and finite-polynomial reduction for each fixed depth. A universal explicit root and simplicity classification for that factor remains open. Uniform optimality follows from the equality already established at $n = M + 1$.

3.8 Isometric continuation of the four dyadic packets

The exact displacement law also determines the images of the packets after continuous extension to the dyadic integers.

Theorem 3.25 (Isometric packet bijections)**.** *For $0 \le j < 4$, define on natural numbers*

$$f_j(n) = \frac{U_j(n) - j!}{2^{d_j}}, \qquad (d_0, d_1, d_2, d_3) = (1, 1, 5, 3).$$

There is a unique continuous map $\Phi_j : \mathbb{Z}_2 \to \mathbb{Z}_2$ whose value at every $n \in \mathbb{N}$ equals the embedded rational $f_j(n)$. It is an isometric bijection and $\Phi_j(0) = 0$:

$$|\Phi_j(x) - \Phi_j(y)|_2 = |x - y|_2 \qquad (x, y \in \mathbb{Z}_2).$$

In particular, every element of $\mathbb{Z}_2$ has exactly one preimage.

Proof. For $n > 0$, the displacement law at row zero gives $v_2(U_j(n) - j!) = v_2(n) + d_j$, so $f_j(n) \in \mathbb{Z}_2$. The value at zero is zero. Applying the same law to the smaller of two unequal natural numbers shows

$$|f_j(n) - f_j(m)|_2 = |n - m|_2.$$

The natural numbers are dense in $\mathbb{Z}_2$, and the target is complete. The map therefore extends continuously. The distance identity extends on the dense product of natural-number points, making the extension an isometry. Density also proves uniqueness among all continuous maps with these prescribed values.

To prove surjectivity, use compactness. For an isometry g of a compact metric space into itself, the sequence of iterates $g^n(x)$ has a convergent subsequence. Two sufficiently close iterates, with exponents $a < b$, yield $d(x, g^{b-a}(x))$ equally small after removing a isometric iterations. Since $b - a > 0$, the latter point is in the image of g. Thus the image is dense. It is also compact and hence closed, so it is the whole space. Apply this to Φ_j on $\mathbb{Z}_2$.

The general ingredients are `KomorebiPaperIX.DensePadicIsometry.existsUnique_extensionEquiv` and `KomorebiPaperIX.CompactSelfIsometry.surjective`. The packet specialization is `KomorebiPaperIX.DyadicFourIsometry.existsUnique_isometry`. Uniqueness among continuous maps is `KomorebiPaperIX.DyadicFourIsometry.unique_continuous`. □

Corollary 3.26 (Exact image of the original coefficients)**.** *The continuous extension of the original sequence is*

$$\widetilde{U}_j(x) = j! + 2^{d_j}\Phi_j(x).$$

It is injective, its image is exactly $j! + 2^{d_j}\mathbb{Z}_2$, and

$$|\widetilde{U}_j(x) - \widetilde{U}_j(y)|_2 = 2^{-d_j}|x - y|_2.$$

Every point of that affine image has exactly one preimage in $\mathbb{Z}_2$.

Proof. The formula agrees with U_j on every natural number. Continuity and the distance equality follow from the corresponding properties of Φ_j. Its surjectivity gives precisely the displayed affine image, and multiplication by the nonzero scalar 2^{d_j} preserves injectivity. The declarations are `KomorebiPaperIX.Dy`

`adicFourIsometry.originalExtension_nat`, `KomorebiPaperIX.DyadicFourIsometry.originalExtension_dist`, and `KomorebiPaperIX.DyadicFourIsometry.originalExtension_range`. □

The four rational packet sequences thus extend to bijections onto their exact dyadic images. The proof uses density, completeness, and the displacement law. The strengthening chapters supply the further factorial and Taylor-coefficient argument for analyticity, including exact radii in addresses zero, one and two. The analytic polynomial solution maps constructed later rest on separate hypotheses and a separate proof.

4 Threshold-free reciprocal transfer at prime-power section orders

The completion of Nishibuchi's conjecture fixes the requested eventual congruence. The stronger question is whether the sufficient starting row can be removed, and how much precision the difference order and the step actually provide. This section answers the first question at every prime-power section order. Subsequent sections give a factorial improvement and exact results at section order four.

Throughout these sections, the normalized source and its reciprocal are

$$G_{N,j}(t) = j! \sum_{n\ge 0} \frac{t^{Nn}}{(Nn+j)!}, \qquad F_{N,j}(t) = G_{N,j}(t)^{-1} = \sum_{n\ge 0} C_{N,j}(n) \frac{t^{Nn}}{(Nn)!}, \tag{4.1}$$

where $N \ge 1$ and $0 \le j < N$. In particular, $C_{N,j}(0) = 1$. The coefficients in the original convention satisfy

$$E^{(N,j)}_{Nn} = j! C_{N,j}(n), \qquad E^{(N,j)}_{d} = 0 \quad (N \nmid d). \tag{4.2}$$

Thus every valuation of a nonzero difference gains $v_p(j!)$ on returning to the original coefficients. This factor must be retained when stating optimal periods or the final congruence.

Write $Sf(n) = f(n+1)$ and $\Delta_H = S^H - 1$. A mixed difference $\Delta_{H_1} \cdots \Delta_{H_k}$ acts on the row variable n, rather than on the full Euler subscript. We use $v_p(0) = +\infty$. Orders and starting rows are nonnegative integers. Steps are positive integers unless stated otherwise. An empty mixed difference is the original value, and a zero ordinary step makes every nonempty product containing it zero.

4.1 The Hurwitz lattice and translated differential flatness

Definition 4.1 (Hurwitz integral series)**.** For a prime p, let

$$\mathcal{H}_p = \left\{ \sum_{d\ge 0} f_d \frac{t^d}{d!} : f_d \in \mathbb{Z}_p \right\} \subset \mathbb{Q}_p[[t]].$$

For $N = p^a$ and $\lambda \in \mathbb{Z}_p$, put

$$D = \frac{d}{dt}, \qquad L_\lambda = \frac{D^N - \lambda}{p}.$$

A series A is λ-flat if $L_\lambda^k A \in \mathcal{H}_p$ for every $k \ge 0$.

Products preserve $\mathcal{H}_p$ because the coefficient at factorial degree d is

$$(AB)_d = \sum_{i=0}^{d} \binom{d}{i} a_i b_{d-i}.$$

The derivative D acts by the coefficient shift $(DA)_d = a_{d+1}$. Consequently every nonnegative power of D preserves the lattice. If $A \in \mathcal{H}_p$ has unit constant term, its reciprocal belongs to the same lattice: with $B = A^{-1}$,

$$b_0 = a_0^{-1}, \qquad b_d = -a_0^{-1} \sum_{i=1}^{d} \binom{d}{i} a_i b_{d-i}. \tag{4.3}$$

If A is supported at degrees divisible by N, this recurrence also proves that B has the same support.

Lemma 4.2 (Translated product formula)**.** *For $N = p^a$, $a \geq 1$, and $\lambda, \mu \in \mathbb{Z}_p$,*

$$L_{\lambda+\mu}(AB) = (L_\lambda A)B + A(L_\mu B) + \sum_{i=1}^{N-1} c_i (D^i A)(D^{N-i} B), \qquad c_i = \frac{1}{p}\binom{N}{i} \in \mathbb{Z}. \tag{4.4}$$

Flatness types add under multiplication.

Proof. The identity $(1+X)^{p^a} = 1 + X^{p^a}$ over $\mathbb{F}_p$ shows that every interior binomial coefficient $\binom{N}{i}$ is divisible by p. Subtract $(\lambda+\mu)AB$ from the ordinary Nth derivative product formula and divide by p to obtain (4.4).

For completeness, the iterated formula is an integral multinomial formula, rather than a product rule with unspecified remainders. On the tensor of the two factors use the mutually commuting operators

$$L_\lambda \otimes 1, \quad 1 \otimes L_\mu, \quad c_i D^i \otimes D^{N-i} \quad (1 \leq i < N).$$

Applying multiplication after the kth power of their sum gives exactly $L^k_{\lambda+\mu}(AB)$. Expanding it yields terms indexed by $a, b, e_1, \ldots, e_{N-1} \geq 0$, with $a + b + \sum_i e_i = k$:

$$\frac{k!}{a!b!\prod_i e_i!} \prod_i c_i^{e_i} (D^\alpha L^a_\lambda A)(D^\beta L^b_\mu B), \quad \alpha = \sum_i i e_i, \quad \beta = \sum_i (N-i) e_i. \tag{4.5}$$

Every scalar is integral. If A and B have the stated flatness types, both factors in every term belong to $\mathcal{H}_p$, as does their product. □

Lemma 4.3 (Reciprocal transfer)**.** *If A is λ-flat and has unit constant term, then A^{-1} is $(-\lambda)$-flat.*

Proof. Set $B = A^{-1}$. Its order-zero integrality was established in (4.3). Assume by induction that $L^b_{-\lambda} B \in \mathcal{H}_p$ for $b < k$. Since $AB = 1$,

$$L^k_0(AB) = \left(\frac{D^N}{p}\right)^k 1 = 0 \qquad (k > 0).$$

Use (4.5) with $\mu = -\lambda$. Exactly one term has inverse order $b = k$: it has $a = 0$ and all $e_i = 0$, and is $AL^k_{-\lambda} B$. In every other term $b < k$, so its second factor is integral by induction and derivative-shift integrality. Its first factor is integral by the flatness of A, and its scalar is integral. Hence $AL^k_{-\lambda} B \in \mathcal{H}_p$. Multiplying by the already integral B proves $L^k_{-\lambda} B \in \mathcal{H}_p$. This induction takes place in the entire Hurwitz lattice. It places no restriction on the coefficient degree or the starting row. □

4.2 The actual Euler source

The packed factorial coefficient of $G_{N,j}$ is

$$g_{N,j}(n) = \frac{j!(Nn)!}{(Nn+j)!} = \prod_{i=1}^{j} \left(1 + \frac{N}{i} n\right)^{-1}. \tag{4.6}$$

The empty product is one. If $N = p^a$ and $1 \leq i < N$, then $v_p(i) < a$, so $N/i \in p\mathbb{Z}_p$. Every affine denominator in (4.6) is therefore a unit on $\mathbb{Z}_p$.

For $s \in p\mathbb{Z}_p$, an exact finite-difference identity is

$$\Delta_1^k \frac{1}{1+sn} = \frac{(-s)^k k!}{\prod_{h=0}^{k}(1+s(n+h))}. \tag{4.7}$$

It follows by induction, subtracting adjacent rational functions. Each successive subtraction adds the factor $-(k+1)s$ in the numerator. Its denominator is a unit, so it belongs to $p^k\mathbb{Z}_p$. The discrete Leibniz formula

$$\Delta_1^k(fg)(n) = \sum_{r=0}^{k} \binom{k}{r} (\Delta_1^r f)(n)(\Delta_1^{k-r} g)(n+r) \tag{4.8}$$

then proves $\Delta_1^k g_{N,j}(n) \in p^k\mathbb{Z}_p$ for every k, n. The coefficient at degree Nn of $L_1^k G_{N,j}$ is precisely $p^{-k}\Delta_1^k g_{N,j}(n)$, and the other residue classes vanish. Thus the actual source is 1-flat.

Theorem 4.4 (All-row prime-power transfer)**.** *Let p be prime, $a \geq 1$, $N = p^a$, and $0 \leq j < N$. The coefficients $C_{N,j}(n)$ belong to $\mathbb{Z}_p$ for all $n \geq 0$. Set $A_{N,j}(n) = (-1)^n C_{N,j}(n)$ and $T_H = S^H - (-1)^H$. For $k \geq 1$ and positive $H_1, \ldots, H_k$,*

$$v_p(\Delta_{H_1} \cdots \Delta_{H_k} A_{N,j}(n)) \geq k + \sum_{\nu=1}^{k} v_p(H_\nu), \tag{4.9}$$

$$v_p(T_{H_1} \cdots T_{H_k} E_{Nn}^{(N,j)}) \geq v_p(j!) + k + \sum_{\nu=1}^{k} v_p(H_\nu). \tag{4.10}$$

At $p = 2$, the ordinary differences of $C_{N,j}$ and of the original coefficients satisfy the same bounds. These dyadic statements also hold for $N = 1$.

Proof. Reciprocal transfer gives $L_{-1}^k F_{N,j} \in \mathcal{H}_p$. Extraction of the packed coefficient gives $(S+1)^k C_{N,j}(n) \in p^k\mathbb{Z}_p$. Moreover,

$$\Delta_1^k A_{N,j}(n) = (-1)^{n+k}(S+1)^k C_{N,j}(n),$$

so $A_{N,j}$ has the ordinary p^k difference property. At $p = 2$, $L_1 = L_{-1} - 1$. Its integral binomial expansion on $F_{N,j}$ gives $\Delta_1^k C_{N,j}(n) \in 2^k\mathbb{Z}_2$ directly. For $N = 1$ the interior sum in the product formula is empty, so the same argument applies without change. Equivalently, $F_{1,0}(t) = e^{-t}$.

To retain the valuation of a step, let B be any sequence satisfying $\Delta_1^m B \in p^m\mathbb{Z}_p$ at every order and row. Use the finite operator identity

$$\Delta_H = \sum_{i=1}^{H} \binom{H}{i} \Delta_1^i.$$

The relation $i\binom{H}{i} = H\binom{H-1}{i-1}$ implies

$$v_p\left(p^i \binom{H}{i}\right) \geq i + v_p(H) - v_p(i) \geq 1 + v_p(H).$$

Multiplying these identities for the k steps, every term of total order M has its scalar multiplied by p^M, and is divisible by $p^{k+\sum_\nu v_p(H_\nu)}$. This proves the mixed-step bound. Finally,

$$\Delta_H A_{N,j}(n) = (-1)^{n+H} T_H C_{N,j}(n).$$

Iteration contributes only a global sign. Multiplying by $j!$ proves (4.10). □

Corollary 4.5 (Threshold-free dyadic congruence)**.** *For $N = 2^a$, $a \geq 0$, all permitted j, and $n \geq 0$,*

$$v_2(\Delta_{H_1} \cdots \Delta_{H_k} E_{Nn}^{(N,j)}) \geq v_2(j!) + k + \sum_{\nu=1}^{k} v_2(H_\nu). \tag{4.11}$$

In particular, Δ_H^k gains $k(1 + v_2(H))$ bits before normalization. For $r > v_2(j!)$, the row displacement $H = 2^{\max(0, r - v_2(j!) - 1)}$ is a sufficient period modulo 2^r from row zero. If $r \leq v_2(j!)$, all original coefficients vanish modulo 2^r.

Remark 4.6 (Necessary boundaries). At an odd prime the ordinary step-one difference cannot replace the sign-twisted operator in the general theorem. For $j = 0$, $C_{N,0}(0) = 1$ and $C_{N,0}(1) = -1$, so their ordinary difference is -2, a unit at every odd prime. The proof also does not extend unchanged to non-prime-power N, whose interior binomial coefficients need not be divisible by the chosen prime. Neither observation is a counterexample to Nishibuchi's original eventual congruence.

5 Factorial precision at section order four

Write $C_j = C_{4,j}$ and $F_j = F_{4,j}$. The all-row theorem removes the threshold, but at $N = 4$ it leaves a further factorial gain unused. The exact algebra below proves that gain for all four addresses and identifies several infinite families where it is sharp.

Theorem 5.1 (Four-address factorial bound)**.** *For $j \in \{0, 1, 2, 3\}$, $n \geq 0$, $k \geq 1$, and positive mixed steps,*

$$v_2(\Delta_{H_1} \cdots \Delta_{H_k} C_j(n)) \geq k + v_2(k!) + \sum_{\nu=1}^{k} v_2(H_\nu) + \beta_j, \quad (\beta_0, \beta_1, \beta_2, \beta_3) = (0, 0, 3, 1). \tag{5.1}$$

Address two also satisfies

$$v_2(\Delta_{H_1} \cdots \Delta_{H_k} C_2(n)) \geq 2k + v_2(k!) + \left\lfloor \frac{k}{2} \right\rfloor + \sum_{\nu=1}^{k} v_2(H_\nu). \tag{5.2}$$

For the original coefficients, the offsets in (5.1) are $(0, 0, 4, 2)$. No positive-order offset is asserted for the empty difference.

The proof of the first two addresses uses one classical arithmetic input: Frobenius's exact congruence for the ordinary Euler numbers in the sech convention, as stated and derived by Gessel [2], Section 9. The address-two and address-three bounds below are finite Bernoulli calculations and do not require that input. A divided-power argument is necessary: ordinary integral moments alone do not justify division by $k!$.

5.1 Euler moments and an integral divided-power algebra

Let $\mathcal{L}$ be the ordinary Euler evaluation functional on a variable $\mathcal{E}$, defined by

$$\mathcal{L}(\mathcal{E}^d) = \mathrm{Euler}_d, \qquad \sum_{d \geq 0} \mathrm{Euler}_d \, \frac{t^d}{d!} = \operatorname{sech} t.$$

The functional is linear. It is not a multiplicative evaluation. Independent variables mean that moments of polynomials in separate variables factor. Odd moments vanish. Frobenius's congruence is

$$v_2\left(\sum_{r=0}^{m}(-1)^{m-r}\binom{m}{r}\operatorname{Euler}_{2n+2r}\right)=m+v_2(m!)\qquad(n,m\geq 0).\tag{5.3}$$

For $m=0$, the assertion is that every even Euler number is odd. With $P=(\mathcal{E}^2-1)/2$ and $\gamma_m(P)=P^m/m!$, the case $n=0$ says

$$\mathcal{L}(\gamma_m(P))\in\mathbb{Z}_2^{\times}\qquad(m\geq 0).\tag{5.4}$$

Introduce an independent Euler variable $\mathcal{F}$ and $Q=(\mathcal{F}^2-1)/2$.

Put $K=\mathbb{Q}_2(i)$, $R=\mathbb{Z}_2[i]$, $a=(1+i)/2$, and $b=(1-i)/2$. The exact identity

$$F_0(t)=\frac{2}{\cosh t+\cos t}=\operatorname{sech}(at)\operatorname{sech}(bt)\tag{5.5}$$

gives, for $U=a\mathcal{E}+b\mathcal{F}$, $\mathcal{L}(U^{4n})=C_0(n)$. Although a and b have negative valuation, their denominators disappear from the following exact polynomial identities:

$$\begin{aligned}U^2&=\mathcal{E}\mathcal{F}+i(P-Q),\\ H_0:=\frac{U^4-1}{2}&=P+Q-\frac{P^2}{2}-\frac{Q^2}{2}+3PQ+i\mathcal{E}\mathcal{F}(P-Q).\end{aligned}\tag{5.6}$$

Let $\Gamma_R(P,Q)$ be the R-subalgebra generated by all $\gamma_m(P)$ and $\gamma_r(Q)$. Adjoin $\mathcal{E},\mathcal{F}$ with

$$\mathcal{E}^2=1+2P,\qquad\mathcal{F}^2=1+2Q,$$

and call the resulting algebra $\mathcal{A}_0$. Its elements are finite expressions. No completion is being presumed. It is generated as a $\Gamma_R(P,Q)$-module by $1,\mathcal{E},\mathcal{F},\mathcal{E}\mathcal{F}$. The functional maps this module to R. For an even basis term this is (5.4) and independence. For a basis term with an odd Euler factor the moment is zero, since P and Q are even polynomials in their respective variables.

Every displayed component of H_0 has all its divided powers in $\mathcal{A}_0$. Besides the generators, the needed identities are

$$\begin{aligned}\gamma_m(P^2/2)&=\frac{(2m)!}{2^m m!}\gamma_{2m}(P),\\ \gamma_m(3PQ)&=3^m m!\gamma_m(P)\gamma_m(Q),\\ \gamma_m(P-Q)&=\sum_{r=0}^{m}(-1)^r\gamma_{m-r}(P)\gamma_r(Q).\end{aligned}\tag{5.7}$$

The first scalar counts partitions into pairs and is an integer. For the last term of H_0, multiply the third identity by $(i\mathcal{E}\mathcal{F})^m$ and reduce the Euler powers using the integral quadratic relations. Finally,

$$\gamma_k(X+Y)=\sum_{r=0}^{k}\gamma_r(X)\gamma_{k-r}(Y)$$

proves $\gamma_k(H_0)\in\mathcal{A}_0$. Applying the functional and putting $W=U^4-1=2H_0$ gives

$$\mathcal{L}(W^m)\in 2^m m!R\qquad(m\geq 0).\tag{5.8}$$

These moments are rational. The identity $R \cap \mathbb{Q}_2 = \mathbb{Z}_2$, obtained from the linear independence of $1, i$ over $\mathbb{Q}_2$, descends every such divisibility statement to $\mathbb{Z}_2$. No field property of $R/2R$ is needed.

For every starting row,

$$\Delta_1^k C_0(n) = \mathcal{L}(U^{4n} W^k) = \sum_{s=0}^{n} \binom{n}{s} \mathcal{L}(W^{k+s}). \tag{5.9}$$

Each summand lies in $2^k k! \mathbb{Z}_2$, proving the factorial bound for address zero from row zero onward.

5.2 A finite step-expansion lemma

The conversion from unit steps to arbitrary mixed steps is used several times, so it is useful to make it explicit. Write $\Delta = \Delta_1$. For $H > 0$,

$$\Delta_H = \sum_{m=1}^{H} \binom{H}{m} \Delta^m. \tag{5.10}$$

A mixed term with local orders $m_1, \dots, m_k \geq 1$ and $M = \sum_\nu m_\nu$ therefore has valuation at least

$$M + v_2(M!) + \beta + \sum_{\nu} \bigl(v_2(H_\nu) - v_2(m_\nu) \bigr)$$

if the unit-order estimate has offset β for every positive order. The inequalities

$$m - 1 \geq v_2(m), \qquad M \geq k, \qquad v_2(M!) \geq v_2(k!)$$

make this at least $k + v_2(k!) + \beta + \sum_\nu v_2(H_\nu)$. Every expansion is finite. This proves the desired mixed-step transfer without an exchange of limits.

5.3 An elementary Bernoulli denominator bound

Let B_m denote the Bernoulli numbers with $B_1 = -1/2$. The identity obtained by substituting $u = e^t - 1$ into $\log(1+u)/u$ is

$$B_m = \sum_{r=0}^{m} (-1)^r \frac{r!}{r+1} \left\{ {m \atop r} \right\}, \tag{5.11}$$

where the braces are Stirling numbers of the second kind. Each $2r!/(r+1)$ is dyadically integral. Indeed, if $s = v_2(r+1) > 0$, then $r \geq 2^s - 1$ and

$$v_2(r!) \geq v_2((2^s - 1)!) = 2^s - 1 - s \geq s - 1.$$

The last inequality is $2^s \geq 2s$. The case $s = 0$ is immediate. Consequently

$$2B_m \in \mathbb{Z}_2 \qquad (m \geq 0). \tag{5.12}$$

Thus the transfer factors below require no appeal to the von Staudt–Clausen theorem.

5.4 Address one and the scaled-binomial transfer

The address-one source is $G_{4,1}(t) = (\sinh t + \sin t)/(2t)$. The identities $a+b=1$, $a-b=i$, and $ab=1/2$ give

$$D_1(t) := G_{4,1}(t)F_0(t) = \frac{1}{2}\left(\frac{\tanh(at)}{at} + \frac{\tanh(bt)}{bt}\right). \tag{5.13}$$

For example, its numerator follows from

$$\sinh t + \sin t = 2b\sinh(at)\cosh(bt) + 2a\cosh(at)\sinh(bt),$$

while $\cosh t + \cos t = 2\cosh(at)\cosh(bt)$. Only degrees divisible by four survive. Its actual Hurwitz packets are

$$D_1(t) = \sum_{i\ge 0} d_i \frac{t^{4i}}{(4i)!}, \qquad d_i = \left(-\frac{1}{4}\right)^i \frac{2^{4i+2}(2^{4i+2}-1)B_{4i+2}}{(4i+2)(4i+1)}. \tag{5.14}$$

The constant is one. Since $v_2(4i+2)=1$, the elementary Bernoulli bound shows $v_2(d_i)\ge 2i$. Hurwitz inversion therefore gives

$$D_1(t)^{-1} = \sum_{i\ge 0} h_i \frac{t^{4i}}{(4i)!}, \qquad h_0 = 1, \quad v_2(h_i)\ge 2i.$$

This follows by induction from the inverse recurrence: for packet index i, every product $d_r h_{i-r}$ has valuation at least $2i$, and its binomial multiplier is integral. Because $F_1 = F_0 D_1^{-1}$,

$$C_1(n) - C_0(n) = \sum_{i\ge 1} h_i \binom{4n}{4i} C_0(n-i). \tag{5.15}$$

At a natural n this is a finite sum, with $i \le n$.

Here is the polynomial estimate that supplies one additional bit. For $i \ge 1$, put $P_i(x) = 4^i\binom{4x}{4i}$. Its constant is zero, and its degree-d coefficient is

$$[x^d]P_i(x) = \frac{4^i 4^d s(4i,d)}{(4i)!}, \tag{5.16}$$

where $s(m,d)$ is a signed Stirling number of the first kind. In each product contributing to $s(4i,d)$, at most $d-1$ of the $2i-1$ even integers in $1,\dots,4i-1$ can be omitted. Thus

$$v_2(s(4i,d)) \ge \max(0, 2i-d).$$

Writing $s_2(i)$ for the number of ones in the binary expansion of i, and using $v_2((4i)!) = 4i - s_2(i)$, gives

$$v_2([x^d]P_i) \ge 2d - 2i + s_2(i) + \max(0,2i-d) \ge d + s_2(i) \ge d+1 \quad (d\ge 1). \tag{5.17}$$

For $k\ge 1$, $\Delta_1^k x^d$ vanishes when $d<k$ and is an integer polynomial with values divisible by $k!$. To see the latter, expand $x^d = \sum_r \left\{ {d \atop r} \right\} r!\binom{x}{r}$ and apply $\Delta_1^k\binom{x}{r} = \binom{x}{r-k}$. It follows that

$$\Delta_1^k P_i(x) \in 2^{k+1}k!\mathbb{Z}_2 \qquad (k\ge 0,\ x\in\mathbb{Z}_2). \tag{5.18}$$

For $k=0$ the bound follows directly from the coefficient estimate.

To apply discrete products in (5.15) without a moving truncation, first extend C_0 to $\mathbb{Z}_2$ by its uniformly convergent Newton series. The all-row bound $v_2(\Delta_1^m C_0(0)) \geq m$ proves this convergence. Its factorial bounds extend to every dyadic starting point by continuity and approximation with natural rows. The sum in (5.15) is then uniformly convergent on $\mathbb{Z}_2$: both the binomial polynomial and $C_0(x-i)$ are integral-valued and $v_2(h_i) \geq 2i$.

For the pointwise product $P_i(x)C_0(x-i)$, the discrete Leibniz formula has scalar divisibility

$$\binom{k}{r}(2^{r+1}r!)(2^{k-r}(k-r)!) = 2^{k+1}k!.$$

Multiplication by $h_i/4^i \in \mathbb{Z}_2$ and uniform summation now give

$$v_2(\Delta_1^k(C_1 - C_0)(n)) \geq k + v_2(k!) + 1 \qquad (k, n \geq 0). \tag{5.19}$$

The same extra bit holds for positive mixed steps by (5.10). Combining this with the address-zero bound proves Theorem 5.1 for address one.

5.5 Central factorials and integral Bernoulli divided powers

Lemma 5.2 (Bernoulli divided-power moments)**.** *Let Z be the ordinary Bernoulli variable, $\mathcal{L}(Z^r) = B_r$, with exponential transform $t/(e^t-1)$. For $P = Z(Z+1)$ and $\mu_m = \mathcal{L}(P^m/m!)$,*

$$\mu_m \in \mathbb{Z}_2, \qquad v_2(\mu_m) \geq s_2(m) - 1 \quad (m \geq 1). \tag{5.20}$$

Moreover, μ_m is odd exactly when $m = 0$ or m is a positive power of two.

Proof. Define the central-factorial basis polynomials

$$P_r(X) = \prod_{a=0}^{r-1}(X - a(a+1)).$$

At $X = Z(Z+1)$, they have the exact factorization

$$P_r(Z(Z+1)) = \prod_{a=0}^{r-1}(Z-a)(Z+a+1) = (2r)!\binom{Z+r}{2r}. \tag{5.21}$$

The Bernoulli transform gives $\mathcal{L}((1+T)^Z) = \log(1+T)/T$, whence $\mathcal{L}(\binom{Z}{j}) = (-1)^j/(j+1)$. Finite Vandermonde expansion therefore gives

$$\begin{aligned}\mathcal{L}\left(\binom{Z+r}{2r}\right) &= (-1)^r \sum_{q=0}^{r}(-1)^q\binom{r}{q}\frac{1}{r+q+1} \\ &= (-1)^r\frac{(r!)^2}{(2r+1)!}.\end{aligned} \tag{5.22}$$

The last equality is the rational identity obtained by expanding $\int_0^1 t^r(1-t)^r\,dt$. This use of an ordinary finite integral makes no assertion about a positive or bounded p-adic measure. In particular,

$$\mathcal{L}(P_r(P)) = (-1)^r\frac{(r!)^2}{2r+1}.$$

Expand $X^m = \sum_{r=0}^{m} T(m,r)P_r(X)$. Since $XP_r(X) = P_{r+1}(X) + r(r+1)P_r(X)$, these integer coefficients satisfy

$$T(m+1,r) = T(m,r-1) + r(r+1)T(m,r), \quad T(0,0) = 1. \tag{5.23}$$

Every $r(r+1)$ is even. Induction, including the boundary indices, proves $2^{m-r} \mid T(m,r)$ for $0 \le r \le m$. For $m > 0$ the $r = 0$ term vanishes. Each remaining summand of $\mathcal{L}(P^m/m!)$ has valuation at least

$$m - r + 2v_2(r!) - v_2(m!) = r + s_2(m) - 2s_2(r) \ge s_2(m) - 1 \ge 0. \tag{5.24}$$

Here $r \ge 2s_2(r) - 1$ follows from $r \ge 2^{s_2(r)} - 1$ and $2^u \ge 2u$ for $u \ge 1$. This proves integrality and the stronger bound.

If m is not a power of two, $s_2(m) \ge 2$ makes μ_m even. If m is a positive power of two, the only central indices which can contribute an odd residue are $r = 1$ and $r = 3$, since $r - 2s_2(r) = -1$ only at these two positive integers. The $r = 1$ term is odd: $T(m,1) = 2^{m-1}$ and $v_2(m!) = m - 1$. For $m \ge 4$ a power of two, the $r = 3$ term is even. More explicitly,

$$\frac{T(m,3)}{2^{m-3}} = h_{m-3}(1,3,6), \qquad \sum_{d \ge 0} h_d(1,3,6)t^d = \frac{1}{(1-t)(1-3t)(1-6t)}.$$

Reduction modulo two gives $(1-t)^{-2}$, whose degree $m-3$ coefficient has parity $m - 2 = 0$. At $m = 1, 2$ the $r = 3$ term is absent, and the $r = 1$ term is again odd. Finally $\mu_0 = 1$. □

5.6 Address two and its stronger filtration

The variable $\mathcal{B} = 2Z + 1$ has transform

$$e^t \frac{2t}{e^{2t} - 1} = \frac{t}{\sinh t}.$$

Its odd moments vanish, and $P = (\mathcal{B}^2 - 1)/4 = Z(Z+1)$ has the divided-power moments of Lemma 5.2. Introduce an independent copy $\mathcal{D}$ and $Q = (\mathcal{D}^2 - 1)/4$. The exact factorization

$$F_2(t) = \frac{t^2}{\cosh t - \cos t} = \frac{at}{\sinh(at)} \frac{bt}{\sinh(bt)} \tag{5.25}$$

shows that $U = a\mathcal{B} + b\mathcal{D}$ satisfies $\mathcal{L}(U^{4n}) = C_2(n)$. Direct expansion gives

$$H_2 := \frac{U^4 - 1}{4} = P + Q - P^2 - Q^2 + 6PQ + i\mathcal{B}\mathcal{D}(P - Q). \tag{5.26}$$

Let $\mathcal{A}_2$ be the divided-power algebra over R generated by P, Q, adjoining $\mathcal{B}, \mathcal{D}$ with $\mathcal{B}^2 = 1 + 4P$, $\mathcal{D}^2 = 1 + 4Q$. The functional is integral on its module basis $1, \mathcal{B}, \mathcal{D}, \mathcal{B}\mathcal{D}$ by the Bernoulli lemma, independence, and vanishing of odd moments. Every component in (5.26) has integral divided powers, by the same finite identities as before. P^2 is even easier than $P^2/2$. Consequently

$$\mathcal{L}((U^4 - 1)^m) \in 4^m m! \mathbb{Z}_2, \qquad v_2(\Delta_1^k C_2(n)) \ge 2k + v_2(k!). \tag{5.27}$$

The starting-row conclusion follows from the finite base expansion (5.9), now with $W = 4H_2$.

The low Newton coefficients of the actual reciprocal are

$$C_2(0)=1,\quad C_2(1)=-\frac{1}{15},\quad C_2(2)=\frac{13}{45},\qquad a_1=-\frac{16}{15},\quad a_2=\frac{64}{45}, \tag{5.28}$$

where $a_m=\Delta_1^m C_2(0)$. Thus $v_2(a_1)=4$ and $v_2(a_2)=6$. For $m\ge 3$, (5.27) bounds a_m by $2m+v_2(m!)$. The finite shifted Newton formula

$$\Delta_1^k C_2(n)=\sum_{m=k}^{n+k} a_m\binom{n}{m-k} \tag{5.29}$$

therefore gives $v_2(\Delta_1^k C_2(n))\ge k+v_2(k!)+3$ for every $k\ge 1$. For $k\ge 3$ this is $2k\ge k+3$. For $k=1,2$ it uses the exact initial coefficients and the higher tail bound. The finite step expansion proves the offset three in (5.1).

There is a still stronger filtration. Put

$$X=P+Q,\qquad \tau=i\mathcal{B}\mathcal{D},\qquad \epsilon=1+\tau.$$

Then the exact identities are

$$H_2=\epsilon X+2G,\quad G=-\gamma_2(P)-\gamma_2(Q)+3PQ-\tau Q,\quad \epsilon^2=2V,\quad V=\tau-2X-8PQ. \tag{5.30}$$

Every divided power of G is integral component by component. The finite addition identity gives

$$\gamma_k(H_2)=\sum_{r=0}^{k}2^r\gamma_r(G)\epsilon^{k-r}\gamma_{k-r}(X)\in 2^{\lfloor k/2\rfloor}\mathcal{A}_2, \tag{5.31}$$

because the rth term belongs to $2^{r+\lfloor (k-r)/2\rfloor}\mathcal{A}_2$. Applying the functional, rational descent, and the base-index expansion proves the unit-step version of (5.2). For a mixed term of total order M, its lower bound exceeds the target at order k by at least

$$2(M-k)+\left\lfloor\frac{M}{2}\right\rfloor-\left\lfloor\frac{k}{2}\right\rfloor+v_2(M!)-v_2(k!)-\sum_{\nu}v_2(m_\nu)\ge 0.$$

Indeed $\sum_\nu v_2(m_\nu)\le M-k$. This proves the stronger mixed bound. The earlier offset-three bound is retained, since it is stronger at the lowest orders.

5.7 Address three and cancellation of the apparent pole

The address-three source is $G_{4,3}(t)=3(\sinh t-\sin t)/t^3$. Addition identities give

$$\sinh t-\sin t=2a\sinh(at)\cosh(bt)+2b\cosh(at)\sinh(bt),\qquad \cosh t-\cos t=2\sinh(at)\sinh(bt).$$

Consequently

$$D_3(t):=G_{4,3}(t)F_2(t)=\frac{3}{2}\left(\frac{\coth(at)}{at}+\frac{\coth(bt)}{bt}\right). \tag{5.32}$$

This expression is a power series: its two polar terms cancel because $a^{-2}+b^{-2}=0$. Its constant is one, only degrees divisible by four survive, and the Bernoulli expansion gives

$$D_3(t)=\sum_{i\ge 0} d_i\frac{t^{4i}}{(4i)!},\qquad d_i=3\left(-\frac{1}{4}\right)^i\frac{2^{4i+2}B_{4i+2}}{(4i+2)(4i+1)}. \tag{5.33}$$

Again $v_2(d_i)\ge 2i$, and the inverse coefficients h_i have the same bound. Since $F_3=F_2D_3^{-1}$,

$$C_3(n)-C_2(n)=\sum_{i\ge 1} h_i\binom{4n}{4i}C_2(n-i). \tag{5.34}$$

The scaled-binomial argument (5.18) applies unchanged. The basic bound for C_2 includes order zero. Its continuous extension is available from the threshold-free theorem. Thus the shifted sums converge uniformly on $\mathbb{Z}_2$, and the pointwise product rule proves

$$v_2(\Delta_1^k(C_3-C_2)(n))\ge k+v_2(k!)+1\qquad (k,n\ge 0). \tag{5.35}$$

At every positive order C_2 has three extra bits, so this gives the one-bit offset for C_3. Finite step expansion finishes the proof of Theorem 5.1.

6 Sharp higher-difference families

The lower bounds do not mean that every mixed stencil has exactly the stated valuation. Addresses zero and one have a complete classification of when the leading factorial precision is attained. Address two has exact mixed precision at every positive power-of-two order.

Theorem 6.1 (Exact factorial precision at addresses zero and one)**.** *Let $j\in\{0,1\}$, $k\ge 1$, $n\ge 0$, and $H_1,\dots,H_k>0$. Put*

$$L=k+v_2(k!)+\sum_{\nu=1}^{k} v_2(H_\nu),\qquad e=\#\{\nu:2\mid H_\nu\}.$$

The mixed difference has valuation exactly L if k is odd or e is even. If k is even and e is odd, it has valuation at least $L+1$. In particular, for every homogeneous positive step,

$$v_2(\Delta_H^k C_j(n))=k+v_2(k!)+kv_2(H). \tag{6.1}$$

Proof. Return to the Euler variables of address zero and put $X=P+Q$, $\tau=i\mathcal{E}\mathcal{F}$, $\epsilon=1+\tau$. Direct rearrangement of (5.6) gives

$$H_0=\gamma_2(X)+\epsilon X+2G,\qquad G=-\gamma_2(P)-\gamma_2(Q)+PQ-\tau Q,\qquad \epsilon^2=2(\tau-P-Q-2PQ). \tag{6.2}$$

The divided powers of G are integral by the same component formulas used above. Thus modulo $2\mathcal{A}_0$, $\gamma_k(H_0)$ equals the divided power of $\gamma_2(X)+\epsilon X$. The identity

$$\gamma_r(\gamma_2(X))=\frac{(2r)!}{2^r r!}\gamma_{2r}(X)$$

has an odd integer scalar. Every term involving ϵ^j for $j \geq 2$ vanishes modulo two. The surviving zero and first powers give

$$\gamma_k(H_0) \equiv \gamma_{2k}(X) + \epsilon\gamma_{2k-1}(X) \pmod{2\mathcal{A}_0}. \tag{6.3}$$

The multiplication coefficient in the second term is $2k-1$, also odd. By the odd moments (5.4) and independence,

$$\mathcal{L}(\gamma_m(P+Q)) \equiv m+1 \pmod 2.$$

The τ-weighted moment vanishes because it contains an odd power of each Euler variable. Therefore the first term of (6.3) evaluates to one modulo two and the second to zero. Hence $\mathcal{L}(\gamma_k(H_0))$ is odd at every order, including order zero. This proves

$$v_2(\Delta_1^k C_0(0)) = k + v_2(k!).$$

In the base-row expansion (5.9), every $s > 0$ term has at least one extra bit after division by $2^k k!$. Thus the same exact valuation holds at every starting row. The extra-bit transfer (5.19) proves it for address one as well.

It remains to track possible ties in the mixed-step expansion. For local orders $m_\nu \geq 1$ and total M, the excess over L is at least

$$\left(M - k - \sum_\nu v_2(m_\nu)\right) + \left(v_2(M!) - v_2(k!)\right). \tag{6.4}$$

The first bracket is nonnegative, and equality requires every m_ν to be one or two. Two or more occurrences of two make the second bracket positive, since the intervening factorial interval then contains an even number. Exactly one occurrence of two can tie only when k is even. Its binomial coefficient can have the minimally allowed valuation only if its associated step is even.

The all-one multi-index contributes one after normalization by 2^L. When k is even, each even step supplies exactly one further tied term, again with normalized residue one. For example, $\binom{H}{2} = H(H-1)/2$ attains $v_2(H) - 1$ exactly when H is even. All remaining factors and the exact normalized order-$k+1$ difference are odd. Thus the total normalized parity is one for odd k, and $1 + e$ for even k. This proves the classification. In the homogeneous case, e is zero or k, so it is even whenever k is even, proving (6.1). □

Remark 6.2 (A mixed cancellation). The exceptional class can gain more than one bit. The exact values

$$\Delta_1\Delta_2 C_0(0) = -33728, \qquad \Delta_1\Delta_2 C_1(0) = -\frac{150208}{585}$$

both have valuation six, whereas their baseline L is four. The theorem classifies attainment of the baseline. It does not give a complete deeper valuation in the cancellation class.

Theorem 6.3 (Exact address-two power orders)**.** *For every starting row $n \geq 0$ and all positive mixed steps,*

$$v_2(\Delta_{H_1} \cdots \Delta_{H_k} C_2(n)) = V_2(k) + \sum_{\nu=1}^{k} v_2(H_\nu) \tag{6.5}$$

whenever k is a positive power of two, where

$$V_2(1) = 4, \qquad V_2(2) = 6, \qquad V_2(k) = 2k + v_2(k!) + \frac{k}{2} \quad (k \geq 4).$$

For the original coefficients, the right side gains one bit.

Proof. For $k = 2^r \geq 4$, put $q = k/2$, which is even. Normalize the exact expansion (5.31) by 2^q before reducing modulo two. Its uth auxiliary term has excess $u + \lfloor (k-u)/2 \rfloor - q = \lfloor u/2 \rfloor$. Only auxiliary indices zero and one can therefore survive:

$$\frac{\gamma_k(H_2)}{2^q} \equiv V^q \gamma_k(X) + \epsilon V^{q-1} G \gamma_{k-1}(X) \pmod{2\mathcal{A}_2}. \tag{6.6}$$

Here $V \equiv \tau \pmod 2$ and $\tau^2 \equiv 1 \pmod 2$. Since q is even and $\epsilon\tau \equiv \epsilon \pmod 2$, this reduces to $\gamma_k(X) + \epsilon G \gamma_{k-1}(X)$. Moreover, $G \equiv \gamma_2(X) + \tau Q \pmod 2$. After evaluation, every term with a single τ vanishes, so the second contribution reduces to

$$\mathcal{L}\big((\gamma_2(X) + Q)\gamma_{k-1}(X)\big).$$

The $\gamma_2(X)$ product has scalar $\binom{k+1}{2}$, which is even because $4 \mid k$. The other contribution expands as

$$\mathcal{L}(Q\gamma_{k-1}(P+Q)) = \sum_{a=0}^{k-1} (k-a)\mu_a \mu_{k-a}. \tag{6.7}$$

An odd summand would require $k-a$ to be odd and μ_{k-a} to be odd. By Lemma 5.2, this requires $k-a = 1$. Then $a = k-1$ is not a power of two and μ_a is even. Hence the second contribution is zero modulo two.

For the first contribution, independence gives $\mathcal{L}(\gamma_k(P+Q)) = \sum_{a=0}^{k} \mu_a \mu_{k-a}$. The parity generating series of these convolution moments is

$$(1 + t + t^2 + t^4 + t^8 + \cdots)^2 = 1 + t^2 + t^4 + t^8 + \cdots \quad \text{in } \mathbb{F}_2[[t]].$$

Its coefficient is one at every $k = 2^r \geq 4$. Thus the normalized moment in (6.6) is odd and

$$v_2(\Delta_1^k C_2(0)) = 2k + v_2(k!) + k/2.$$

Inserting $U^{4n} = (1 + 4H_2)^n$ introduces only corrections with strictly higher valuation, by the filtered bound at orders $k + s$ for $s > 0$. The equality consequently holds at every starting row.

For mixed steps the all-one local multi-index gives the claimed leading term. A higher term of total order $M > k$ has excess at least

$$2(M-k) + \left\lfloor \frac{M}{2} \right\rfloor - \frac{k}{2} + v_2(M!) - v_2(k!) - \sum_{\nu} v_2(m_\nu) \geq M - k \geq 1.$$

Hence the leading term cannot cancel.

At order one, a_1 in (5.28) has valuation four and the Newton tail starts at valuation six. Its shifted value remains exact. In the step expansion a local order two can lose at most one bit through its binomial coefficient, so every correction is still above $4 + v_2(H_1)$. At order two, a_2 has valuation six and the next coefficient has lower bound eight from the stronger filtration. A total-order-three correction loses at most one bit, so it stays above the leading valuation six, while later orders gain still more. The same argument proves exactness for both mixed steps. □

Remark 6.4 (What the power orders do not decide). The exact orders in Theorem 6.3 form an infinite family. They do not supply a complete valuation formula at non-power-of-two orders in address two, nor an exact higher-difference formula at address three. Numerical patterns at other orders remain bounded observations unless proved separately.

7 Exact first differences, least periods, and dyadic images

The factorial estimates are stronger than needed for the optimal first-difference law. A general Newton criterion gives the exact law from the threshold-free bound and finitely many rational coefficients. This route also yields all addresses at ranks two and eight, and an infinite family at every larger dyadic rank.

Lemma 7.1 (A first-difference criterion). *Let $C : \mathbb{Z}_{\geq 0} \to \mathbb{Z}_2$ have Newton coefficients $a_k = \Delta_1^k C(0)$. Suppose for an integer $b \geq 0$ that*

$$v_2(a_1) = b, \qquad v_2(a_k) \geq b + 1 + \lfloor \log_2 k \rfloor \quad (k \geq 2). \tag{7.1}$$

Then for every $n \geq 0$ and $H > 0$,

$$v_2(C(n+H) - C(n)) = b + v_2(H). \tag{7.2}$$

The Newton interpolation extends continuously to $\mathbb{Z}_2$ and satisfies the same identity for any two distinct dyadic arguments.

Proof. At a natural argument the exact Newton expansion is finite. Vandermonde gives

$$\binom{n+H}{k} - \binom{n}{k} = \sum_{i=1}^{k} \binom{H}{i}\binom{n}{k-i}.$$

For $1 \leq i \leq H$, $v_2(\binom{H}{i}) \geq v_2(H) - v_2(i) \geq v_2(H) - \lfloor \log_2 k \rfloor$. Terms with $i > H$ vanish. Thus each Newton summand with $k \geq 2$ has valuation at least $b + v_2(H) + 1$. The $k = 1$ summand is Ha_1, of exact valuation $b + v_2(H)$, proving (7.2).

The coefficient hypothesis implies $a_k \to 0$ dyadically, so the Newton series converges uniformly on $\mathbb{Z}_2$, where $\binom{x}{k}$ is integral-valued. For distinct $x, y \in \mathbb{Z}_2$, approximate the pair by natural integer pairs with their difference valuation eventually equal to $v_2(x-y)$. The corresponding function differences have the fixed exact valuation $b + v_2(x-y)$. A limit of elements with that fixed valuation has the same valuation: the normalized residues are units, and $\mathbb{Z}_2^\times$ is closed. □

Theorem 7.2 (Exact four-address first differences). *For every $n \geq 0$, $H > 0$, and $j \in \{0,1,2,3\}$,*

$$v_2(C_j(n+H) - C_j(n)) = v_2(H) + b_j, \qquad (b_0, b_1, b_2, b_3) = (1,1,4,2), \tag{7.3}$$

$$v_2(E^{(4,j)}_{4(n+H)} - E^{(4,j)}_{4n}) = v_2(H) + B_j, \qquad (B_0, B_1, B_2, B_3) = (1,1,5,3). \tag{7.4}$$

Consequently, the least positive row period modulo 2^r is exactly

$$P_j(r) = 2^{\max(0, r - B_j)} \qquad (r \geq 1). \tag{7.5}$$

The corresponding displacement in the original Euler subscript is $4P_j(r)$.

Proof. The actual reciprocal recurrence is

$$C_{N,j}(n) = -\sum_{q=1}^{n} \binom{Nn}{Nq} g_{N,j}(q) C_{N,j}(n-q), \qquad C_{N,j}(0) = 1. \tag{7.6}$$

For $N = 4$, the four kernels are

$$1, \qquad \frac{1}{4q+1}, \qquad \frac{1}{(4q+1)(2q+1)}, \qquad \frac{3}{(4q+1)(2q+1)(4q+3)}.$$

The threshold-free theorem gives $v_2(a_k) \geq k$ in every address. The following exact values cover all orders where that bound does not already imply (7.1):

j	k	a_k	$v_2(a_k)$
0	1	-2	1
0	2	72	3
1	1	$-6/5$	1
1	2	$184/45$	3
2	1	$-16/15$	4
2	2	$64/45$	6
2	3	$-14848/1365$	9
2	4	$71426048/69615$	13
2	5	$-25509691392/85085$	16
2	6	$149113198870528/765765$	22
3	1	$-36/35$	2
3	2	$256/231$	8
3	3	$-65792/35035$	8
3	4	$161644544/4849845$	15

They are finite rational evaluations of (7.6), followed by $a_k = \sum_{h=0}^{k} (-1)^{k-h} \binom{k}{h} C_j(h)$. For addresses zero and one, $k \geq 3$ is covered by the generic bound. For address two, $k \geq 7$ is covered. For address three, $k \geq 5$ is covered. In each range the elementary inequality is $k - \lfloor \log_2 k \rfloor \geq b_j + 1$. Lemma 7.1 proves the normalized identity. Multiplication by $j!$ proves the original identity.

A row displacement H preserves the original coefficient modulo 2^r at even one row exactly when $v_2(H) + B_j \geq r$. The least positive such integer is $2^{\max(0, r - B_j)}$, and the same displacement works at every row. This proves both optimality and the absence of a starting threshold. □

Corollary 7.3 (Exact image and residue enumeration)**.** *Let $\widetilde{C}_j$ denote the dyadic Newton interpolation. The map*

$$T_j(x) = \frac{\widetilde{C}_j(x) - 1}{2^{b_j}}$$

is a bijective isometry $\mathbb{Z}_2 \to \mathbb{Z}_2$, and

$$\widetilde{C}_j(\mathbb{Z}_2) = 1 + 2^{b_j}\mathbb{Z}_2, \qquad j!\widetilde{C}_j(\mathbb{Z}_2) = j! + 2^{B_j}\mathbb{Z}_2. \tag{7.7}$$

For $r > B_j$, one least period modulo 2^r visits every residue in $j! + 2^{B_j}\mathbb{Z}/2^r\mathbb{Z}$ exactly once. For $r \leq B_j$, there is one residue and the least row period is one.

Proof. The exact difference identity gives $v_2(T_j(x) - T_j(y)) = v_2(x - y)$ and $T_j(0) = 0$. For every $s \geq 1$, the map induces an injection of $\mathbb{Z}_2/2^s\mathbb{Z}_2$ into itself. It is a bijection because both sets have 2^s elements. These quotient bijections are compatible with reduction. Inverting them gives a compatible preimage system for every dyadic integer, proving surjectivity. Multiplication by $j!$ changes the image ideal by exactly $v_2(j!)$. The finite quotient bijection is also precisely the residue enumeration in a least row period. □

7.1 An infinite exact family at all dyadic ranks

Theorem 7.4 (Lower-half exact laws). *Let $N = 2^a \geq 4$ and $0 \leq j < N/2$. Then for all $n \geq 0$ and $H > 0$,*

$$v_2(C_{N,j}(n + H) - C_{N,j}(n)) = 1 + v_2(H). \tag{7.8}$$

Its normalized interpolation is a bijection onto $1 + 2\mathbb{Z}_2$. For the original coefficients, the least row period modulo 2^r is $2^{\max(0,r-1-v_2(j!))}$.

Proof. Every slope N/i in the source has valuation at least two, since $i \leq j < N/2$. Hence $g(1) \equiv 1 \pmod 4$ and $g(2) \equiv 1 \pmod 8$. The first two Newton coefficients from the reciprocal recurrence are

$$a_1 = -g(1) - 1, \qquad a_2 = \binom{2N}{N} g(1)^2 - g(2) + 2g(1) + 1. \tag{7.9}$$

The first has valuation exactly one. Also $\binom{2N}{N} \equiv 6 \pmod 8$ for every $N = 2^a \geq 2$. To see this, write

$$B_a = \binom{2^{a+1}}{2^a} = 2 \prod_{h=1}^{2^a-1} \left(1 + \frac{2^a}{h}\right).$$

The even-h factors give B_{a-1}. The odd-h factors are one modulo four for $a \geq 2$. Since B_{a-1} has valuation one, $B_a \equiv B_{a-1} \pmod 8$, and $B_1 = 6$. Therefore $a_2 \equiv 6 - 1 + 2 + 1 = 0 \pmod 8$. The global Mahler bound covers all $k \geq 3$, completing the criterion with $b = 1$. The period and image deductions are the same as above. The proof also covers $N = 2, j = 0$, whose kernel is identically one. □

7.2 Complete exact laws at ranks two and eight

Proposition 7.5 (Small-rank complete isometry table). *Every address at $N \in \{2, 4, 8\}$ satisfies*

$$v_2(C_{N,j}(n + H) - C_{N,j}(n)) = b_{N,j} + v_2(H).$$

The following entries are ordered by $j = 0, \ldots, N - 1$:

N	*normalized shifts* $b_{N,j}$	*original shifts* $B_{N,j} = b_{N,j} + v_2(j!)$
2	1, 2	1, 2
4	1, 1, 4, 2	1, 1, 5, 3
8	1, 1, 1, 1, 4, 3, 2, 2	1, 1, 2, 2, 7, 6, 6, 6

For each entry, the least original row period is $2^{\max(0,r-B_{N,j})}$, its Euler subscript displacement is N times that period, and the exact-image and residue-enumeration conclusions hold with the corresponding shifts.

Proof. Rank four was proved above. At ranks two and eight the finite criterion is verified by the actual rational recurrence (7.6). The following valuation lists record every initial Newton coefficient needed in addition to the generic tail $v_2(a_k) \geq k$:

N	j	$b_{N,j}$	$v_2(a_1), v_2(a_2), \ldots$ through the finite cutoff
2	0	1	1, 3
2	1	2	2, 5, 9, 11
8	0	1	1, 3
8	1	1	1, 3
8	2	1	1, 3
8	3	1	1, 3
8	4	4	4, 6, 9, 13, 16, 20
8	5	3	3, 6, 10, 13, 17
8	6	2	2, 6, 8, 13
8	7	2	2, 11, 8, 15

The first entries can also be read directly from $a_1 = -1 - \binom{N+j}{j}^{-1}$. At rank eight they are respectively

$$-2,\ -\frac{10}{9},\ -\frac{46}{45},\ -\frac{166}{165},\ -\frac{496}{495},\ -\frac{1288}{1287},\ -\frac{3004}{3003},\ -\frac{6436}{6435}.$$

All later entries in the table are finite rational arithmetic, with full numerator and denominator records retained in the accompanying exact certificate `all_rank_extensions_verified.json`. Every entry with $k \geq 2$ meets $b_{N,j} + 1 + \lfloor \log_2 k \rfloor$. Beyond the displayed cutoff, the inequality $k \geq b_{N,j} + 1 + \lfloor \log_2 k \rfloor$ holds at every order. Thus the finite table and the proved infinite tail establish the full hypothesis of Lemma 7.1. This is a finite coefficient proof followed by a universal tail argument, rather than extrapolation from sampled rows or steps. □

Remark 7.6 (Failure of a universal upper-half exact law). The all-rank lower bound remains valid in every address. The exact first-difference law does not automatically extend to all upper-half addresses. Exact rational recurrence calculations give

(N, j)	$v_2(C(1) - C(0))$	$v_2(C(2) - C(0))$	naive $b + v_2(2)$
$(16, 9)$	5	7	6
$(32, 18)$	6	6	7
$(32, 19)$	5	7	6

For example, at $(N, j) = (16, 9)$ the first difference is $-2042976/2042975$, whereas the two-row difference is $-2215603929728/2215923048625$. These exact counterexamples refute the additional universal isometry proposal. They preserve the threshold-free lower bound and the original conjecture.

8 Analytic interpolation and exact Taylor radii

The threshold-free Mahler theorem gives continuous interpolation. Analytic interpolation needs a stronger estimate, and the factorial bounds provide it directly. The ordinary Taylor radius is determined by the coefficient growth, including infinite exact subsequences.

Theorem 8.1 (Taylor coefficient bounds and radii). *For $j = 0, 1, 2, 3$, the dyadic interpolation has an ordinary power series*

$$\widetilde{C}_j(x) = 1 + \sum_{\ell \geq 1} d_{j,\ell} x^\ell, \qquad v_2(d_{j,\ell}) \geq \ell + \beta_j.$$

Its Taylor series converges for $|x|_2 < 2$. At addresses zero and one,

$$v_2(d_{j,\ell}) = \ell \quad (\ell \geq 1), \qquad R_0 = R_1 = 2. \tag{8.1}$$

At address two,

$$v_2(d_{2,\ell}) \geq \max\left(2\ell + \left\lfloor \frac{\ell}{2} \right\rfloor, \ell + 3\right), \qquad R_2 = 2^{5/2}. \tag{8.2}$$

The radius at address three is at least two. Its exact radius is not asserted here. The stated exact radii at addresses zero, one, and two hold at every center in $\mathbb{Z}_2$.

Proof. Put $a_m = \Delta_1^m C_j(0)$ and expand the falling factorial in the Newton series. The ordinary coefficients are

$$d_{j,\ell} = \sum_{m \geq \ell} \frac{a_m}{m!} s(m, \ell). \tag{8.3}$$

Since $s(m, \ell)$ is integral and $v_2(a_m/m!) \geq m + \beta_j$, the coefficient sum converges and has valuation at least $\ell + \beta_j$. The sum exchange is justified on $\mathbb{Z}_2$ by these uniform geometric coefficient bounds. The ordinary power series agrees there with the Newton interpolation and converges whenever $|x|_2 < 2$.

For $j = 0, 1$, the term $m = \ell$ in (8.3) has exact valuation ℓ, since $s(\ell, \ell) = 1$ and the Newton valuation is exact. Every later term has valuation at least $\ell + 1$. Thus $v_2(d_{j,\ell}) = \ell$, and the coefficient radius is exactly two. At a center $x_0 \in \mathbb{Z}_2$, the coefficient of y^ℓ in the translated series is

$$\sum_{m \geq \ell} d_{j,m} \binom{m}{\ell} x_0^{m-\ell}. \tag{8.4}$$

Its initial term again has exact valuation ℓ, and all later terms have at least one more bit. The exact radius is therefore two at every integral center.

For address two, the stronger factorial filtration gives the lower bound in (8.2). At each $\ell = 2^r \geq 4$, Theorem 6.3 makes the $m = \ell$ term in (8.3) have valuation $2\ell + \ell/2 = 5\ell/2$. Every $m > \ell$ term has strictly greater lower bound $2m + \lfloor m/2 \rfloor$. Hence

$$v_2(d_{2,\ell}) = 5\ell/2 \qquad (\ell = 2^r \geq 4).$$

The universal lower bound and this unbounded exact subsequence prove that the coefficient radius is exactly $2^{5/2}$. Translation by an integral center preserves the same unique leading coefficients at these degrees in (8.4), proving the exact radius at every such center. □

Remark 8.2 (Boundary interpretation). For addresses zero and one, at an argument of absolute value two every positive-degree Taylor term has valuation zero, so that ordinary Taylor series diverges. For address two, over a complete extension admitting arguments of absolute value $2^{5/2}$, the power-of-two-degree terms have valuation zero and fail to tend to zero. These statements concern the Taylor expansions just constructed. They do not prohibit a different analytic continuation. On $\mathbb{Q}_2$-valued arguments, open-disc notation must be read with its discrete value group. The coefficient radius is the precise invariant in the theorem.

9 The final congruence in the original Euler convention

The preceding bounds can be stated as one uniform congruence without suppressing the address normalization. This is the strengthened formula for the four-address family, valid from the first row.

Corollary 9.1 (Final common-step congruence). *Let $j \in \{0,1,2,3\}$, $n \geq 0$, and $k, H \geq 1$. Define*

$$A_0(k) = A_1(k) = k, \qquad A_2(k) = \max\left(k+4,\ 2k+\left\lfloor \frac{k}{2} \right\rfloor + 1\right), \qquad A_3(k) = k+2.$$

Then

$$\boxed{\sum_{i=0}^{k} (-1)^{k-i} \binom{k}{i} E^{(4,j)}_{4(n+iH)} \equiv 0 \pmod{2^{\,v_2(k!)+kv_2(H)+A_j(k)}}.} \tag{9.1}$$

For $j = 0, 1$, this displayed exponent is the exact valuation for every n, k, H in the stated range. For $j = 2$, the exact positive power-of-two-order valuations are given by Theorem 6.3, with one added bit.

Proof. The left side is $j!\Delta_H^k C_j(n)$. At addresses zero and one, $v_2(j!) = 0$ and the exact homogeneous formula gives the exponent. At address two, $v_2(2!) = 1$. The maximum of (5.1) and (5.2) yields $\max(k+4, 2k+\lfloor k/2 \rfloor + 1)$ after removing the common $v_2(k!) + kv_2(H)$. At address three, the one-bit normalized offset and $v_2(3!) = 1$ give $k+2$. □

For mixed steps the same corollary holds with $kv_2(H)$ replaced by $\sum_\nu v_2(H_\nu)$ and the binomial stencil replaced by $j!\Delta_{H_1} \cdots \Delta_{H_k} C_j(n)$. At addresses zero and one, exactness is then governed by the parity classification in Theorem 6.1. At first order these bounds are exact in every address, with original valuation offsets $(1, 1, 5, 3)$. The least periods are those in (7.5).

9.1 Proof coverage and remaining questions

These sections give detailed mathematical proofs. Formal coverage is statement-specific. The Lean sources include the rank-four homogeneous bound at every row, the sharp first-difference laws, least periods, and dyadic isometry and image conclusions.

The all-rank dyadic and general prime-power transfer arguments, factorial improvements, mixed leading-parity classification, Bernoulli power-order sharpness, all-rank lower-half exact laws, rank-eight extension, and exact Taylor-radius arguments have written proofs but no dedicated Lean formalization. Mathematical review and exact computation do not extend their formal coverage.

The completed external statement is Nishibuchi's Conjecture 3.9 in its prescribed parameter family and coefficient normalization. These stronger congruences enlarge its dyadic branch and remove its starting threshold there. They do not settle every Euler problem. In particular, the following questions remain separate:

- a complete exact higher-difference law at all non-power-of-two orders in address two;
- complete higher-difference valuations and the exact ordinary Taylor radius in address three;

- a classification of the upper-half dyadic addresses having an exact first-difference metric law at arbitrary larger ranks;
- the distinct universal simplicity or nonvanishing question for the later Euler-tail residuals, and the original native Paper IX conjectures beyond the completed external statement.

The exact counterexamples above rule out the naive universal upper-half isometry, and mixed cancellations rule out unconditional baseline sharpness for arbitrary stencils. No global historical-priority or novelty assertion is made for these strengthened statements.

10 Finite obstructions, compatible lifts, and deformation

The arithmetic results above concern particular families. We now study the underlying correction problem, from finite polynomial lifts to continuous parameter charts and quantitative deformation. Throughout, we distinguish three objects: a residual obstruction, the set of correcting digits, and a root in a completion. A vanishing obstruction at one precision gives a lift to the next. Continuing indefinitely requires additional hypotheses.

Unless a different coefficient ring is specified, a polynomial system is a finite list of integer polynomials. All divisibility conditions on vectors are coordinatewise. For a positive integer q, write $S_q = \mathbb{Z}/q\mathbb{Z}$ and use an overline for reduction modulo q. For a prime p, write $\mathbb{F}_p = S_p$, normalize $|p|_p = p^{-1}$, and put

$$B_L(x) = x + p^L\mathbb{Z}_p^d.$$

An integer center is included in this notation by its natural image in $\mathbb{Z}_p^d$. All dimensions below are finite and may be zero. A statement over S_q allows composite q and $q = 1$ when explicitly stated. A cardinality formula in terms of vector-space rank uses prime p.

10.1 The polynomial correction equation

For $F = (F_1, \dots, F_e) \in \mathbb{Z}[X_1, \dots, X_d]^e$, define its evaluated Jacobian by the formal partial derivatives:

$$DF(x)_{ij} = (\partial_j F_i)(x), \qquad J_x = DF(x) \bmod q : S_q^d \longrightarrow S_q^e.$$

The obstruction therefore uses the Jacobian of the given polynomials. The following algebraic Taylor identity relates this linear map to polynomial evaluation.

Lemma 10.1 (Polynomial Taylor remainder)**.** *Let R be a commutative ring, $P \in R[X_1, \dots, X_d]$, $a \in R^d$, and $c \in R$. There is a polynomial $Q \in R[U_1, \dots, U_d]$, with $Q(0) = 0$, such that for every $u \in R^d$,*

$$P(a + cu) = P(a) + c\sum_{j=1}^{d}(\partial_j P)(a)u_j + c^2 Q(u). \tag{10.1}$$

In particular, when $R = \mathbb{Z}$ and a, u, c are integral, subtracting the first two terms on the right from $P(a + cu)$ gives a multiple of c^2.

Proof. Apply polynomial induction using constants, addition, and multiplication by a variable. Constants have zero remainder, and remainders add. For the multiplication step, suppose the assertion is known for P and write $D_P(U) = \sum_j(\partial_j P)(a)U_j$. Multiplication of its expansion by $a_i + cU_i$ gives constant term $P(a)a_i$, linear term $c(a_i D_P(U) + P(a)U_i)$, and remainder

$$c^2\big(Q(U)(a_i + cU_i) + D_P(U)U_i\big).$$

The product rule identifies the linear term with the derivative of PX_i. The displayed remainder vanishes at $U = 0$. This constructs the polynomial remainder before evaluation at u, even over rings where division by c would be invalid. □

The general polynomial identity is formalized by `Komorebi.PolynomialTaylorRing.exists_eval_scaled_remainder`. Its integer divisibility form is `Komorebi.PolynomialTaylor.taylor_dvd`.

Theorem 10.2 (Finite polynomial obstruction)**.** *Let $q \geq 1$, $L \geq 1$, $x \in \mathbb{Z}^d$, and suppose $F(x) \in q^L\mathbb{Z}^e$. Define the exact integer residual r_x by $F(x) = q^L r_x$, and put*

$$\mathcal{O}_x = S_q^e / \operatorname{im} J_x, \qquad o_x = [\overline{r_x}].$$

Then $\mathcal{O}_x$ is finite and

$$o_x = 0 \quad \Longleftrightarrow \quad \exists y \in \mathbb{Z}^d : \quad y \equiv x \pmod{q^L}, \qquad F(y) \equiv 0 \pmod{q^{L+1}}. \tag{10.2}$$

No surjectivity or nonsingularity assumption is required.

Proof. Every point in the lower residue class has the form $y = x + q^L t$ with $t \in \mathbb{Z}^d$. By Lemma 10.1 and $2L \geq L + 1$,

$$F(x + q^L t) \equiv q^L \big(r_x + DF(x)t\big) \pmod{q^{L+1}}.$$

The integer q^L is nonzero. Cancelling it in the corresponding divisibility condition proves

$$F(x + q^L t) \equiv 0 \pmod{q^{L+1}} \quad \Longleftrightarrow \quad \overline{r_x} + J_x \bar{t} = 0. \tag{10.3}$$

Integer vectors reduce onto S_q^d. The equation on the right is solvable exactly when $\overline{r_x}$ belongs to $\operatorname{im} J_x$, since that image is closed under negation. This is precisely $o_x = 0$. Finiteness follows because $\mathcal{O}_x$ is a quotient of the finite module S_q^e. □

The formal theorem `Komorebi.PolynomialObstruction.finite_polynomial_obstruction` presents the image using the integer-domain map $\mathbb{Z}^d \xrightarrow{DF(x)} \mathbb{Z}^e \to S_q^e$. Reduction onto S_q^d identifies that image with $\operatorname{im} J_x$. The class-preserving comparison is explicit in `Komorebi.PolynomialLiftCounts.obstructionEquiv`. The change of presentation does not change the distinguished residual class.

Proposition 10.3 (Affine depth zero)**.** *Let $F(x) = Ax - b$ for an integer linear map $A : \mathbb{Z}^d \to \mathbb{Z}^e$. The criterion of Theorem 10.2 holds for every $L \geq 0$, with $J = A \bmod q$.*

Proof. The affine identity $F(x + q^L t) = F(x) + q^L A t$ has no quadratic remainder. The proof of (10.3) therefore needs no inequality involving $2L$. The residual and the finite quotient are obtained as above. □

The affine statement is formalized by `Komorebi.NativeAffine.finite_affine_obstruction`. Positive depth is essential in the nonlinear theorem: for $F(X) = X^2 - 1$, $q = 2$, $L = 0$, and $x = 0$, the Jacobian is zero and the residual class is nonzero, yet $y = 1$ is a root modulo two in the same residue modulo one.

Proposition 10.4 (Independence of the integer representative)**.** *Under the hypotheses of Theorem 10.2, let $x' = x + q^L s$ and write $F(x') = q^L r_{x'}$. Then*

$$J_{x'} = J_x, \qquad \overline{r_{x'}} = \overline{r_x} + J_x \bar{s}.$$

Consequently the two residual classes coincide in the common quotient $S_q^e / \operatorname{im} J_x$.

Proof. Polynomial evaluation respects coordinatewise congruence. Apply this first to every formal partial derivative: $x' \equiv x \pmod{q}$ gives $J_{x'} = J_x$. Next apply (10.1) to F at scale q^L. Subtract the two exact residual identities and cancel q^L to obtain the displayed relation modulo q. Its additional term belongs to the common Jacobian image, so it vanishes in the quotient. □

This comparison is formalized by `Komorebi.PolynomialRepresentative.representative_independence`. This proves independence of the integer representative within a fixed polynomial presentation. It makes no identification of the raw cokernels of different equation lists. For example, adjoining a zero equation leaves the roots unchanged while adding an S_q summand to the raw cokernel.

10.2 One correction shared by two systems

The next obstruction concerns compatibility between individually attainable corrections. Its algebraic form works over an arbitrary commutative ring. Let U, V, W be R-modules and let $J : U \to V$, $K : U \to W$ be linear. Define

$$C(J,K) = U/(\ker J + \ker K). \tag{10.4}$$

An attainable value Ju has label $[u] \in C(J,K)$. This is independent of the choice of its preimage because $\ker J$ is killed in the quotient. Similarly, Kv has label $[v]$. Denote these maps by $\lambda_J : \operatorname{im} J \to C(J,K)$ and $\lambda_K : \operatorname{im} K \to C(J,K)$.

Theorem 10.5 (Common correction and fiber product)**.** *For every $u, v \in U$,*

$$[u] = [v] \text{ in } C(J,K) \quad \Longleftrightarrow \quad \exists w \in U :\ Jw = Ju, \quad Kw = Kv. \tag{10.5}$$

Both label maps are surjective, and the image of the joint map is exactly the fiber product:

$$\operatorname{im}\big(U \to \operatorname{im} J \times \operatorname{im} K,\ u \mapsto (Ju, Ku)\big) = \operatorname{im} J \times_{C(J,K)} \operatorname{im} K. \tag{10.6}$$

If either V or W is finite, then $C(J,K)$ is finite.

Proof. If $[u] = [v]$, write $u - v = s + t$ with $s \in \ker J$ and $t \in \ker K$. Then $w = u - s = v + t$ satisfies both required equalities. Conversely, a common w gives

$$u - v = (u - w) + (w - v) \in \ker J + \ker K.$$

Every class $[u]$ is the label of Ju and of Ku, proving surjectivity. For attainable $a = Ju$ and $b = Kv$, the first equivalence says exactly that equal labels are equivalent to a simultaneous preimage. This proves (10.6). Finally, a finite target has finite image, and the associated surjective label map makes $C(J,K)$ finite. □

These statements are `Komorebi.SharedCorrection.quotient_mk_eq_iff_common` and `Komorebi.SharedCorrection.joint_range_eq_fiber`, together with the finite-target corollaries in the same module. The quotient also has the expected universal property: every linear map from U annihilating both kernels factors uniquely through $C(J,K)$. Equivalently, compatible linear observations on $\operatorname{im} J$ and $\operatorname{im} K$ factor uniquely through their label maps. This is formalized by `Komorebi.SharedCorrection.common_paired_universal`.

Corollary 10.6 (Simultaneous polynomial lifting)**.** *Let $F \in \mathbb{Z}[X_1, \dots, X_d]^e$ and $G \in \mathbb{Z}[X_1, \dots, X_d]^f$ have a common lower root x modulo q^L, where $q \geq 1$ and $L \geq 1$. Use the integer-domain reduced Jacobians $J : \mathbb{Z}^d \to S_q^e$ and $K : \mathbb{Z}^d \to S_q^f$. Suppose $u, v \in \mathbb{Z}^d$ are separately valid corrections for F and G, respectively. Then*

$$[u] = [v] \text{ in } \mathbb{Z}^d/(\ker J + \ker K)$$

if and only if a single $y \equiv x \pmod{q^L}$ solves both systems modulo q^{L+1}. Each separate label is independent of the chosen valid correction. The common quotient is finite.

Proof. For each system, (10.3) translates a valid next root into a linear correction equation. Once u corrects F, another digit w corrects F precisely when $Jw = Ju$. The analogous condition for G is $Kw = Kv$. Theorem 10.5 now gives the criterion. Two valid corrections of one block differ by a vector in its Jacobian kernel, so they have equal labels. Finiteness follows from either finite residue target. An unconditional formulation quantifies over separately valid u, v with equal labels, thereby including their existence in the criterion rather than assuming it. □

See `Komorebi.PolynomialShared.joint_lift_iff_class_eq` and `Komorebi.PolynomialShared.finite_polynomial_pair_compatibility`.

For affine integer systems $F(X) = AX - b$ and $G(X) = BX - c$, where $A : \mathbb{Z}^d \to \mathbb{Z}^e$ and $B : \mathbb{Z}^d \to \mathbb{Z}^f$ are linear, Corollary 10.6 holds for $q \geq 1$ and every $L \geq 0$, including depth zero. Here x is a common root modulo q^L, and J and K are the reductions of A and B with domain $\mathbb{Z}^d$. Given separately valid corrections u, v, a simultaneous next lift exists if and only if their classes in $\mathbb{Z}^d/(\ker J + \ker K)$ agree. The quotient is finite, and each label is independent of the chosen valid correction. Indeed, Proposition 10.3 supplies the correction equation without a positive-depth restriction, and the proof of Theorem 10.5 then applies unchanged. The formal statement is `Komorebi.AffinePair.joint_lift_iff_class_eq`. Quantifying over separately valid corrections with equal labels also includes their existence in the criterion, as in `Komorebi.AffinePair.finite_affine_pair_compatibility`. Separate liftability alone is insufficient. At $x = 0$ modulo two, $F(X) = X$ and $G(X) = X - 2$ both lift to modulus four, but their correcting digits are respectively 0 and 1 modulo two. No single residue solves both equations modulo four.

10.3 Correction torsors and exact residue counts

Integer representatives and residue classes at the next level must also be distinguished. For $q \geq 1$ and $L \geq 0$, the map

$$S_q^d \longrightarrow \{y \in (\mathbb{Z}/q^{L+1}\mathbb{Z})^d : y \equiv x \pmod{q^L}\}, \qquad t \longmapsto x + q^L\widetilde{t}$$

is a bijection, where $\widetilde{t}$ is any integer representative. Independence of the representative and injectivity both follow by cancelling q^L in integer divisibility. Surjectivity follows by expressing the lower congruence as a multiple of q^L. This is the equivalence `Komorebi.ResidueLiftDigits.digitEquivResidue`.

At positive polynomial depth, restrict it to the correction fiber

$$\mathcal{T}_x = \{t \in S_q^d : \overline{r_x} + J_x t = 0\}$$

and the lift set

$$\mathcal{L}_{x,L} = \{y \in (\mathbb{Z}/q^{L+1}\mathbb{Z})^d : y \equiv x \pmod{q^L},\ F(y) = 0\}.$$

The polynomial predicate in the second display is evaluation in the residue ring. Evaluation on canonical integer representatives gives the same predicate, because integer polynomial evaluation respects congruence.

Theorem 10.7 (Torsor and lift cardinalities)**.** *Under the hypotheses of Theorem 10.2, there is an equivalence $\mathcal{T}_x \simeq \mathcal{L}_{x,L}$. Every nonempty fiber is a torsor for* $\ker J_x$ *under addition of correction digits. If $q = p$ is prime and $\rho_x = \operatorname{rank}_{\mathbb{F}_p} J_x$, then*

$$\#\mathcal{L}_{x,L} = \begin{cases} p^{d-\rho_x}, & o_x = 0, \\ 0, & o_x \neq 0, \end{cases} \qquad \#\mathcal{O}_x = p^{e-\rho_x}. \tag{10.7}$$

Proof. Equation (10.3) identifies exactly which points of the residue fiber satisfy the equations, proving the restricted equivalence. If $u, t \in \mathcal{T}_x$, subtraction gives $J_x(t-u) = 0$. Conversely, adding any element of $\ker J_x$ preserves the correction equation. The unique kernel vector carrying u to t is $t-u$, so the action is free and transitive. Choosing one valid digit identifies the fiber with the kernel, without making that choice part of its translation action.

For prime p, rank-nullity gives $\dim \ker J_x = d - \rho_x$ and $\dim(\mathbb{F}_p^e / \operatorname{im} J_x) = e - \rho_x$. The cardinality of an n-dimensional $\mathbb{F}_p$-space is p^n. Combine these identities with the obstruction criterion and the residue equivalence. □

The cardinality formula is formalized by `Komorebi.PolynomialLiftCounts.finite_polynomial_lift_count`. The explicit torsor and chosen-point equivalence are developed in `Komorebi.FiniteFiberCounts.translate_exists_unique` and `Komorebi.PolynomialLiftCounts.liftEquivKernel`. For composite q, the torsor and kernel cardinality remain valid, while the vector-space rank formula is unavailable. Multiplication by two on $\mathbb{Z}/4\mathbb{Z}$ already has a kernel of size two.

10.4 Smooth compatible towers and exact roots

Surjectivity removes every residual obstruction and persists throughout a positive-depth residue ball. This supplies the additional hypothesis needed to iterate the finite theorem.

Theorem 10.8 (Compatible polynomial tower)**.** *Let $q \geq 1$, $L \geq 1$, $F \in \mathbb{Z}[X_1, \ldots, X_d]^e$, and $x \in \mathbb{Z}^d$ satisfy $F(x) \in q^L\mathbb{Z}^e$. Suppose $J_x : S_q^d \to S_q^e$ is surjective. There is a single sequence $z_n \in \mathbb{Z}^d$ such that*

$$z_0 = x, \qquad F(z_n) \in q^{L+n}\mathbb{Z}^e,$$
$$z_{n+1} - z_n \in q^{L+n}\mathbb{Z}^d, \qquad J_{z_n} = J_x.$$

For $a \leq b$, it also satisfies $z_b - z_a \in q^{L+a}\mathbb{Z}^d$.

Proof. At level $N = L + n$, divide the residual by q^N. Surjectivity supplies $t \in S_q^d$ with $J_{z_n} t = -\overline{F(z_n)/q^N}$. Choose an integer representative and apply (10.3) to obtain z_{n+1}. The new point is congruent to z_n modulo q. Evaluation of each formal partial derivative therefore gives $J_{z_{n+1}} = J_{z_n}$.

Construct the sequence recursively, retaining the root condition and the fixed Jacobian at each step. Surjectivity at every later stage then follows from the single initial assumption. The cross-level congruence follows by induction, adding consecutive differences whose divisibilities all imply divisibility by q^{L+a}. □

The full tower statement is `Komorebi.PolynomialIntegerTower.exists_compatible_tower_strong`. The proof constructs a compatible path using classical choice. It does not claim an optimized procedure for selecting its digits.

Theorem 10.9 (Completion and smooth branching)**.** *In Theorem 10.8, let $q = p$ be prime. The tower can be chosen with a limit $a \in \mathbb{Z}_p^d$ such that*

$$F(a) = 0, \qquad z_n \longrightarrow a, \qquad a - z_n \in p^{L+n}\mathbb{Z}_p^d \quad (n \geq 0).$$

At each stage, the number of distinct next-level residue roots over z_n is exactly p^{d-e}, and the finite obstruction module has one element. If $d = e$, there is exactly one root of F in $B_L(x)$.

Proof. Cross-level compatibility bounds the supremum distance between later terms by $p^{-(L+n)}$. Completeness gives a limit, and closed norm bounds retain the congruence to every z_n. View the coefficients of the original integer polynomials in $\mathbb{Z}_p$. Their evaluations satisfy both $F_i(z_n) \to F_i(a)$, by continuity, and $F_i(z_n) \to 0$, by their growing divisibility. Uniqueness of limits gives exact vanishing.

Surjectivity gives rank $J_x = e \leq d$. Theorem 10.7 then gives p^{d-e} next residue roots and obstruction cardinality one at every stage.

For square uniqueness, let $a, b \in B_L(x)$ be arbitrary exact roots. Their canonical integer truncations are genuine roots in the respective finite residue rings, since evaluation commutes with reduction. They agree at depth L. If they agree at depth $N \geq L$, both next residues belong to the same lift set, which has cardinality $p^{d-d} = 1$. Induction gives agreement at every depth. The residue maps separate p-adic integers, so $a = b$. Existence was already supplied by the tower. □

The endpoint construction is `Komorebi.PolynomialPadicLift.exists_padic_root_with_tower`, the branching statement is `Komorebi.PolynomialSmoothCounts.exists_regular_tower`, and uniqueness for all roots in the ball is `Komorebi.PolynomialPadicUnique.exists_unique_padic_root`.

Remark 10.10. The one-step singular criterion and the smooth infinite theorem have different hypotheses. The polynomial $X^2 - 5$ has odd roots modulo two and four but has no root modulo eight. Thus a previous zero obstruction does not force the next one to vanish. Also, rectangular surjectivity alone does not imply uniqueness: $F(X, Y) = X$ has the distinct dyadic roots $(0, 0)$ and $(0, 2)$ in the same residue ball modulo two. These examples show why the hypotheses of the tower theorem and its uniqueness clause are needed.

10.5 Coefficient stability and continuous root charts

Proposition 10.11 (Smooth coefficient stability)**.** *Let p be prime, $M \geq 1$, $F, H \in \mathbb{Z}[X_1, \ldots, X_d]^e$, and $c \in p^M\mathbb{Z}$. Suppose $DF(x) \bmod p$ is surjective for an integer $x \in \mathbb{Z}^d$. If $a \in \mathbb{Z}_p^d$ satisfies $F(a) = 0$ and $a \equiv x \pmod p$, then there is a root b of $G = F + cH$ with $b - a \in p^M\mathbb{Z}_p^d$.*

If $d = e$ and $M \geq L \geq 1$, every pair of roots $a, b \in B_L(x)$ of F and G, respectively, satisfies $b - a \in p^M\mathbb{Z}_p^d$. The perturbed root is unique in that ball whenever it exists.

Proof. Since $p \mid c$, differentiation gives $DG(x) \equiv DF(x) \pmod p$. Truncate a to an integer vector y at depth M. Then $F(y) \equiv 0 \pmod{p^M}$, hence also $G(y) \equiv 0 \pmod{p^M}$. Congruence of y and x modulo p preserves the reduced Jacobian. The smooth root theorem gives $b \equiv y \equiv a \pmod{p^M}$.

In the square case this constructed root lies in $B_L(x)$ because $M \geq L$. Square uniqueness for G identifies it with every competing root in that ball. The construction therefore gives the precision assertion for an arbitrary root there. □

See `Komorebi.PolynomialRootStability.exists_nearby_perturbed_root` and `Komorebi.PolynomialRootStability.perturbed_roots_congruent`. The scalar c may be negative or zero. The weighted theorems below allow arbitrary integral p-adic coefficients and give an explicit first-order displacement.

Theorem 10.12 (Continuous charts with a selected Jacobian minor)**.** *Let p be prime, $L \geq 1$, $F \in \mathbb{Z}[X_1, \ldots, X_{e+k}]^e$, and $x \in \mathbb{Z}^{e+k}$ satisfy $F(x) \in p^L\mathbb{Z}^e$. Suppose the full reduced Jacobian is surjective. There is a permutation σ of the coordinates such that, writing $\sigma x = (y_0, t_0)$ with e solved coordinates and k parameter coordinates, the parameter ball $T = t_0 + p^L\mathbb{Z}_p^k$ is homeomorphic to the entire root locus*

$$\mathcal{R} = \{z \in B_L(x) : F(z) = 0\}.$$

The inverse homeomorphism is the actual free-coordinate projection $z \mapsto \mathrm{free}(\sigma z)$. If $h : T \to \mathcal{R}$ is the forward map, then for every $N \geq 0$,

$$h(t) \equiv h(u) \pmod{p^N} \quad \Longleftrightarrow \quad t \equiv u \pmod{p^N}. \tag{10.8}$$

Equivalently, $\sigma h(t) = (\phi(t), t)$ for a continuous $\phi : T \to y_0 + p^L \mathbb{Z}_p^e$ whose graph is the entire reordered root locus.

Proof. First consider a square integer polynomial map P whose reduced Jacobian at x is surjective. Its Jacobian is invertible over $\mathbb{F}_p$. A digit comparison using Taylor expansion shows that equal outputs modulo p^{N+1} force equal inputs modulo p^{N+1} whenever the inputs already agree modulo p^N and belong to $B_1(x)$. Induction and integer truncation give, for arbitrary $a, b \in B_1(x)$,

$$P(a) \equiv P(b) \pmod{p^N} \quad \Longleftrightarrow \quad a \equiv b \pmod{p^N}.$$

More generally, for a rectangular map with surjective reduced Jacobian,

$$P(B_L(x)) = P(x) + p^L \mathbb{Z}_p^e. \tag{10.9}$$

One inclusion follows from polynomial congruence. For integer targets in the right-hand ball, subtract the target from the constant terms and use the smooth root theorem. For arbitrary p-adic targets, approximate by integer truncations. The input ball is compact, so its continuous image is closed. It contains all these approximants and hence their limit. This argument does not assume that independently chosen preimages form a compatible sequence.

For square P, the resulting bijection between the two compact residue balls is continuous, and its target is Hausdorff. It is therefore a homeomorphism, with the same congruence preservation for its inverse.

Now suppose a chosen set of e columns of $DF(x) \bmod p$ is independent, and put those coordinates first. Apply the square result to the augmented polynomial map

$$\Psi(Y, T) = (F(Y, T), T).$$

Its reduced Jacobian has upper blocks $(D_Y F, D_T F)$ and lower blocks $(0, I_k)$, so it is invertible. For $t \in T$, the target $(0, t)$ belongs to $\Psi(x) + p^L \mathbb{Z}_p^{e+k}$ because $F(x) \equiv 0 \pmod{p^L}$. The inverse of Ψ at that target gives the unique root with parameters t. The inverse congruence property gives one direction of (10.8). Projection onto the parameter coordinates gives the other.

Finally, surjectivity of the original rectangular Jacobian guarantees a basis among its columns. Extend the corresponding injection of coordinate indices to a permutation σ. Renaming the variables by σ^{-1} transports polynomial evaluation and every formal partial derivative. The fixed-coordinate construction therefore applies to the original system after undoing the permutation. □

The main theorem is `Komorebi.PolynomialGeneralChart.exists_parameter_homeomorph`. The square local inverse and surjectivity for arbitrary targets are `Komorebi.PolynomialLocalInverse.localHomeomorph` and `Komorebi.PolynomialLocalSurjective.exists_padic_preimage`. The center x is only an approximate root: the chart need not satisfy $\phi(t_0) = y_0$ unless $F(x) = 0$ exactly. The assertion selects suitable coordinates. It does not permit an arbitrary prescribed solved block.

10.6 Prescribed parameters and their obstruction

Suppose now that the split into solved variables and parameter variables is fixed in advance. Let

$$F \in \mathbb{Z}[Y_1, \dots, Y_m, T_1, \dots, T_k]^e, \qquad x = (y_0, t_0),$$

and assume $F(x) = q^L r_x$ with $q \geq 1$ and $L \geq 1$. Write the reduced Jacobian as

$$DF(x) \bmod q = (J_x \; K_x), \qquad J_x : S_q^m \to S_q^e, \quad K_x : S_q^k \to S_q^e.$$

For a prescribed parameter digit $v \in S_q^k$, let $\mathcal{L}_{x,L,v}$ be the set of next residue roots over x whose parameter coordinates are $t_0 + q^L \widetilde{v}$ modulo q^{L+1}.

Theorem 10.13 (Prescribed-parameter obstruction and count)**.** *Define*

$$o_x(v) = [\overline{r_x} + K_x v] \in S_q^e / \operatorname{im} J_x.$$

Then $\mathcal{L}_{x,L,v}$ is nonempty if and only if $o_x(v) = 0$. When nonempty, it is a torsor for $\ker J_x$*. If $q = p$ is prime and $\rho_x = \operatorname{rank}_{\mathbb{F}_p} J_x$, then*

$$\#\mathcal{L}_{x,L,v} = \begin{cases} p^{m-\rho_x}, & o_x(v) = 0, \\ 0, & o_x(v) \neq 0, \end{cases} \qquad \#(\mathbb{F}_p^e / \operatorname{im} J_x) = p^{e-\rho_x}. \tag{10.10}$$

The criterion holds uniformly for every prescribed v without a surjectivity hypothesis.

Proof. A candidate for the next lift has the form $x + q^L(\widetilde{u}, \widetilde{v})$, with solved digit $u \in S_q^m$. Its Taylor correction equation is

$$\overline{r_x} + J_x u + K_x v = 0.$$

Solvability is exactly vanishing of the displayed cokernel class. Restrict the residue-digit equivalence to the prescribed parameter coordinates. This identifies the lift fiber with the solved-digit fiber. Translation by $\ker J_x$ is free and transitive on any nonempty such fiber. The prime-field count follows from rank-nullity as before. □

The formal statements start from the lower root and construct its residual: `Komorebi.PolynomialPrescribedObstruction.finite_prescribed_obstruction` and `Komorebi.PolynomialPrescribedObstruction.finite_prescribed_lift_count`. For $F(Y, T) = T$ at the dyadic origin, the full Jacobian $(0\ 1)$ is surjective but $J_x = 0$. Prescribing $v = 1$ forces $T = 2 \pmod 4$, so no root exists. Prescribing $v = 0$ gives two choices of Y modulo four over the initial zero residue. This example explains why the criterion depends on the solved block, rather than merely on the full Jacobian.

Theorem 10.14 (Every compatible integer parameter path)**.** *In the preceding notation, assume J_x is surjective. For every supplied integer path $t_n \in \mathbb{Z}^k$ satisfying*

$$t_0 = \operatorname{free}(x), \qquad t_{n+1} - t_n \in q^{L+n}\mathbb{Z}^k,$$

there is a compatible polynomial tower $z_n \in \mathbb{Z}^{m+k}$ with

$$z_0 = x, \quad \operatorname{free}(z_n) = t_n, \quad F(z_n) \in q^{L+n}\mathbb{Z}^e, \quad z_{n+1} - z_n \in q^{L+n}\mathbb{Z}^{m+k}.$$

The free-coordinate equality is exact in integers. Both reduced Jacobian blocks remain fixed, and $z_b - z_a \in q^{L+a}\mathbb{Z}^{m+k}$ *whenever* $a \le b$.

Proof. At level $N = L + n$, write the supplied parameter increment exactly as $t_{n+1} - t_n = q^N w$ with $w \in \mathbb{Z}^k$. Surjectivity of the solved block gives a digit u satisfying $J_{z_n} u = -\overline{F(z_n)/q^N} - K_{z_n}\overline{w}$. Choose an integer representative $\widetilde{u}$ and set $z_{n+1} = z_n + q^N(\widetilde{u}, w)$. Its parameter coordinates equal the supplied target exactly. Taylor expansion proves the next root condition, while congruence modulo q preserves the full reduced Jacobian. Construct the sequence recursively, preserving the exact parameter coordinates and the fixed solved Jacobian. The earlier cross-level argument proves all the stated integer congruences. □

This is `Komorebi.PolynomialPrescribedIntegerTower.exists_prescribed_tower_strong`. In particular, no assumption about solvability at each later level has been added to the initial surjectivity condition.

Theorem 10.15 (Arbitrary p-adic parameter endpoints)**.** *Let* $q = p$ *be prime in Theorem 10.14. For every* $\tau \in t_0 + p^L\mathbb{Z}_p^k$*, there are an integer tower* z_n *and* $b \in \mathbb{Z}_p^{m+k}$ *such that*

$$F(b) = 0, \qquad \mathrm{free}(b) = \tau, \qquad z_n \longrightarrow b, \qquad b - z_n \in p^{L+n}\mathbb{Z}_p^{m+k}.$$

The initial value is $z_0 = x$*. At every stage and for every proposed parameter digit* $v \in \mathbb{F}_p^k$*, the corresponding next residue fiber has exactly* p^{m-e} *elements. If* $m = e$*, then for each* τ *there is exactly one such root in* $B_L(x)$*, independently of all choices of integer approximants and correcting digits.*

Proof. Set the first integer parameter approximation equal to the prescribed t_0. For $n \ge 1$, use canonical representatives of τ mod p^{L+n}. The initial congruence and truncation precision give

$$\tau - t_n \in p^{L+n}\mathbb{Z}_p^k.$$

Subtracting consecutive relations gives compatibility in $\mathbb{Z}_p$. Faithfulness of integer divisibility under $\mathbb{Z} \hookrightarrow \mathbb{Z}_p$ gives compatibility in $\mathbb{Z}$, and the same norm bounds give $t_n \to \tau$. Theorem 10.14 and completion now produce b with exact polynomial vanishing and all retained precisions. Each free coordinate has both the corresponding coordinate of b and that of τ as its limit, proving exact parameter equality.

The solved Jacobian remains surjective, so every shifted obstruction $[\overline{r} + K_{z_n} v]$ vanishes. Formula (10.10) therefore gives p^{m-e} choices for every parameter digit at every stage. When $m = e$, the fixed-coordinate chart in the proof of Theorem 10.12 contains every root in the initial ball with the specified parameters. Its uniqueness proves the endpoint assertion. This is uniqueness of the actual endpoint, not of the integer representatives used to approach it. □

The endpoint theorems are `Komorebi.PolynomialPrescribedPadicTower.exists_prescribed_padic_root_with_tower` and `Komorebi.PolynomialPrescribedPadicTower.exists_unique_prescribed_padic_root`. The separate supplied-path theorem `Komorebi.PolynomialPrescribedPadicTower.exists_root_with_prescribed_path` accepts any compatible integer parameter path with limit τ. For $m > e$, endpoint uniqueness is false in general: the system $F(Y_1, Y_2, T) = Y_1$ has two distinct roots $(0, 0, 0)$ and $(0, 2, 0)$ in the same dyadic ball with identical parameter value.

10.7 Weighted lifting for a nonunit Jacobian

The remaining theorems in this section allow arbitrary coefficients and centers in $R = \mathbb{Z}_p$. They concern square solved Jacobians invertible over $\mathbb{Q}_p$, even when their reductions modulo p are singular. The exponent controlling an integral inverse is retained explicitly.

Theorem 10.16 (Weighted nonlinear lifting). *Let p be prime, $d, s, r \in \mathbb{N}$, $F \in R[X_1, \dots, X_d]^d$, and $a \in R^d$. Set $J = DF(a)$. Suppose*

$$J \in \mathrm{GL}_d(\mathbb{Q}_p), \qquad p^s J^{-1} \in M_d(R), \qquad F(a) \in p^r R^d, \qquad r > 2s. \tag{10.11}$$

Then there is exactly one root b of F in $a + p^{s+1}R^d$, and it satisfies

$$b - a \in p^{r-s} R^d. \tag{10.12}$$

Uniqueness holds throughout the full ball of depth $s + 1$.

Proof. Let $A = p^s J^{-1} \in M_d(R)$. Inclusion into $\mathbb{Q}_p$ and its injectivity give the two integral identities

$$AJ = JA = p^s I_d.$$

These identities are also an equivalent integral certificate for the first two hypotheses of (10.11). In particular, A is injective: $Aw = 0$ implies $p^s w = JAw = 0$, hence $w = 0$.

Precondition the polynomial system by A and set $c = p^{s+1}$. Its derivative at a is $AJ = p^s I_d$. Lemma 10.1 gives a polynomial vector Q with $Q(0) = 0$ and

$$(AF)(a + cu) = (AF)(a) + p^{2s+1}u + p^{2s+2}Q(u).$$

Since A is integral, $(AF)(a) \in p^r R^d$. The strict integer inequality $r > 2s$ permits $k = r - (2s + 1) \geq 0$ and a vector $C \in p^k R^d$ such that $(AF)(a) = p^{2s+1}C$. The normalized root equation is therefore

$$u = -C - pQ(u). \tag{10.13}$$

Integral polynomial evaluation is 1-Lipschitz for the supremum p-adic metric: a common divisibility of input differences is preserved under addition and multiplication by integral elements. Consequently the right side of (10.13) has contraction constant $|p|_p < 1$ on the complete space R^d. It has a unique fixed point u.

To obtain the sharper displacement, begin with $u \in R^d$. If $u \in p^n R^d$, then $Q(0) = 0$ and polynomial congruence give $Q(u) \in p^n R^d$. For $n < k$, both C and $pQ(u)$ are divisible by p^{n+1}. Equation (10.13) therefore improves the divisibility of u by one digit. Induction gives $u \in p^k R^d$. Thus $b = a + p^{s+1}u$ satisfies (10.12), because $s + 1 + k = r - s$. Its normalized preconditioned value vanishes, and injectivity of A gives $F(b) = 0$.

Every competing root $z \in a + p^{s+1}R^d$ can be written $z = a + p^{s+1}w$. Its root equation implies the same fixed-point equation after cancellation of the nonzero scalar p^{2s+1}. Contraction uniqueness gives $w = u$, proving uniqueness on the entire stated ball. □

The existence and uniqueness statements are `Komorebi.PolynomialWeightedLift.exists_weighted_root` and `Komorebi.PolynomialWeightedLift.exists_unique_weighted_root`. The inverse hypothesis in Lean

specifies an integral matrix whose image is exactly $p^s J^{-1}$. It does not substitute a potentially larger determinant valuation for s.

Example 10.17 (Strict threshold and displacement boundary)**.** For $p = 2$, $F(X) = X^2 + 3$, and $a = 1$, one has $F(a) = 4$ and $DF(a) = 2$. Thus $s = 1$ and $r = 2$ satisfy every displayed hypothesis except the strict inequality. No root exists in $\mathbb{Z}_2$, since none exists modulo eight. Hence $r \geq 2s$ cannot replace $r > 2s$ uniformly. Also, $F(X) = p^s X + p^r$ has root $-p^{r-s}$, whose displacement is not divisible by p^{r-s+1}. The guaranteed displacement cannot uniformly gain a digit.

10.8 First-order coefficient and parameter motion

Theorem 10.18 (Weighted coefficient deformation)**.** *Let $F, H \in R[X_1, \ldots, X_d]^d$, $F(a) = 0$, and $J = DF(a)$. Suppose $J \in \mathrm{GL}_d(\mathbb{Q}_p)$, $p^s J^{-1} \in M_d(R)$, and $M > 2s$. For $G = F + p^M H$, there is exactly one root $b \in a + p^{s+1}R^d$. It satisfies $b - a \in p^{M-s}R^d$ and, in $\mathbb{Q}_p^d$,*

$$b - a = -p^M J^{-1} H(a) + \varepsilon, \qquad \varepsilon \in p^{2M-3s} R^d. \tag{10.14}$$

Only the original Jacobian $DF(a)$ is subject to an inverse hypothesis.

Proof. Retain the original certificate $A = p^s J^{-1}$ and put $c = p^{s+1}$. Taylor expansion and a polynomial difference identity yield polynomial vectors Q_F, Q_H, both zero at the origin, such that

$$(AF)(a + cu) = p^{2s+1}u + p^{2s+2}Q_F(u), \qquad (AH)(a + cu) = AH(a) + cQ_H(u).$$

Consequently

$$(AG)(a + cu) = p^{2s+1}\big(C + u + pQ(u)\big),$$

where

$$C = p^{M-(2s+1)}AH(a), \qquad Q = Q_F + p^{M-s-1}Q_H, \qquad Q(0) = 0.$$

All exponents are nonnegative. The same contraction and divisibility argument as in Theorem 10.16 gives the root, the displacement p^{M-s}, and full-ball uniqueness. This constructs the root without introducing an inverse hypothesis for $DG(a)$.

For the error estimate, let $\delta = b - a$ and $D = M - s$. Taylor's theorem for the preconditioned polynomial gives

$$E_F = (AF)(b) - (AF)(a) - p^s\delta \in p^{2D}R^d.$$

Polynomial congruence gives $E_H = (AH)(b) - (AH)(a) \in p^D R^d$. The equations $F(a) = 0$ and $G(b) = 0$ imply

$$p^s\delta + p^M AH(a) = -E_F - p^M E_H \in p^{2D}R^d,$$

because $M + D \geq 2D$. Cancel p^s in the integral domain R to obtain

$$\delta + p^{M-s}AH(a) \in p^{2M-3s}R^d.$$

This integral vector is ε. After inclusion into $\mathbb{Q}_p$, $p^{M-s}A = p^M J^{-1}$ gives (10.14). □

The complete theorem is `Komorebi.PolynomialRootMotion.exists_unique_root_motion`. The error depth exceeds the displacement depth by $M - 2s \geq 1$. It is a guaranteed divisibility, not an assertion of exact valuation for every system.

Theorem 10.19 (Joint coefficient and parameter deformation)**.**

Let $F, H \in R[Y_1, \dots, Y_e, T_1, \dots, T_k]^e$ and $a = (y_0, t_0) \in R^{e+k}$ satisfy $F(a) = 0$. Define the actual blocks

$$J = D_Y F(a) \in M_e(R), \qquad K = D_T F(a) \in M_{e\times k}(R).$$

Suppose $J \in \mathrm{GL}_e(\mathbb{Q}_p)$, $p^s J^{-1} \in M_e(R)$, and $M > 2s$. For every $v \in R^k$, set

$$\tau = t_0 + p^M v, \qquad G = F + p^M H.$$

There is exactly one $y \in y_0 + p^{s+1}R^e$ with $G(y, \tau) = 0$. It satisfies

$$\begin{aligned} &y - y_0 \in p^{M-s}R^e, \\ &y - y_0 = -p^M J^{-1}\big(H(a) + Kv\big) + \varepsilon, \qquad \varepsilon \in p^{2M-3s}R^e. \end{aligned} \tag{10.15}$$

The equality involving J^{-1} is in $\mathbb{Q}_p^e$, with an integral error vector. The parameter equality is exact.

Proof. Use the augmented polynomial systems

$$\mathcal{F}(Y, T) = (F(Y, T), T - t_0), \qquad \mathcal{H}(Y, T) = (H(Y, T), -v).$$

Then $\mathcal{F}(a) = 0$, and its derivative is

$$B = D\mathcal{F}(a) = \begin{pmatrix} J & K \\ 0 & I_k \end{pmatrix}.$$

For $A = p^s J^{-1} \in M_e(R)$ and $c = p^s$, define

$$C = \begin{pmatrix} A & -AK \\ 0 & cI_k \end{pmatrix}.$$

The identities $AJ = JA = cI_e$ give $CB = BC = cI_{e+k}$. In the second product, the upper right block is $-JAK + cK = 0$. In the first, it is $AK - AK = 0$. Thus augmentation preserves the original inverse bound s.

Theorem 10.18 gives a unique root b of $\mathcal{F} + p^M\mathcal{H}$ in $a + p^{s+1}R^{e+k}$, with displacement depth $M - s$. Its last equations say exactly $b_T = t_0 + p^M v = \tau$. Its first equations are $G(b) = 0$. The integral first-order expression uses

$$C\begin{pmatrix} H(a) \\ -v \end{pmatrix} = \begin{pmatrix} A(H(a) + Kv) \\ -p^s v \end{pmatrix}.$$

Projection onto the solved coordinates gives

$$b_Y - y_0 + p^{M-s}A(H(a) + Kv) \in p^{2M-3s}R^e.$$

The same inclusion identity as before converts this to (10.15).

Finally, if $z \in y_0 + p^{s+1}R^e$ is any competing solved root with parameters τ, then (z, τ) belongs to the full augmented ball. Indeed, $M > 2s$ implies $M \geq s + 1$. Full-point uniqueness therefore gives $(z, \tau) = b$. This comparison proves uniqueness on exactly the solved ball stated in the theorem. □

The exact solved-coordinate statement is `Komorebi.PolynomialJointDeformation.exists_joint_deformation`, with its unique-existence interface `Komorebi.PolynomialJointDeformation.exists_unique_joint_deformation`.

The triangular inverse identities hold over arbitrary commutative rings, so they apply in particular over the p-adic integers.

Example 10.20 (First-order sign and error precision)**.** For $p = 2$, $s = 0$, $M = 2$, $F(Y, T) = Y + T$, $H = 1$, $a = 0$, and $v = 1$, the prescribed parameter is $\tau = 4$ and the solved root is $y = -8$. Here $J = K = 1$, and the forcing term is $H(a) + Kv = 2$. Omitting the parameter term would predict -4, and reversing its sign would predict 0. The corresponding errors -4 and -8 are both outside $2^{2M}\mathbb{Z}_2 = 16\mathbb{Z}_2$. Thus either change would violate the stated error bound.

The error exponent cannot uniformly be increased. For $F(Y, T) = Y + Y^2 + T$, $H = 0$, $a = 0$, $p = 2$, $s = 0$, $M = 1$, and $v = 1$, there is an even root y of $y + y^2 + 2 = 0$. Its equation forces $y \equiv 2 \pmod 4$ and $y + 2 = -y^2$, so

$$4 \mid y + 2, \qquad 8 \nmid y + 2.$$

Thus the error depth $2M - 3s = 2$ is attained even for parameter-only motion. The same quadratic with a constant coefficient perturbation gives the coefficient-only boundary. These examples refute a uniform extra error digit. They do not assert optimality for every individual choice of p, s, M.

The combined results establish finite singular obstructions, smooth compatible towers, full continuous root charts after a suitable coordinate choice, and quantitative deformation for a rationally invertible solved Jacobian. Rationally rank-deficient persistence remains a separate problem. The analytic solution-map theorem in the next section supplies the regularity conclusion for these same derivative blocks.

11 Analytic regularity of the local solution map

The deformation estimates control how far an exact root moves under a small perturbation. We now show that its local dependence on the parameters is analytic, and compute the derivative from the polynomial Jacobian. The analytic argument takes place over a complete normed field. For integral p-adic data, we first include the coefficients and base point in $\mathbb{Q}_p$. $\mathbb{Z}_p$ itself is not a vector space over $\mathbb{Q}_p$.

Let $\mathbb{K}$ be a complete nontrivially normed field. Let $e, k \in \mathbb{N}$, and write the variables as $(Y, T) \in \mathbb{K}^e \times \mathbb{K}^k$. For

$$F \in \mathbb{K}[Y_1, \dots, Y_e, T_1, \dots, T_k]^e, \qquad a = (y_0, t_0),$$

define the matrices of evaluated formal partial derivatives

$$J = D_Y F(a) \in M_e(\mathbb{K}), \qquad K = D_T F(a) \in M_{e\times k}(\mathbb{K}). \tag{11.1}$$

Rows index equations and columns index variables. We first establish that these formal derivatives are the derivatives of the evaluation map.

Lemma 11.1 (Derivative of polynomial evaluation)**.** *For $P \in \mathbb{K}[X_1, \dots, X_n]$, polynomial evaluation is analytic at every point. At $a \in \mathbb{K}^n$ its strict Fréchet derivative is*

$$v \longmapsto \sum_{j=1}^{n} (\partial_j P)(a) v_j.$$

For a finite system, its strict derivative is the continuous linear map represented by the matrix of evaluated formal partial derivatives.

Proof. For the derivative statement, use polynomial induction on constants, addition, and multiplication by a variable. Constants have zero derivative. The sum rule agrees with the additivity of formal partial differentiation. For PX_j, the product rule gives

$$d(PX_j)_a(v) = a_j\, dP_a(v) + P(a)v_j,$$

which agrees with the evaluated formal product rule for every coordinate. The finite product rule for maps to coordinate spaces then assembles the system derivative. Each matrix defines a continuous linear map because the coordinate spaces are finite-dimensional over the complete field. Polynomial analyticity follows from the corresponding polynomial induction in Mathlib and its finite-coordinate assembly. □

The derivative bridge and analytic statements are `Komorebi.PolynomialAnalyticEvaluation.hasStrictFDerivAt_evalSystem`, `Komorebi.PolynomialAnalyticEvaluation.analyticAt_evalSystem`, and `Komorebi.PolynomialAnalyticEvaluation.analyticOnNhd_evalSystem`.

Lemma 11.2 (The augmented derivative)**.** *If $J \in \mathrm{GL}_e(\mathbb{K})$, the polynomial map*

$$\Phi(Y, T) = (F(Y, T), T)$$

has invertible strict derivative at a, with

$$D\Phi(a) = \begin{pmatrix} J & K \\ 0 & I_k \end{pmatrix}, \qquad D\Phi(a)^{-1} = \begin{pmatrix} J^{-1} & -J^{-1}K \\ 0 & I_k \end{pmatrix}. \tag{11.2}$$

The local inverse supplied by this derivative is analytic near $\Phi(a)$.

Proof. The lower coordinates of Φ are the parameter variables. Differentiating them gives the blocks 0 and I_k. Lemma 11.1 identifies the remaining blocks with (11.1). Multiplication of the two matrices in (11.2), in both orders, gives the identity. The resulting linear equivalence is continuous, as is its inverse. Apply the strict inverse-function theorem to Φ. The analytic inverse theorem applies to the same open partial homeomorphism, because Φ is analytic and its derivative is that continuous linear equivalence. It supplies a convergent local power-series representation of this inverse. □

The augmented Jacobian is identified in `Komorebi.PolynomialJointSystem.jacobian_augmented`. The continuous inverse block and its restriction are `Komorebi.PolynomialAnalyticBlocks.upperEquiv` and `Komorebi.PolynomialAnalyticBlocks.inverse_solved_zero`. Analyticity of the same constructed inverse is `Komorebi.PolynomialAnalyticInverse.analyticAt_inverse`.

Theorem 11.3 (Analytic local root graph)**.** *Suppose $F(a) = 0$ and $J \in \mathrm{GL}_e(\mathbb{K})$. There are open neighborhoods $t_0 \in U \subseteq \mathbb{K}^k$ and $y_0 \in V \subseteq \mathbb{K}^e$, and a map $\psi : \mathbb{K}^k \to \mathbb{K}^e$, such that*

$$\psi(t_0) = y_0, \qquad \psi(U) \subseteq V, \qquad \psi \text{ is analytic at every point of } U, \tag{11.3}$$

$$F(y, t) = 0 \iff y = \psi(t) \qquad (t \in U,\ y \in V). \tag{11.4}$$

At the base parameter, the strict Fréchet derivative is

$$\boxed{D\psi(t_0) = -J^{-1}K.} \tag{11.5}$$

In particular, ψ is differentiable on U.

Proof. Let g be the analytic local inverse of Φ supplied by Lemma 11.2. Since $F(a) = 0$, $\Phi(a) = (0, t_0)$ and $g(0, t_0) = a$. Define

$$\psi(t) = \pi_Y g(0, t),$$

where π_Y projects to the solved coordinates. This gives the base value and analyticity at t_0. The chain rule and (11.2) give

$$D\psi(t_0)v = \pi_Y \begin{pmatrix} J^{-1} & -J^{-1}K \\ 0 & I_k \end{pmatrix} \begin{pmatrix} 0 \\ v \end{pmatrix} = -J^{-1}Kv.$$

To obtain the root equivalence on a product neighborhood, we choose the neighborhoods as follows. The source of the open partial homeomorphism defined by Φ is open around a. Its inverse is g. Choose open sets V and U_0 containing y_0 and t_0 such that $V \times U_0$ lies in that source. Restrict U_0 further by the preimage of an open analytic inverse neighborhood under $t \mapsto (0, t)$, the open locus where this same ψ is analytic, and the interior of $\psi^{-1}(V)$. All of these sets contain t_0. For the last set, use the continuity of ψ at t_0 and $\psi(t_0) = y_0 \in V$. Their intersection is an open neighborhood U with $\psi(U) \subseteq V$.

If $t \in U$, $y \in V$ and $F(y, t) = 0$, then $\Phi(y, t) = (0, t)$. The left inverse identity forces $g(0, t) = (y, t)$, hence $y = \psi(t)$. Conversely, the right inverse identity $\Phi(g(0, t)) = (0, t)$ says both that its solved equations vanish and that its parameter coordinates are exactly t. Thus $g(0, t) = (\psi(t), t)$ and $F(\psi(t), t) = 0$. Analyticity at every point of U implies differentiability there. □

This is `Komorebi.PolynomialAnalyticImplicit.exists_analytic_implicit`. Differentiability is also included explicitly in the statement contract `Komorebi.PolynomialRegularityContracts.actual_padic_analytic_root_graph`.

Theorem 11.4 (Regularity of a supplied root selection)**.** *Under the hypotheses of Theorem 11.3, let $h : \mathbb{K}^k \to \mathbb{K}^e$ be continuous at t_0, with $h(t_0) = y_0$. Suppose $F(h(t), t) = 0$ for every t in some neighborhood of t_0. Then h and ψ agree in a neighborhood of t_0. Consequently h is analytic there as a germ and has strict derivative $Dh(t_0) = -J^{-1}K$.*

Proof. Continuity at t_0 places $h(t)$ inside V for all sufficiently close parameters. Intersect this neighborhood with U and the neighborhood on which the root equation holds. Equation (11.4) gives $h(t) = \psi(t)$ throughout the intersection. Analyticity and strict differentiability at a point are unchanged by agreement on a neighborhood. □

The formal result is `Komorebi.PolynomialAnalyticSelection.continuous_selection_regularity`. Its formulation derives $F(a) = 0$ from the root equation near the base parameter and the specified base value.

Corollary 11.5 (Regularity throughout an open parameter set)**.** *Let $U \subseteq \mathbb{K}^k$ be open, and let h be continuous on U. Suppose that for every $t \in U$,*

$$F(h(t), t) = 0, \qquad J_t = D_Y F(h(t), t) \in \mathrm{GL}_e(\mathbb{K}).$$

Then h is analytic at every point of U and its strict derivative is

$$Dh(t) = -J_t^{-1} D_T F(h(t), t) \qquad (t \in U).$$

Proof. At each $t \in U$, openness turns continuity on U into continuity at t and makes the root equation hold on a neighborhood of t. Apply Theorem 11.4 at $(h(t), t)$. □

This is `Komorebi.PolynomialAnalyticSelection.continuous_selection_analyticOnNhd`. The pointwise invertibility assumption is part of this corollary.

Corollary 11.6 (Integral coefficients and centers)**.** *Let p be any prime. Suppose $F \in \mathbb{Z}_p[Y,T]^e$, $a \in \mathbb{Z}_p^{e+k}$, and $F(a) = 0$. Let $\iota : \mathbb{Z}_p \hookrightarrow \mathbb{Q}_p$ be the inclusion. If $\iota(D_Y F(a)) \in \mathrm{GL}_e(\mathbb{Q}_p)$, the polynomial system obtained by including the original coefficients in $\mathbb{Q}_p$ has the analytic local root graph of Theorem 11.3 at $\iota(a)$. The strict derivative at the base is*

$$-\iota(D_Y F(a))^{-1}\iota(D_T F(a)).$$

The open neighborhoods and the output map are in the ambient spaces over $\mathbb{Q}_p$.

Proof. Coefficient inclusion commutes with evaluation and formal partial differentiation. Consequently both Jacobian blocks after inclusion are the entrywise inclusions of the original blocks, and the original exact root remains an exact root. Apply Theorem 11.3 to the system with included coefficients. □

This is `Komorebi.PolynomialRegularityIntegral.exists_analytic_integral_implicit`. It requires no invertibility modulo p. In particular, it includes solved Jacobians singular modulo p but invertible over the fraction field.

Example 11.7 (The derivative sign and a nonlinear control)**.** For $F(Y,T) = Y + T$, the exact branch is $\psi(T) = -T$ and $J = K = 1$. The derivative is -1. Uniqueness of the derivative rules out $+1$ over $\mathbb{Q}_p$, including $p = 2$. The nonlinear polynomial $F(Y,T) = Y + Y^2 + T$ has $F(0,0) = 0$ and $J = K = 1$ there. Applying the formal theorem to this polynomial constructs an analytic local root graph with derivative -1. Thus the example checks the existence conclusion as well as the derivative formula. The declarations and the deliberately rejected positive-sign statement are in the regularity control and statement-contract files.

The results cover arbitrary finite e and k, including zero. The local inverse machinery explicitly handles a zero-dimensional domain. The analytic theorem does not assign a uniform numerical radius to its neighborhoods. The earlier weighted lifting and joint deformation theorems retain their quantitative radii and error bounds, while the present statements establish regularity of the local solution germ. A direct Lean identification with each subtype-valued chart is an additional interface task. General persistence at a fraction-field singular solved block is a separate problem.

12 Open questions and further directions

The arithmetic results above resolve Nishibuchi's conjecture throughout its stated parameter range. The local analyticity and differentiability theorem is also complete under its stated invertibility hypothesis. What remains is a set of extensions and sharper classifications, together with the broader questions raised by the original native seed-calculus program.

12.1 Singular persistence beyond an invertible solved block

The weighted lifting theorem allows the solved Jacobian to be noninvertible modulo p provided that it is invertible over $\mathbb{Q}_p$ with a controlled inverse. This includes a substantial class of lifts often called singular modulo p. The next problem is to understand Jacobians that remain rank-deficient over $\mathbb{Q}_p$, where the inverse construction is no longer available.

For a fixed polynomial system $F \in \mathbb{Z}[X_1, \ldots, X_d]^e$, a precision $L \geq 1$, and a root $\bar{x}$ modulo p^L, let

$$\mathcal{L}_{F,L}(\bar{x}) = \{x' \in (\mathbb{Z}/p^{L+1}\mathbb{Z})^d : F(x') = 0,\ x' \equiv \bar{x} \pmod{p^L}\}.$$

The finite obstruction theorem decides whether this set is empty from the residual digit and reduced Jacobian. When it is nonempty, the theorem also determines its cardinality and affine kernel structure. The conclusion concerns one level: vanishing of the obstruction permits the next step, but does not guarantee that subsequent steps are possible.

For example, $X^2 - 5$ has the root 1 modulo 2, and both 1 and 3 lift it to roots modulo 4. Every odd square is 1 modulo 8, so neither branch continues to a root modulo 8. Thus even a successful first correction can lead to branches that stop at the following level.

We seek structural hypotheses and higher obstruction data that control an entire singular branch, including its behavior under coefficient and parameter deformation. One route is to propagate suitable conditions from level to level. Another is to prove existence at all levels in a form that yields compatible branches. The finite obstruction calculus supplies the tests for individual levels, but a persistence theorem needs a further argument linking them. Any general formulation must allow multiple branches, later obstructions, and changes in the rank of the Jacobian.

12.2 Native 13.2: presentation invariance

The original conjecture asks for a canonical finite obstruction packet whose vanishing is necessary and sufficient for a one-level lift in a finitely presented arithmetic seed system. For a fixed finite polynomial presentation, the chapter supplies the precise obstruction

$$o_{F,\bar{x}} = [r] \in \operatorname{coker}\left(J_{F,\bar{x}} : \mathbb{F}_p^d \longrightarrow \mathbb{F}_p^e\right),$$

where r is the residual digit. We have proved independence from the chosen integer representative. Invariance under a change of equations or presentation requires more.

The raw cokernel already reveals the difficulty. The presentations $F = (X)$ and $G = (X, 0)$ describe the same zero locus over every coefficient ring. At zero their Jacobians are, respectively,

$$\mathbb{F}_p \xrightarrow{1} \mathbb{F}_p, \qquad \mathbb{F}_p \xrightarrow{(1,0)} \mathbb{F}_p^2.$$

Their raw cokernels are 0 and $\mathbb{F}_p$. Both distinguished obstruction classes vanish, but the ambient obstruction groups are not isomorphic. The example rules out the raw cokernel as a presentation-independent object while leaving open the possibility of an intrinsic obstruction construction.

A precise form of Native 13.2 therefore needs four ingredients:

1. a category of seed objects, including how the operators, relations, projectors, weights, and topology enter an object;
2. specified changes of presentation and a proof that they preserve the actual lift problem;
3. an obstruction object that respects dependencies among the relations, together with comparison maps or a universal property;
4. a precise meaning of “finite” and “canonical”, and a proof that vanishing is equivalent to the intended one-step continuation.

For commutative algebra presentations, the relation module offers a natural way to account for dependencies among listed equations. To extend this approach to the full seed vocabulary, we would need an encoding that preserves the lift problem, together with a proof of that preservation. This is one of the links still needed between the concrete obstruction theorem and Native 13.2.

12.3 Native 13.3: finite compatibility, completion, and descent

The original proposed form is

$$X \simeq X_2^{\mathrm{wt}} \times_C {\prod_{p>2}}' X_p.$$

It leaves X, the distinguished subsets defining the restricted product, the maps to C, the ambient category, and the universal meaning of "smallest" unspecified. In particular, one must decide whether X is a global object or a completed object.

The linear compatibility theorem provides one concrete part of this program. If two local observations $J : U \to V$ and $K : U \to W$ are linear maps from the *same* correction module, define

$$C_{J,K} = U/(\ker J + \ker K).$$

The attainable observations $\operatorname{im} J$ and $\operatorname{im} K$ have canonical labels in this quotient. Equality of labels is equivalent to simultaneous realization by a single correction. The joint image is exactly the fiber product over $C_{J,K}$, with the proved linear universal property. The declarations are `Komorebi.SharedCorrection.labels_eq_iff_common`, `Komorebi.SharedCorrection.joint_range_eq_fiber`, and `Komorebi.SharedCorrection.common_universal`.

To apply this result arithmetically, one must construct the common correction module and the observation maps, then show that the resulting compatibility condition agrees with the intended arithmetic one.

Why the global/completed distinction is necessary. Consider constant sequences with integer initial value. Their global parameter space is $\mathbb{Z}$, while their local parameter spaces are $\mathbb{Z}_p$. Under the canonical local maps, the image of the global objects is the diagonal

$$D = \{(n)_p : n \in \mathbb{Z}\} \subseteq \prod_p \mathbb{Z}_p.$$

This diagonal is dense: a basic open set specifies finitely many congruences, and the Chinese remainder theorem provides an integer satisfying them. It is proper: the tuple with 2-adic coordinate zero and all odd-adic coordinates one is not the image of an integer. Indeed an integer zero in $\mathbb{Z}_2$ must be zero, contradicting its 3-adic coordinate.

Consequently this canonical global diagonal cannot be an equality locus

$$\{(a, b) : f(a) = g(b)\} \subseteq \mathbb{Z}_2 \times \prod_{p>2} \mathbb{Z}_p$$

for continuous maps to a Hausdorff space C. Such an equality locus is closed, as the inverse image of the closed diagonal in $C \times C$, whereas D is proper and dense. This topological argument, retained from the native progress note, concerns the stated topological interpretation. It has not been formalized in Lean for this manuscript.

Finite CRT reconstruction leads to the familiar completed object $\widehat{\mathbb{Z}} = \prod_p \mathbb{Z}_p$, but does not identify which local tuples come from a single global integer. A complete form of Native 13.3 must therefore specify finite-level compatibility, transition maps and completion, and any additional global descent condition. If recurrence, spectral, or Frobenius information is to supply that condition, it must be expressed through defined maps or constraints on the local data, with a precise account of how they enter C.

The accompanying `native/Native_Conjectures_Progress.md` records further results in restricted settings: an intrinsic finite Ext^1 obstruction for finitely presented commutative integer algebras, finite CRT reconstruction for polynomial solution sets, and a characterization of rectangular finite relations by equality of common labels. The obstruction result is a stated specialization of a classical external theorem. The CRT and rectangularity results have prose proofs in the note. These are preserved mathematical progress, with the restrictions and source records given there, rather than Lean completions of the general Native 13.2 and 13.3 statements.

12.4 Arithmetic refinements

Write $U_{N,j}(n) = j!C_{N,j}(n)$ and $U_j = U_{4,j}$, and use $v_p(0) = \infty$ when discussing valuation bounds. The following classification questions remain open in this program.

1. **The remaining higher-difference classification.** The new strengthening chapters determine every repeated-step valuation in addresses $j = 0, 1$, give the exact criterion for equality in the common mixed-step lower bound there, and determine address-two valuations at all power-of-two orders. What remains is a complete exact formula in address two at the other orders, a full classification in address three, and the amount of additional cancellation in mixed-step cases where the leading term vanishes. Numerical patterns through a finite range do not settle these questions.

2. **Upper-half addresses at larger dyadic rank.** The exact first-difference laws now include $N = 2, 4, 8$ and every lower-half address for $N = 2^a \geq 4$. Larger upper-half addresses need a finer classification. Explicit counterexamples show that extrapolating one low-order Newton coefficient to a universal metric law is false. A least period is measured in packet rows. Its Euler-degree displacement is NP.

3. **Exact affine Mahler-kernel valuations.** For the kernel of Section 2.7, determine exact values of

$$v_p\big(\Theta_{M,s}(r,k)\big), \qquad \Theta_{M,s}(r,k) = [z^r](1+z)^s((1+z)^M - 1)^k,$$

   beyond the explicit special families. The minimum valuation of the summands gives a lower bound. Equality requires a separate argument excluding cancellation.

4. **Classical tail root classification and simplicity.** The later tail program gives an exact factorization, finite preparation for each fixed depth, and several infinite regular-wall and simplicity families, as summarized in Appendix A. A universal explicit root classification and universal simplicity of the remaining analytic factor are still open. In the exceptional address-one quadratic reduction, the residual task is a nonvanishing discriminant condition. Empty tails remain exactly zero. This problem is distinct from the solved Nishibuchi congruence conjecture.

These refinements build on the proved estimates and exact cases, including the sharp uniform classical dyadic bound and the resolution of Nishibuchi's conjecture.

A Exact classical Euler tails and the remaining simplicity problem

This appendix states the proved reductions for classical Euler tails and the remaining simplicity problem. That problem is distinct from Nishibuchi's Conjecture 3.9, proved by the congruence results of this chapter, and from the presentation and gluing questions Native 13.2 and Native 13.3.

The tail results have mathematical proofs, supplemented in the indicated families by complete coefficient certificates and proved bounds for every omitted coefficient. Bounded sampled values support implementation checks. They do not supply the universal quantifiers. The latest continuation did not run Lean. Its mathematical claims must therefore be read with the formal-coverage distinctions in the Lean guide.

A.1 The ordinary Euler packet identity

To distinguish ordinary signed Euler numbers from the generalized numbers of the main text, write

$$\operatorname{sech} t = \sum_{n\ge 0} \mathcal{E}_n \frac{t^n}{n!}, \qquad \frac{t}{e^t-1} = \sum_{n\ge 0} B_n \frac{t^n}{n!}, \qquad B_1 = -\frac{1}{2}.$$

Throughout this appendix, $v_2(2) = 1$ and $v_2(0) = \infty$. Let $s_2(n)$ be the number of ones in the binary expansion of the nonnegative integer n. Define

$$A(N) = \frac{3^{2N+2}-1}{4(2N+1)(2N+2)}, \qquad \left(\frac{z}{\sinh z}\right)^2 = \sum_{m\ge 0} \beta_m z^{2m}, \qquad \kappa_m = 2^{2m}(2m)!\beta_m.$$

The initial values are $\beta_0 = \kappa_0 = 1$. For $m \ge 1$, differentiation of $z\coth z$ gives

$$\beta_m = -\frac{2^{2m}(2m-1)B_{2m}}{(2m)!}, \qquad \kappa_m = -2^{4m}(2m-1)B_{2m}. \tag{A.1}$$

The classical dyadic Bernoulli denominator law $v_2(B_{2m}) = -1$ and Legendre's formula yield

$$v_2(\beta_m) = s_2(m) - 1, \qquad v_2(\kappa_m) = 4m - 1. \tag{A.2}$$

The source identity

$$\sum_{N\ge 0} A(N)\frac{t^{2N}}{(2N)!} = \frac{\sinh(2t)\sinh t}{2t^2}$$

implies, after multiplication by $4t^2/\sinh^2(2t)$,

$$\mathcal{E}_{2N} = \sum_{m=0}^{N} \kappa_m \binom{2N}{2m} A(N-m). \tag{A.3}$$

For a retained depth $M \ge 0$, put

$$\mathcal{T}_M(N) = \mathcal{E}_{2N} - \sum_{m=0}^{\min(M,N)} \kappa_m \binom{2N}{2m} A(N-m).$$

An empty tail, $N \le M$, is exactly zero.

Proposition A.1 (Sharp uniform classical truncation bound)**.** *For every $M, N \ge 0$,*

$$v_2\big(\mathcal{T}_M(N)\big) \ge 4M + 3.$$

For each fixed M, equality holds at $N = M + 1$.

Proof. The source $A(n)$ is a dyadic unit for every nonnegative integer n. Each nonempty summand has $m \ge M + 1$, so (A.2) and integrality of the binomial coefficient give the asserted bound. At $N = M + 1$, only the first omitted summand remains. Its binomial coefficient and $A(0)$ both equal one. □

Thus later row-dependent cancellation can improve a particular tail, but cannot increase the uniform exponent required to hold at every row.

A.2 A finite carry minimum and an exact all-row factorization

Let $\mathbb{Z}_2\langle x\rangle$ denote the restricted power series: their integral coefficients tend to zero dyadically. Extend A by

$$\mathscr{A}(x) = \frac{9^{x+1} - 1}{8(x+1)(2x+1)}, \qquad \mathscr{A}(-1) = -\frac{\log 9}{8}.$$

The apparent singularity at $x = -1$ is removable. Since $v_2(\log 9) = 3$, its convergent expansion is

$$\mathscr{A}(x) = \frac{\log 9/8}{1 + 2x} \sum_{h \ge 0} \frac{(\log 9)^h}{(h+1)!} (x+1)^h. \tag{A.4}$$

It follows coefficientwise that $\mathscr{A} \in \mathbb{Z}_2\langle x\rangle^{\times}$, $\mathscr{A} \equiv 1 \pmod 2$, and $\mathscr{A}(N) = A(N)$.

Set $r = M + 1 \ge 1$ and define

$$P_q(x) = \prod_{i=0}^{q-1} (x - i)(2x - (2i+1)), \qquad P_0 = 1,$$

$$H_r(x) = \sum_{q \ge 0} 8^q \frac{\beta_{r+q}}{\beta_r} P_q(x) \mathscr{A}(x - q).$$

The coefficient valuations tend to infinity. At any nonnegative integer x, terms with $q > x$ vanish. Cancelling the factorials in (A.3) therefore gives the exact identity

$$\mathcal{T}_{r-1}(N) = \kappa_r \binom{2N}{2r} H_r(N - r) \qquad (N \ge r). \tag{A.5}$$

This is a finite rational identity at every original Euler row.

The scalar packet weights have exact valuations

$$\lambda_r(q) = 3q + s_2(r + q) - s_2(r).$$

Put

$$\mu_r = \min_{q \ge 0} \lambda_r(q), \qquad J_r = \{q : \lambda_r(q) = \mu_r\}, \qquad G_r = 2^{-\mu_r} H_r.$$

Since $\lambda_r(0) = 0$ and $\lambda_r(q) \geq 3q + 1 - s_2(r)$, every minimizing address satisfies

$$0 \leq q \leq \left\lfloor \frac{s_2(r) - 1}{3} \right\rfloor. \tag{A.6}$$

In particular $\mu_r \leq 0$, and the minimum is found by a finite carry calculation. Reduction of the whole series gives

$$\overline{G}_r(X) = \sum_{q \in J_r} X^{\underline{q}} \quad \text{in } \mathbb{F}_2[X]. \tag{A.7}$$

Its highest degree is $\max J_r$, with leading coefficient one. Thus the normalization is the actual Gauss normalization.

Theorem A.2 (Exact classical tail valuation)**.** *For every $r \geq 1$ and $N \geq r$,*

$$v_2\big(\mathcal{T}_{r-1}(N)\big) = 4r - 1 + v_2\binom{N}{r} + \mu_r + v_2 G_r(N - r). \tag{A.8}$$

There are unique factors

$$G_r(X) = W_r(X)U_r(X),$$

where $W_r \in \mathbb{Z}_2[X]$ is monic of degree $d_r = \max J_r$ and $U_r \in \mathbb{Z}_2\langle X\rangle^\times$ satisfies $U_r \equiv 1 \pmod 2$. Consequently $v_2 G_r(x) = v_2 W_r(x)$ for every $x \in \mathbb{Z}_2$, and

$$\deg W_r \leq \left\lfloor \frac{s_2(r) - 1}{3} \right\rfloor.$$

Proof. Equation (A.5), the exact weight in (A.2), and the digit-sum identity $v_2\binom{2N}{2r} = v_2\binom{N}{r}$ prove (A.8). The binomial coefficients themselves need not be equal.

For preparation, start from the monic polynomial $g = \overline{G}_r$ and its zero-one lift W_1, with $U_1 = 1$. Suppose $G_r - W_k U_k$ is coefficientwise divisible by 2^k. Its divided reduction is a finite polynomial because G_r is restricted. Divide it by g in $\mathbb{F}_2[X]$:

$$\overline{(G_r - W_k U_k)/2^k} = gq + s, \qquad \deg s < d_r.$$

With zero-one coefficient lifts, set $W_{k+1} = W_k + 2^k s$ and $U_{k+1} = U_k + 2^k q$. The error is now divisible by 2^{k+1}, the polynomial remains monic of degree d_r, and the unit reduces to one. The sequences converge in the Gauss norm. Uniqueness of quotient and remainder at successive binary digits proves uniqueness of the factors. For $d_r = 0$, take $W_r = 1$. The degree bound follows from (A.6). □

This theorem reduces every depth to a finite polynomial without discarding the infinite analytic tail. It does not explicitly classify every W_r, decide every repeated root from a fixed precision, or prove that all its dyadic roots are simple.

A.3 Regular walls: exact root emergence

For a wall label $j \geq 1$ and $0 \leq q < j$, define

$$e_j(q) = 3q + s_2(j - 1) - s_2(j - q - 1), \qquad E_j = \min_{q<j} e_j(q),$$

$$\Theta(j) = 3j + 1 + s_2(j-1), \qquad L_j = \Theta(j) - E_j.$$

Here E_j is a carry minimum, not an Euler number. A wall label is *regular* when $e_j(q) > 0$ for $1 \le q < j$. For $r = 2^L - j$ with $L > L_j$, put $\delta = L - L_j$. The carry identities give

$$\mu_r = E_j - \delta, \qquad J_r = \{j\}, \qquad G_r(x) = P_j(x)U(x-j) + 2^\delta V(x),$$

where $U \equiv 1 \pmod 2$. For a regular label, also $E_j = 0$ and $V \equiv 1 \pmod 2$.

For $0 \le i < j$, let

$$d_i = v_2(i!) + v_2((j-1-i)!), \qquad k_i = 1 + \lfloor \log_2 \max(i, j-1-i) \rfloor,$$

$$B_i = i + 2^{k_i}\mathbb{Z}_2, \qquad t_i = d_i + k_i.$$

At $j = 1$ use $d_0 = k_0 = t_0 = 0$. The balls B_i partition $\mathbb{Z}_2$. Indeed a residue represented twice among $0, \dots, j-1$ splits into its two children. Every other represented residue remains one ball. On each such ball,

$$P_j(i + 2^{k_i}y) = 2^{t_i} y Q_i(y), \qquad Q_i \in \mathbb{Z}_2\langle y \rangle^\times, \qquad Q_i \equiv 1 \pmod 2.$$

Theorem A.3 (Regular-wall root law)**.** *For every regular label j and every integer $\delta \ge 1$,*

$$v_2 G_r(x) = \begin{cases} \delta, & x \in B_i,\ \delta < t_i, \\ d_i + v_2(x - \alpha_i), & x \in B_i,\ \delta \ge t_i. \end{cases}$$

In the second case there is exactly one root α_i in B_i, it is simple, and $v_2(\alpha_i - i) = \delta - d_i$. Thus the number of dyadic roots is exactly

$$\#\{i : 0 \le i < j,\ t_i \le \delta\}.$$

Proof. If $\delta < t_i$, the unit perturbation has smaller valuation than the skeleton term throughout B_i, so the valuation is exactly δ. Otherwise, after the ball substitution and division by 2^{t_i}, the coefficientwise reduction is $y + c$ for a constant $c \in \mathbb{F}_2$. A restricted integral series with this reduction is a dyadic isometry: division of its difference by $y - z$ gives an odd linear coefficient plus even higher contributions. Binary lifting therefore gives its unique root and exact distance law. Evaluating at $x = i$ gives the stated displacement, since $G_r(i) = 2^\delta V(i)$ has exact valuation δ. The partition proves exhaustion of the roots. □

The largest emergence threshold is

$$\max_i t_i = v_2((j-1)!) + \lceil \log_2 j \rceil.$$

For $j = 2^a$, all thresholds equal $j - 1$. There are no roots before that distance and exactly j simple roots at and after it, within the positive-distance range. The equality and pre-wall cases are also resolved: regular labels $j \ge 2$ have no roots there. $j = 1$ has one simple odd root at equality.

For example, $j = 5$ has $(t_0, \dots, t_4) = (6, 3, 4, 3, 6)$. The exact root counts at distances $1, 2, 3, 4, 5, \ge 6$ are $0, 0, 2, 3, 3, 5$. The older sufficient stages $3, 5, 7$ are not the sharp emergence stages, which are $3, 4, 6$. The first irregular label, $j = 17$, has $V \equiv 1 + X \pmod 2$. The regular-wall theorem does not apply. Complete coefficient certificates close distances 1 through 19, and the general separation theorem gives all seventeen simple roots for $\delta \ge 20$. Those two kinds of evidence together resolve that family.

A.4 What the later simplicity reductions prove

For a general depth r, call $j_r = \max J_r$ its *true terminal*. This definition depends on the actual carry minimum. Rewriting the same integer as another wall expression does not change j_r. The universal simplicity target is

$$\text{for every integer } r \geq 1 \text{ and } x \in \mathbb{Z}_2, \qquad G_r(x) = 0 \implies G_r'(x) \neq 0. \tag{A.9}$$

The following are completed restricted results of the later continuations. Their family statements include a proof that the indicated label is the true terminal throughout the displayed ranges.

Depth r	Odd multiplier range	Outer scales
$B2^L - 129$	$0 < B < 2^{89}$	$L \geq 392$
$B2^L - 161$	$0 < B < 2^{932}$	$L \geq 487$

All dyadic roots are simple in both infinite integer families. For arbitrary larger admissible multipliers, a multiple root with true terminal 129 can occur only at $L = 515$ and in two necessary multiplier classes modulo 2^{90}. With true terminal 161, it can occur only at $L = 640$ and in one necessary multiplier class modulo 2^{935}. These classes are necessary conditions. The records do not assert existence of a singular ordinary Euler index in them.

For terminal 161, the neighboring phases are resolved uniformly: $L = 639$ has exactly one simple root and $L = 641$ exactly three simple roots, for every positive odd multiplier with that true terminal. The middle phase is reduced, before the deeper certificate is applied, to

$$B \equiv 17659 \pmod{2^{18}}, \qquad x \equiv 10202 \pmod{2^{15}}.$$

The 935-bit multiplier condition composes this whole-phase reduction with an inherited 917-bit local parameter certificate. It is neither a new 935-bit reconstruction nor an all-precision interpolation of the undepleted Euler family.

The structural argument also extends beyond lower address one. For a certified true-terminal wall, let a be its last lower minimizing address, $k = j_r - a$ the regular complement, and $t = v_2(k)$. Under the regular lower-address hypotheses of the source theorem, all roots above emerged complement balls are simple. Every root is simple at every wall distance in the band

$$\Theta(a) \leq t < \Theta(a) + v_2(a!).$$

Equality walls are simple even outside that band. This includes certified terminal-258 walls with $a = 2$, $k = 256$, and $L \geq 777$. For $a = 3$, $k = 4096$, only $L = 16385$ remains a possible critical scale. Outside the band, the theorem gives necessary local valuation conditions. It does not exclude the remaining unit cancellation. Irregular lower addresses need their own prefix analysis.

A.5 The actual stationary discriminant

The current focused obstruction is the admitted ordinary-index family

$$r = (17659 + 2^{18}T)2^{640} - 161, \qquad T \in \mathbb{Z}_{\geq 0}, \qquad j_r = 161. \tag{A.10}$$

On its surviving chart define the *actual*, undepleted function

$$K_r(Z) = 2^{-178} G_r(10202 + 2^{15} Z).$$

The complete coefficient theorem gives

$$K_r(Z) = a_r + 2b_r Z + u_r Z^2 + 256 Z^3 R_r(Z), \quad a_r, b_r \in \mathbb{Z}_2, \quad u_r \in \mathbb{Z}_2^{\times}, \quad R_r \in \mathbb{Z}_2\langle Z \rangle. \tag{A.11}$$

Its half derivative is a dyadic isometry. It therefore has a unique critical point $c_r \in \mathbb{Z}_2$. Set $\Phi_r^{\mathrm{act}} = K_r(c_r)$. The earlier independent-undepletion notation for this same scalar is $\Phi_r(2^{2r-25})$. Excluding a multiple root on the surviving chart is exactly the assertion $\Phi_r^{\mathrm{act}} \neq 0$.

Proposition A.4 (Exact quadratic compression)**.** *There is a unique preparation*

$$K_r(Z) = \mathcal{U}_r(Z)\mathcal{W}_r(Z), \qquad \mathcal{W}_r(Z) = Z^2 + 2\beta_r Z + \alpha_r, \qquad \mathcal{U}_r \equiv u_r \pmod{256}.$$

With $\delta_r = \beta_r^2 - \alpha_r$ and $\tau_r = \mathcal{U}_r'(c_r)/\mathcal{U}_r(c_r)$,

$$\delta_r = -\frac{\Phi_r^{\mathrm{act}}}{\mathcal{U}_r(c_r)} \left(1 - \frac{\tau_r^2 \Phi_r^{\mathrm{act}}}{4\mathcal{U}_r(c_r)}\right), \qquad v_2(\delta_r) = v_2(\Phi_r^{\mathrm{act}}). \tag{A.12}$$

The equality includes the zero case.

Proof. The same successive monic polynomial division used in Theorem A.2, started at precision eight, preserves the quadratic and unit reductions of (A.11). Write $W = Z^2 + 2\beta_r Z + \alpha_r$ and $w = W(c_r)$. Stationarity gives $W'(c_r) = -\tau_r w$, while $w = \Phi_r^{\mathrm{act}}/\mathcal{U}_r(c_r)$. The quadratic identity $\beta_r^2 - \alpha_r = W'(c_r)^2/4 - W(c_r)$ proves the formula. Since $\tau_r \in 256\mathbb{Z}_2$, its bracket is a unit. □

This compression retains the unit-cofactor derivative. It does not assert that c_r, α_r, or β_r is rational or algebraic over $\mathbb{Q}$. The remaining arithmetic obligation is therefore

$$\delta_r \neq 0 \quad \text{for every admitted ordinary index in (A.10).} \tag{A.13}$$

Even this assertion would still leave the terminal-129 and higher-address obligations in the universal target (A.9).

A.6 Approximation reaches every depth, but separation remains open

The latest continuation retains the exact Bernoulli undepletion factor

$$e_{r,q} = \frac{1 - 2^{2r-1}}{1 - 2^{2r-1} 4^q}, \qquad q \geq 0.$$

It is a dyadic unit, including $e_{r,0} = 1$. Multiplication by this factor preserves the all-q error of the shifted Jacobi moment model. Consequently the actual model critical values satisfy, for every $m \geq 25$,

$$v_2\big(\Phi_{r,m}^{\mathrm{act}} - \Phi_r^{\mathrm{act}}\big) \geq L_m = 8m - 4s_2(m) - 178, \qquad L_m \longrightarrow \infty. \tag{A.14}$$

The estimate includes every packet and controls motion of the critical point. There is no ceiling at the undepletion exponent $2r - 25$. For each fixed admitted r it implies the exact equivalence

$$\Phi_r^{\mathrm{act}} \neq 0 \quad \Longleftrightarrow \quad \text{there exists } m \geq 25 \text{ such that } v_2(\Phi_{r,m}^{\mathrm{act}}) < L_m. \tag{A.15}$$

Indeed a passing strict test has the same valuation as the limit. Conversely any finite limit valuation is eventually smaller than L_m. The existence of a passing depth for every ordinary index is unproved. Nonzero models at every depth are compatible with an exactly zero limit.

The degree-two preparation also reduces the old representative-height cost to a linear cost, about $2P$ bits at precision P. This remains larger than the P bits needed for a strict nonzero residue certificate. The fixed rational control $(Z - 1/3)^2$ has zero critical value while its least-residue integer discriminant representatives are nonzero at every even $P \geq 6$. Thus a nonzero integer representative alone cannot prove a nonzero dyadic discriminant.

One sufficient new arithmetic input would be an odd-denominator projective quadratic

$$AZ^2 + 2BZ + C \equiv A\mathcal{W}_r(Z) \pmod{2^P}, \qquad A \text{ odd}, \qquad 0 < |B^2 - AC| < 2^P,$$

at a proved precision for every admitted ordinary r. Then $(B^2 - AC)/A^2 \equiv \delta_r \pmod{2^P}$ cannot vanish modulo 2^P. No depth-independent theorem supplying this inequality has been established. The tested recurrence and exterior-contact identities retain balancing terms and do not force a contradiction. Finite exponential models approximate the actual target at every depth, but their order grows with precision, their clearing polynomial has zeros on the actual chart, and their proved construction-specific height cost does not give the required discriminant bound.

A.7 Status and source map

Claim	Status
Nishibuchi Conjecture 3.9 in its stated parameter range	Resolved in the main text
Sharp uniform ordinary Euler tail exponent $4M + 3$	Proved, with formal coverage
Exact tail factorization and finite polynomial at every depth	Proved by an ordinary argument
Regular-wall emergence and indicated integer simplicity families	Proved within their stated hypotheses
Actual quadratic compression and unbounded stationary approximation	Ordinary proof. Formal scope separate.
Nonzero actual stationary discriminant for every admitted index	Open
Universal simplicity of every G_r	Open
Native 13.2 presentation invariance and Native 13.3 global/completed gluing	Separate open general programs

The tail factorization, regular-wall arguments, finite preparation, coefficient cutoffs and higher-address transversality have separate proofs. The stationary discriminant identity and convergence argument leave the arithmetic separation question open. The source notes and their exact locations are collected at the back.

B Detailed continuation derivations

The following sections develop the detailed arguments behind polynomial lifting, correction torsors, compatible towers and local regularity. Each construction retains its stated hypotheses. The formal companion identifies the corresponding declarations and verification records. The main text distinguishes the completed results from the remaining questions.

B.1 Chapter IX: finite polynomial lifting and shared corrections

The nonlinear Taylor argument supplies the correction formula used in one-step polynomial lifting. The statements concern a fixed finite list of integer polynomials. They hold for every positive integer modulus, including composite moduli and modulus one. No Jacobian-surjectivity assumption is needed.

B.1.1 Statement and notation

Let

$$F = (F_1, \dots, F_e) \in \mathbb{Z}[X_1, \dots, X_d]^e, \quad q \geq 1, \quad L \geq 1, \quad x \in \mathbb{Z}^d, \quad F(x) \equiv 0 \pmod{q^L}.$$

Write $R_q = \mathbb{Z}/q\mathbb{Z}$, let ρ_q denote coordinatewise reduction, and put

$$r_x = F(x)/q^L \in \mathbb{Z}^e, \qquad A_x = DF(x) : \mathbb{Z}^d \longrightarrow \mathbb{Z}^e, \qquad J_x = \rho_q \circ A_x.$$

Here A_x is computed from the actual formal partial derivatives of the input polynomials. The Lean map J_x has domain $\mathbb{Z}^d$ and codomain R_q^e, viewed as integer modules. It factors through reduction to R_q^d. The cokernel below is presented directly using its integer-domain image.

Define the finite obstruction module and its distinguished class by

$$\mathcal{O}_x = R_q^e / \operatorname{im} J_x, \qquad o_x = [\rho_q(r_x)] \in \mathcal{O}_x.$$

The checked criterion is

$$\boxed{o_x = 0 \iff \exists y \in \mathbb{Z}^d : \quad y \equiv x \pmod{q^L}, \qquad F(y) \equiv 0 \pmod{q^{L+1}}.}$$

The residual exists by the lower congruence and is unique because $q > 0$. The quotient is finite since its ambient module R_q^e is finite. The theorem permits zero variables or zero equations as well.

B.1.2 The checked Taylor bridge

For every $P \in \mathbb{Z}[X_1, \dots, X_d]$, integer a, and $x, t \in \mathbb{Z}^d$, Lean proves

$$\boxed{a^2 \mid P(x + at) - P(x) - a \sum_{i=1}^{d} (\partial_i P)(x) t_i.}$$

The proof uses polynomial induction: constants, addition, and multiplication by a variable. The product rule for the actual partial derivatives controls the multiplication step. It does not assume a Taylor identity or a liftability condition.

Taking $a = q^L$, the inequality $2L \geq L + 1$ gives

$$F(x + q^L t) \equiv q^L (r_x + A_x t) \pmod{q^{L+1}}.$$

Since $q^L \neq 0$ in the integers, cancellation in divisibility yields

$$F(x + q^L t) \equiv 0 \pmod{q^{L+1}} \iff \rho_q(r_x) + J_x t = 0.$$

Every integer representative of the lower residue has the form $x + q^L t$, and this correction equation has a solution exactly when $o_x = 0$.

The positive-depth hypothesis is necessary for the general nonlinear theorem. For $F(X) = X^2 - 1$, $q = 2$, $L = 0$, $x = 0$, the Jacobian is zero and the residual class is nonzero, yet $y = 1$ is a solution modulo two in the same residue modulo one. Affine systems retain the previously checked $L \geq 0$ theorem.

B.1.3 Independence of the integer representative

Suppose $x' = x + q^L s$ represents the same lower residue, with exact residual $r_{x'}$. Polynomial evaluation respects coordinatewise congruences, including when applied to each partial derivative. Hence

$$J_{x'} = J_x, \qquad \rho_q(r_{x'}) = \rho_q(r_x) + J_x s.$$

The two cokernels therefore have the same ambient module and the same defining submodule, and

$$[\rho_q(r_{x'})] = [\rho_q(r_x)].$$

Lean states this using one explicit common reduced map, avoiding an implicit comparison between differently indexed quotient types. This establishes independence of the integer representative within the fixed polynomial presentation.

Changing the polynomial presentation is a separate question. Appending a zero equation can change the raw cokernel by adding a copy of R_q, even though it does not change the solutions.

B.1.4 Two polynomial blocks and one shared lift

Let $G \in \mathbb{Z}[X_1, \ldots, X_d]^f$ be a second fixed system with the same variables and the same lower root x. Let $K_x = \rho_q \circ DG(x)$, and define

$$\mathcal{C}_x = \mathbb{Z}^d / (\ker J_x + \ker K_x).$$

This quotient is finite: it is a quotient of the finite image of J_x, or equivalently of the finite image of K_x.

Suppose $u, v \in \mathbb{Z}^d$ are separately valid corrections:

$$F(x + q^L u) \equiv 0 \pmod{q^{L+1}}, \qquad G(x + q^L v) \equiv 0 \pmod{q^{L+1}}.$$

Then

$$\boxed{\begin{array}{c} [u] = [v] \text{ in } \mathcal{C}_x \iff \exists y \equiv x \pmod{q^L} : \\ F(y) \equiv 0 \pmod{q^{L+1}}, \quad G(y) \equiv 0 \pmod{q^{L+1}}. \end{array}}$$

The labels are independent of the choices of valid u and v. An unconditional version asks for separately valid corrections with equal labels. It does not assume that each block is liftable.

Taylor transport turns a common correction t into the simultaneous equations $J_x t = J_x u$ and $K_x t = K_x v$. The previously checked common-quotient theorem gives precisely the displayed equivalence. Separate solvability alone does not imply joint solvability. The controls include $F(X) = X$, $G(X) = X - 2$, starting at $x = 0$ modulo two and lifting to modulus four.

B.2 Chapter IX: correction torsors and exact polynomial lift counts

The correction-digit torsor gives exact prime-field lift counts. The counts apply to distinct next-level residue classes satisfying the actual polynomial equations. They do not count integer representatives, of which there can be infinitely many.

B.2.1 The theorem

Let p be prime, $L \geq 1$, and

$$F \in \mathbb{Z}[X_1, \ldots, X_d]^e, \qquad x \in \mathbb{Z}^d, \qquad F(x) \equiv 0 \pmod{p^L}.$$

Write

$$r_x = F(x)/p^L, \qquad b_x = r_x \bmod p, \qquad A_x = DF(x) \bmod p : \mathbb{F}_p^d \longrightarrow \mathbb{F}_p^e, \qquad \rho_x = \operatorname{rank}_{\mathbb{F}_p} A_x.$$

The actual lift set is

$$\mathcal{L}_{x,L} = \left\{ y \in (\mathbb{Z}/p^{L+1}\mathbb{Z})^d : y \equiv x \pmod{p^L}, \quad F(y) = 0 \right\},$$

where polynomial evaluation in the displayed set is modulo p^{L+1}. Define

$$\mathcal{O}_x = \mathbb{F}_p^e / \operatorname{im} A_x, \qquad o_x = [b_x].$$

Lean proves

$$\boxed{\#\mathcal{L}_{x,L} = \begin{cases} p^{d-\rho_x}, & o_x = 0, \\ 0, & o_x \neq 0, \end{cases} \qquad \#\mathcal{O}_x = p^{e-\rho_x}.}$$

These formulas permit singular Jacobians and zero variables or zero equations. Nonsingularity is not assumed. In particular, rank alone gives the size of a nonempty lift fiber. The residual obstruction determines whether it is empty.

B.2.2 Why these are actual residue-class counts

For every positive integer q, including composite moduli and modulus one, and every $L \geq 0$, the checked map

$$\Phi_{x,L} : (\mathbb{Z}/q\mathbb{Z})^d \longrightarrow \{ y \bmod q^{L+1} : y \equiv x \pmod{q^L} \}, \qquad t \longmapsto x + q^L \widetilde{t}$$

is a bijection. Here $\widetilde{t}$ is the canonical integer representative of the digit vector. The entire residue fiber therefore has q^d elements. Injectivity is proved by cancelling q^L in the corresponding integer divisibility statement. Surjectivity comes from the lower-residue congruence.

The formal type `ActualLifts` is a subtype of these genuine `ZMod (q^(L+1))` residue vectors. Its polynomial predicate is evaluated on canonical integer representatives and tested for divisibility by

q^{L+1}. The checked polynomial congruence theorem makes that predicate independent of the integer representative. Thus using canonical representatives does not discard or duplicate residue classes.

At positive depth, the preceding actual multivariable Taylor theorem gives

$$F(x + p^L\widetilde{t}) \equiv p^L(r_x + DF(x)\widetilde{t}) \pmod{p^{L+1}}.$$

The new bridge proves that the evaluated integer Jacobian reduces to the actual $\mathbb{F}_p$-linear map A_x. Restricting $\Phi_{x,L}$ therefore gives an explicit equivalence

$$\boxed{\{t \in \mathbb{F}_p^d : b_x + A_x t = 0\} \simeq \mathcal{L}_{x,L}.}$$

The proof uses the actual formal partial derivatives of the original polynomial list.

B.2.3 The torsor

Let $\mathcal{T}_x = \{t : b_x + A_x t = 0\}$. Its natural kernel action is

$$k \cdot t = k + t, \qquad k \in \ker A_x.$$

For every pair $u, t \in \mathcal{T}_x$, exactly one kernel vector sends u to t, namely $t - u$. Thus every nonempty correction fiber is a torsor for $\ker A_x$. Choosing one valid digit u gives

$$\mathcal{T}_x \simeq \ker A_x, \qquad t \longmapsto t - u.$$

Lean constructs an explicit `AddTorsor` structure for the digit fiber, proves the unique translation property, and supplies a chosen-point equivalence from the actual residue lift set to the kernel. A basepoint is required for this equivalence, but the translation action itself does not depend on choosing one.

The torsor and residue bijection remain valid over every positive modulus at positive polynomial depth. The displayed powers involving vector-space rank are restricted to prime moduli.

B.2.4 Connecting the old obstruction to the new count

The earlier obstruction used the integer-domain map

$$J_x = \rho_p \circ DF(x) : \mathbb{Z}^d \to \mathbb{F}_p^e.$$

The new count uses $A_x : \mathbb{F}_p^d \to \mathbb{F}_p^e$. Reduction of integer vectors onto finite vectors is surjective, so the two maps have the same image after restricting scalars. Lean constructs a class-preserving integer-linear equivalence

$$\mathbb{F}_p^e / \operatorname{im} J_x \simeq \mathbb{F}_p^e / \operatorname{im} A_x.$$

Consequently the cardinality theorem counts the original obstruction group, preserving its distinguished residual class. It is not merely a formula for a separately introduced comparison object.

Rank-nullity gives $\dim \ker A_x = d - \rho_x$, and the quotient dimension is $e - \rho_x$. Cardinalities of finite vector spaces complete both formulas.

B.3 Chapter IX: compatible polynomial towers and p-adic roots

The nonsingular construction passes from one-step polynomial lifting to an infinite compatible tower and an actual p-adic root. Surjectivity is required only of the reduced Jacobian at the initial root. The proof derives its persistence, constructs the tower, proves convergence and verifies the original polynomial equations at the limit.

B.3.1 Main theorem

Let p be prime, $L \geq 1$, and

$$F \in \mathbb{Z}[X_1, \ldots, X_d]^e, \qquad x \in \mathbb{Z}^d, \qquad F(x) \equiv 0 \pmod{p^L}.$$

Assume the actual reduced Jacobian

$$A_x = DF(x) \bmod p : \mathbb{F}_p^d \longrightarrow \mathbb{F}_p^e$$

is surjective. Then Lean proves that there is a point

$$\boxed{a \in \mathbb{Z}_p^d, \qquad F(a) = 0, \qquad a \equiv x \pmod{p^L}.}$$

Here the coefficients of the original integer polynomials are cast into $\mathbb{Z}_p$, and their multivariable evaluation is exactly zero. This is an existence theorem for a fixed polynomial presentation with the stated Jacobian hypothesis.

The stronger checked statement constructs $z_n \in \mathbb{Z}^d$, $n \geq 0$, with

$$\begin{aligned} z_0 &= x, \\ F(z_n) &\equiv 0 \pmod{p^{L+n}}, \\ z_{n+1} &\equiv z_n \pmod{p^{L+n}}, \\ DF(z_n) \bmod p &= A_x, \\ z_n &\longrightarrow a \quad \text{in } \mathbb{Z}_p^d, \\ a - z_n &\in p^{L+n}\mathbb{Z}_p^d. \end{aligned}$$

The last inclusion retains every prescribed precision. It is a divisibility lower bound, not an assertion that the error has exactly that valuation. An approximation can already equal the limiting root.

B.3.2 Why the single initial hypothesis suffices

The one-step Taylor theorem already supplies the exact correction equation

$$b_n + A_{z_n} t = 0, \qquad b_n = F(z_n)/p^{L+n} \bmod p.$$

Surjectivity supplies a correcting digit for every residual b_n. The chosen correction gives an actual new integer point z_{n+1}, using the proved nonlinear Taylor remainder.

Every coordinate change is divisible by p^{L+n}, hence by p. Each formal partial derivative is itself an integer polynomial, so its value is unchanged modulo p. Therefore

$$A_{z_{n+1}} = A_{z_n} = A_x.$$

The proof assumes no separate surjectivity or solvability statement at later levels. A dependent recursion chooses each next point from the proved one-step existence theorem. It produces one compatible sequence, rather than unrelated witnesses at different precisions.

The integer tower construction works more generally for every positive modulus q, including composite q and $q = 1$, with a surjective map over $\mathbb{Z}/q\mathbb{Z}$. The p-adic completion and the rank-based branching formulas in this block use prime p.

B.3.3 Convergence and exact polynomial vanishing

Compatibility implies, for $m \geq n$,

$$p^{L+n} \mid z_m - z_n.$$

After casting to $\mathbb{Z}_p$, this bounds each coordinate distance by $p^{-(L+n)}$, so the sequence is Cauchy. Completeness supplies its limit. Closed norm bounds show that the limit retains the congruence at every stage.

The generic convergence theorem is proved independently of the polynomial application. It also proves

$$p^{L+n} \mid v_n \text{ for all } n \quad \Longrightarrow \quad v_n \longrightarrow 0 \text{ in } \mathbb{Z}_p.$$

Apply this to each integer sequence $F_i(z_n)$. Continuity of multivariable polynomial evaluation also gives $F_i(z_n) \to F_i(a)$. Uniqueness of limits then yields $F_i(a) = 0$.

The cast-evaluation identity is explicitly checked, so the continuous function is the evaluation of the original polynomials. Convergence and polynomial vanishing are conclusions, not assumptions of the main existence theorem.

B.3.4 Exact number of choices at each level

Surjectivity implies

$$\operatorname{rank}_{\mathbb{F}_p} A_x = e, \qquad e \leq d.$$

Combining this with the preceding exact residue-lift count gives
