$$\boxed{\#\mathcal{L}_{z_n, L+n} = p^{d-e} \quad \text{for every } n.}$$

These are distinct solutions modulo p^{L+n+1} lying above the selected point modulo p^{L+n}. The original finite obstruction group at each smooth point has cardinality one.

The theorem constructs one path through these finite choices. When $d > e$, it does not claim that all paths have the same limit. The generic uniqueness theorem concerns the limit of a fixed sequence only.

B.3.5 Boundary controls

The positive control theorems and rejected invalid proofs cover three distinctions.

1. **An initial lift does not guarantee an infinite tower without the Jacobian condition.** $X^2 - 5$ has the odd lower root modulo two and a lift modulo four, but no root modulo eight. Lean proves that no integer tower can continue through all precisions in this example.
2. **Surjective rectangular Jacobians do not give uniqueness of all roots.** The system $F(X, Y) = X$ has a surjective Jacobian and distinct dyadic roots $(0, 0)$ and $(0, 2)$, both in the same residue modulo two.

3. **The retained initial precision cannot be increased without justification.** For $F(X) = X - 2$, zero is a lower root modulo two with surjective derivative, but its exact root two does not retain zero modulo four.

The controls are theorem checks of these explicit examples. They supplement the universal proof audit and do not replace it.

For several polynomial blocks, the hypothesis applies to their combined system. Surjectivity of each block separately does not imply surjectivity of the combined Jacobian or shared liftability. The preceding shared-correction obstruction remains relevant in that situation.

B.4 Polynomial roots under coefficient perturbation

The argument proves uniqueness of roots for square systems and nearby-root stability for finite systems of integer polynomials. The polynomials and their partial derivatives are evaluated directly. No root-uniqueness or perturbation-stability premise is assumed.

B.4.1 Notation

Let p be prime, $L \geq 1$, and

$$F, H \in \mathbb{Z}[X_1, \ldots, X_d]^e, \qquad x \in \mathbb{Z}^d.$$

Write

$$A_x = DF(x) \bmod p : \mathbb{F}_p^d \longrightarrow \mathbb{F}_p^e, \qquad B_L(x) = x + p^L \mathbb{Z}_p^d.$$

For an integer c, the perturbed system is the actual polynomial list

$$G = F + cH.$$

There is no restriction on the sign of c, and $c = 0$ is allowed. Divisibility conclusions give lower bounds on precision and allow zero differences.

B.4.2 1. Unique roots for square systems

If $d = e$, A_x is surjective, and $F(x) \equiv 0 \pmod{p^L}$, then

$$\boxed{\exists!\, a \in B_L(x) : F(a) = 0.}$$

The stronger comparison lemma proves that any two exact roots of F in $B_L(x)$ coincide, without needing a separate lower-root hypothesis.

Proof implemented. Map every arbitrary p-adic root into the actual residue rings $\mathbb{Z}/p^n\mathbb{Z}$, and choose its canonical integer representative. Evaluation commutes with reduction, so these representatives are genuine finite polynomial roots. The preceding count theorem gives exactly $p^{d-d} = 1$ next-level residue lift. Inductively any two roots agree at every precision. The p-adic residue maps separate points, so the roots are equal. Existence is the preceding checked tower theorem.

This extends uniqueness from the limit of a selected sequence to **all exact roots in the prescribed ball**.

B.4.3 2. Coefficient perturbations preserve smooth liftability

If $p^L \mid c$, the actual identities give

$$G(x) = F(x) + cH(x), \qquad DG(x) \equiv DF(x) \pmod{p}.$$

Thus if $F(x) \equiv 0 \pmod{p^L}$ and A_x is surjective, then

$$\exists b \in B_L(x) : G(b) = 0.$$

This theorem allows rectangular systems. The evaluation, derivative and Jacobian identities are proved from the polynomial definition $G_i = F_i + C(c)H_i$, rather than supplied as hypotheses. Algebraic congruence helpers also permit composite moduli. Exact p-adic root existence uses prime p.

B.4.4 3. Nearby roots for rectangular systems

Let $M \geq 1$ and $p^M \mid c$. Suppose A_x is surjective and $a \in \mathbb{Z}_p^d$ is an exact root of F with $a \equiv x \pmod{p}$. Then

$$\boxed{\exists b \in \mathbb{Z}_p^d : \quad G(b) = 0, \qquad b \equiv a \pmod{p^M}.}$$

No uniqueness is claimed when $d > e$.

Proof implemented. Truncate a to an integer vector y modulo p^M. It is an actual lower root of F, and its reduced Jacobian agrees with A_x. Apply the coefficient-perturbed existence theorem at precision M, then combine the two congruences through y.

B.4.5 4. Full precision for the unique root of a square system

Suppose $d = e$, $M \geq L \geq 1$, $p^M \mid c$, and A_x is surjective. If

$$a, b \in B_L(x), \qquad F(a) = 0, \qquad G(b) = 0,$$

then

$$\boxed{b - a \in p^M \mathbb{Z}_p^d.}$$

In particular, for $G = F + p^M H$, no p-adic digits below depth M are changed in the selected root.

The formalization also proves a combined existence theorem. Starting only with $F(x) \equiv 0 \pmod{p^L}$, it constructs an original root $a \in B_L(x)$ and proves that there is exactly one $b \in B_L(x)$ satisfying $G(b) = 0$ and $b \equiv a \pmod{p^M}$. The comparison theorem shows that the precision bound holds for every root of G in that ball, so uniqueness is not obtained merely by adding a restrictive displacement condition.

Proof implemented. Section 3 produces a nearby root b'. Since $M \geq L$, it belongs to $B_L(x)$. The perturbed Jacobian remains surjective, and square uniqueness identifies b' with the arbitrary root b.

B.5 Chapter IX: continuous p-adic parameter charts

B.5.1 Main statement

Let p be prime, $L \geq 1$, $e, q \geq 0$, and

$$F \in \mathbb{Z}[X_1, \ldots, X_{e+q}]^e, \qquad x \in \mathbb{Z}^{e+q}, \qquad F(x) \equiv 0 \pmod{p^L}.$$

Assume the actual reduced Jacobian

$$A_x = DF(x) \bmod p : \mathbb{F}_p^{e+q} \longrightarrow \mathbb{F}_p^e$$

is surjective. All vector congruences are coordinatewise.

There is a coordinate permutation σ, with $(\sigma z)_i = z_{\sigma(i)}$. Write $\sigma z = (y, t)$, using e solved coordinates and q free coordinates. Define

$$(y_0, t_0) = \sigma x, \qquad B = x + p^L \mathbb{Z}_p^{e+q}, \qquad T = t_0 + p^L \mathbb{Z}_p^q, \qquad \mathcal{R} = \{z \in B : F(z) = 0\}.$$

There is a homeomorphism

$$h : T \xrightarrow{\sim} \mathcal{R}, \qquad h^{-1}(z) = \text{free}(\sigma z).$$

Equivalently, a continuous function $\phi : T \to y_0 + p^L \mathbb{Z}_p^e$ gives the entire root locus through $\sigma h(t) = (\phi(t), t)$. Every parameter has exactly one corresponding root in B. For every $N \geq 0$,

$$\boxed{h(t) \equiv h(u) \pmod{p^N} \iff t \equiv u \pmod{p^N}.}$$

The coordinate choice is a conclusion. A suitable minor and a preexisting chart are not hypotheses. The theorem covers the original root locus after undoing the coordinate reordering. Since x is an approximate root, it does not assert $\phi(t_0) = y_0$ unless $F(x) = 0$ exactly. The cases $p = 2$, $L = 1$, $e = 0$, and $q = 0$ are included.

B.5.2 Supporting theorems

For a rectangular integer polynomial system with a surjective reduced Jacobian at x, and $L \geq 1$,

$$F(x + p^L \mathbb{Z}_p^d) = F(x) + p^L \mathbb{Z}_p^e.$$

This covers arbitrary p-adic output targets. No lower-root hypothesis is needed.

When $d = e$, the actual restricted polynomial map is a homeomorphism. Moreover, for arbitrary $a, b \in x + p\mathbb{Z}_p^d$ and every $N \geq 0$,

$$F(a) \equiv F(b) \pmod{p^N} \iff a \equiv b \pmod{p^N}.$$

Its inverse therefore preserves every congruence depth.

B.5.3 Proof structure

1. The actual integer Taylor formula gives one additional input digit from one additional output digit when the reduced square Jacobian is surjective. Its finite domain and codomain have the same size, so it is injective. Induction gives every integer precision.
2. Canonical integer truncations of arbitrary p-adic vectors preserve evaluation modulo each power of p. Applying the integer result to truncations proves the p-adic congruence equivalence.
3. Subtracting an integer target from the constant terms leaves the actual Jacobian unchanged. The previous root-lifting theorem supplies a preimage. The image of the compact input ball is closed and contains the convergent truncations of every admissible p-adic target, hence contains the target. No compatibility of arbitrarily chosen preimages is assumed.

4. In the square case, the resulting continuous bijection from a compact ball to a Hausdorff ball is a homeomorphism. Its forward map is actual polynomial evaluation, and its inverse solves the output equation.
5. For a specified surjective solved-variable block, apply this inverse to the actual augmented polynomial map
$$\Psi(y,t) = (F(y,t),t).$$
Its derivative has an identity free-coordinate block. The inverse at $(0,t)$ gives the root. The lower-root congruence places this target in the output ball. Injectivity proves uniqueness and full graph coverage. Projection identifies the inverse chart and reflects congruences.
6. The columns of a surjective finite-dimensional linear map contain a basis. Select those columns and extend their injection to a coordinate permutation. Polynomial renaming by σ^{-1} transports actual evaluations and partial derivatives. The fixed-coordinate chart then gives the main theorem on the entire original root locus.

B.5.4 Scope

Coefficients are integers. Roots and parameters are arbitrary p-adic points. This supplies continuous polynomial parameter charts. Analyticity, differentiability, arbitrary p-adic coefficient interfaces, weighted lifting for nonunit Jacobians, and first-order root-motion estimates are separate.

Full Jacobian surjectivity need not allow an arbitrary prescribed parameter choice. At the dyadic origin, $F(X,T) = X^2 - T$ has a surjective full Jacobian but zero X-derivative. Prescribing $T = 2$ gives no root even modulo 4. Suitable coordinates instead solve for T.

B.5.5 Verification and provenance

The eight new mathematical modules contain 75 declarations: 60 theorems and 15 definitions. The active polynomial dependency set contains 25 mathematical modules. Counts including inherited support and theorem contracts are recorded separately in the final report.

The exact universal statements are Lean theorems, not conclusions from sampled numerical tests. The fresh gate rebuilds project sources with warnings treated as errors, checks expanded theorem contracts, audits explicit declarations, and checks rejected invalid extensions. Only propext, Classical.choice, and Quot.sound are permitted as axiom dependencies.

B.6 Chapter IX: weighted nonlinear lifting

B.6.1 The theorem

Let p be prime, $R = \mathbb{Z}_p$, $K = \mathbb{Q}_p$, and $d, s, r \in \mathbb{N}$. Let $F = (F_1, \ldots, F_d) \in R[X_1, \ldots, X_d]^d$, $a \in R^d$, and let
$$J = DF(a) = \left(\partial_j F_i(a)\right)_{i,j}.$$

Assume

$$J \in \mathrm{GL}_d(K), \qquad p^s J^{-1} \in M_d(R), \qquad F(a) \in p^r R^d, \qquad r > 2s.$$

Then

$$\boxed{\exists!\, b \in a + p^{s+1}R^d :\ F(b) = 0,} \qquad \boxed{b - a \in p^{r-s}R^d.}$$

All vector divisibility assertions are coordinatewise. The uniqueness predicate is the entire ball of depth $s+1$: competitors need not be assumed to have depth $r-s$. The theorem permits arbitrary integral p-adic coefficients and centers, every prime including two, and dimension zero. It retains the supplied inverse-denominator exponent s. There is no replacement by a determinant valuation. Integrality of $p^s J^{-1}$ is expressed in Lean by existence of an integral matrix with exactly that image under the coefficient inclusion $R \hookrightarrow K$.

B.6.2 Proof

Write $A = p^s J^{-1} \in M_d(R)$. Then

$$AJ = JA = p^s I.$$

The formal matrix bridge proves the equivalence with the stated fraction-field hypotheses, including nonsingularity. In particular, multiplication by A is injective, since multiplication by J sends $Av = 0$ to $p^s v = 0$.

Put $G = AF$, $t = p^{s+1}$, and $k = r - (2s+1)$. Taylor expansion of the actual preconditioned polynomials gives one polynomial system Q such that

$$G(a + tu) = G(a) + p^{2s+1}u + p^{2s+2}Q(u), \qquad Q(0) = 0.$$

This expansion is proved first over every commutative ring. Its remainder is a polynomial valid for every u, not a pointwise quotient depending on u. Since $G(a) \in p^r R^d$, it can be written $p^{2s+1}C$ with $C \in p^k R^d$. Thus

$$G(a + tu) = p^{2s+1}\big(C + u + pQ(u)\big).$$

Integral polynomial evaluation is 1-Lipschitz in the supremum p-adic metric. Consequently $T(u) = -C - pQ(u)$ has contraction constant $|p|_p < 1$ on the complete space R^d, and has exactly one fixed point u.

For completeness, the sharp precision is additional to this fixed-point existence. Inductively, if $u \in p^n R^d$, then polynomial congruence and $Q(0) = 0$ imply $Q(u) \in p^n R^d$. For $n < k$, the equation $u = -C - pQ(u)$ therefore gives $u \in p^{n+1}R^d$. Starting at $n = 0$, this proves $u \in p^k R^d$. Hence $b = a + tu$ satisfies

$$b - a \in p^{s+1+k}R^d = p^{r-s}R^d.$$

The normalization and injectivity of A give $F(b) = 0$.

Every other $z \in a + p^{s+1}R^d$ has the form $a + tw$. If $F(z) = 0$, the same normalization, with cancellation of the nonzero scalar p^{2s+1}, gives $w = T(w)$. Fixed-point uniqueness implies $w = u$, hence $z = b$.

B.6.3 Boundary and sharpness

The strict inequality cannot in general be weakened to $r \geq 2s$: for $p = 2$, $F(X) = X^2 + 3$, and $a = 1$, we have $F(a) = 4$, $DF(a) = 2$, and may take $s = 1, r = 2$. Yet no root exists in $\mathbb{Z}_2$, since there is none modulo eight. The auxiliary Lean controls prove this obstruction and the exact residual depth.

The displacement exponent cannot uniformly be increased by one. For $F(X) = p^s X + p^r$ at $a = 0$, with $r > 2s$, its root is $b = -p^{r-s}$, which is not divisible by p^{r-s+1}. The controls prove the linear root and the absence of that extra digit for all primes.

B.7 Chapter IX: weighted first-order root motion

B.7.1 The theorem

Let p be prime, $R = \mathbb{Z}_p$, $K = \mathbb{Q}_p$, and $d, s, M \in \mathbb{N}$. Let $F, H \in R[X_1, \dots, X_d]^d$, let $a \in R^d$ satisfy $F(a) = 0$, and set

$$J = DF(a), \qquad G = F + p^M H.$$

Assume

$$J \in \mathrm{GL}_d(K), \qquad p^s J^{-1} \in M_d(R), \qquad M > 2s.$$

Then there is exactly one root b of G in $a + p^{s+1}R^d$. It satisfies

$$b - a \in p^{M-s}R^d,$$

and there is $\varepsilon \in p^{2M-3s}R^d$ such that, in K^d,

$$\boxed{b - a = -p^M J^{-1} H(a) + \varepsilon.}$$

The inverse in this formula belongs to the original Jacobian $DF(a)$. The theorem constructs the perturbed root from these hypotheses and proves uniqueness throughout the full ball of depth $s + 1$. It does not require an additional Jacobian hypothesis on G. Coefficients and centers are arbitrary integral p-adic elements. Every prime and finite square dimension are included, including $p = 2$ and dimension zero.

The error depth exceeds the displacement depth by

$$(2M - 3s) - (M - s) = M - 2s \geq 1.$$

Thus the first-order term determines strictly more digits than the displacement bound alone. These are guaranteed divisibility bounds. Equality of valuations is not asserted for every system.

B.7.2 Root construction with the original inverse

Write $A = p^s J^{-1} \in M_d(R)$, so $AJ = JA = p^s I$. Let $t = p^{s+1}$ and $k = M - (2s + 1) \geq 0$. The actual polynomial Taylor and difference identities give polynomial systems Q_F, Q_H, both vanishing at zero, such that

$$(AF)(a + tu) = p^{2s+1}u + p^{2s+2}Q_F(u),$$
$$(AH)(a + tu) = (AH)(a) + tQ_H(u).$$

Consequently

$$(AG)(a + tu) = p^{2s+1}\big(C + u + pQ(u)\big),$$

where

$$C = p^k AH(a), \qquad Q = Q_F + p^{M-s-1}Q_H, \qquad Q(0) = 0.$$

All exponents are nonnegative under $M > 2s$. Actual integral polynomial evaluation is 1-Lipschitz, so $u \mapsto -C - pQ(u)$ is a strict contraction on the complete space R^d. Its unique fixed point inherits the depth k of C, because $Q(0) = 0$. Thus $b = a + tu$ has displacement depth $s + 1 + k = M - s$.

The certificate $JA = p^s I$ makes multiplication by A injective, so the normalized zero is an actual root of G. Every root in $a + tR^d$ has the form $a + tw$ and satisfies the same fixed-point equation. This proves uniqueness on the entire stated ball using the original matrix certificate.

B.7.3 The first-order error

Put $\delta = b - a$ and $L = M - s$. The displacement form of Taylor's theorem, proved over any commutative ring, gives

$$E_F = (AF)(b) - (AF)(a) - p^s\delta \in p^{2L}R^d.$$

Polynomial congruence gives

$$E_H = (AH)(b) - (AH)(a) \in p^L R^d.$$

Since $F(a) = 0$ and $G(b) = 0$,

$$p^s\delta + p^M AH(a) = -E_F - p^M E_H.$$

We have $M + L \geq 2L$, so the right side lies in $p^{2L}R^d$. Cancelling the nonzero scalar p^s proves the integral estimate

$$\delta + p^{M-s}AH(a) \in p^{2M-3s}R^d.$$

Define this integral vector to be ε. Under $R \hookrightarrow K$, the exact identity $p^{M-s}A = p^M J^{-1}$ gives the displayed first-order formula. The Lean bridge checks matrix evaluation and all coefficient inclusions explicitly.

B.7.4 Sharpness and the strict threshold

For $p = 2$, take $F(X) = X + X^2$, $H(X) = 1$, $a = 0$, $s = 0$, $M = 1$. There is a unique root $b \in 2\mathbb{Z}_2$ of $X + X^2 + 2$. Its equation gives $b + 2 = -b^2$. It also forces $b \equiv 2 \pmod 4$. Therefore

$$v_2(b + 2) = 2 = 2M - 3s.$$

The accompanying Lean controls show that the error is divisible by four and is not divisible by eight. This refutes a uniform replacement of $2M - 3s$ by $2M - 3s + 1$, even for a one-variable unit Jacobian.

The prior strict-threshold example also applies to perturbations: take $F(X) = X^2 - 1$, $H(X) = 1$, $a = 1$, $p = 2$, $s = 1$, $M = 2$. Then $F(a) = 0$, $DF(a) = 2$, and $F + 2^2H = X^2 + 3$ has no root modulo eight, hence none in $\mathbb{Z}_2$. The new explanatory identification uses the previously checked no-root polynomial. The strict inequality $M > 2s$ cannot uniformly be replaced by $M \geq 2s$.

B.8 Chapter IX: prescribed-parameter polynomial lifting

B.8.1 Setup and exact lift set

Let $q > 0$, $L \geq 1$, and $m, k, e \geq 0$. Write $S = \mathbb{Z}/q\mathbb{Z}$. Let

$$F \in \mathbb{Z}[Y_1, \ldots, Y_m, T_1, \ldots, T_k]^e, \qquad x = (y_0, t_0) \in \mathbb{Z}^{m+k}, \qquad F(x) \equiv 0 \pmod{q^L}.$$

The actual lower root supplies the unique integral residual

$$r = q^{-L}F(x) \in \mathbb{Z}^e, \qquad \bar{r} = r \bmod q \in S^e.$$

Let the actual reduced Jacobian blocks be

$$J = (D_Y F)(x) \bmod q : S^m \to S^e, \qquad K = (D_T F)(x) \bmod q : S^k \to S^e.$$

For a prescribed parameter digit $v \in S^k$, choose its canonical integral representative $\widehat{v}$. Define $\mathcal{L}_v$ to be the set of actual residue vectors $z \in (\mathbb{Z}/q^{L+1}\mathbb{Z})^{m+k}$ satisfying

$$z \equiv x \pmod{q^L}, \qquad F(z) \equiv 0 \pmod{q^{L+1}}, \qquad z_T \equiv t_0 + q^L \widehat{v} \pmod{q^{L+1}}.$$

The formal predicate uses canonical integer representatives for evaluation and the lower congruence. The previously checked polynomial congruence theorem and digit-to-residue equivalence establish the actual residue-class interpretation. Changing an integral representative of a parameter digit by a multiple of q does not change its prescribed residue modulo q^{L+1}.

B.8.2 The obstruction theorem

Define the finite solved-block cokernel and its parameter-dependent class by

$$\mathcal{C}_x = S^e / \operatorname{im} J, \qquad o_x(v) = [\bar{r} + Kv] \in \mathcal{C}_x.$$

Then

$$\boxed{\mathcal{L}_v \neq \varnothing \iff o_x(v) = 0.}$$

More precisely, the checked digit-to-lift equivalence is

$$\boxed{\mathcal{L}_v \cong \{u \in S^m : Ju = -\bar{r} - Kv\}.}$$

It sends a solved digit u to the actual next residue represented by $x + q^L(\widehat{u}, \widehat{v})$. The obstruction depends on the solved block J, not on the range of the full map $(J\ K)$.

Every nonempty $\mathcal{L}_v$ has a checked free and transitive action of $\ker J$. The action is defined without choosing a base lift. Choosing one valid solved digit then gives an explicit bijection $\mathcal{L}_v \cong \ker J$. In particular, for every positive modulus,

$$o_x(v) = 0 \quad \Longrightarrow \quad \#\mathcal{L}_v = \#\ker J.$$

These results permit composite q, the degenerate modulus $q = 1$, and zero dimensions. Neither J nor the full reduced Jacobian is assumed surjective.

B.8.3 Exact prime-field counts

When $q = p$ is prime, put $\rho = \operatorname{rank}_{\mathbb{F}_p} J$. Then

$$\boxed{\#\mathcal{L}_v = \begin{cases} p^{m-\rho}, & o_x(v) = 0, \\ 0, & o_x(v) \neq 0, \end{cases}} \qquad \boxed{\#\mathcal{C}_x = p^{e-\rho}.}$$

The count is of distinct actual residue classes at level $L+1$. The solved dimension m, rather than the total number $m+k$ of variables, appears in the exponent because the parameter digit is fixed. These rank formulas are asserted only over prime fields.

The main wrapper assumes only the original lower polynomial congruence. It constructs one residual r and supplies the criterion and count uniformly for every v, together with the exact obstruction cardinality.

B.8.4 Proof and dependency chain

The actual derivative calculation gives

$$(DF(x) \bmod q)(u,v) = Ju + Kv.$$

Taylor expansion at depth $L \geq 1$ makes the quadratic remainder divisible by q^{L+1}. Therefore the digit (u,v) is a polynomial lifting correction exactly when

$$\bar{r} + Ju + Kv = 0.$$

The quotient class $[\bar{r} + Kv]$ vanishes exactly when this equation admits u. This uses additive inverses in the image of J, so the sign agrees with the actual Taylor equation.

The earlier unrestricted correction-digit equivalence is then restricted to the predicate that the parameter digit equals v. Taking free coordinates commutes with forming digit residues, and digit residues are injective in the digit. Consequently the restricted equivalence enforces exactly the actual parameter residue condition on $\mathcal{L}_v$.

Translation by $\ker J$ acts freely and transitively on the solved-digit fiber. Transporting this explicit action through the residue equivalence yields the torsor on $\mathcal{L}_v$. Rank-nullity over $\mathbb{F}_p$ then gives the two displayed cardinalities. No numerical enumeration is used to establish the general theorem.

B.8.5 Why the solved block matters

Take $F(Y,T) = T$, $q = 2$, $L = 1$, and $x = (0,0)$. The full Jacobian $(0\ 1)$ is surjective, but $J = 0$. Prescribing $v = 1$ forces $T \equiv 2 \pmod 4$, which cannot satisfy $F = 0 \pmod 4$. Prescribing $v = 0$ gives exactly two lifts, corresponding to $Y \equiv 0, 2 \pmod 4$.

The Lean controls check this actual polynomial example. Thus full-Jacobian surjectivity alone does not make every prescribed coordinate choice admissible. The automatic coordinate selection in the earlier chart theorem is compatible with this obstruction.

B.9 Chapter IX: compatible towers with prescribed parameters

The construction gives actual compatible polynomial towers from initial solved-block surjectivity, for every compatible integer parameter path. For a prime base, it constructs such a path for every p-adic parameter in the initial ball and proves an exact polynomial endpoint with all retained precisions. The formal companion identifies the six supporting modules and their recorded compiler and axiom-audit results.

B.9.1 Statement and notation

Let $q > 0$, $L \geq 1$, and

$$F \in \mathbb{Z}[Y_1, \ldots, Y_m, T_1, \ldots, T_k]^e, \qquad x = (y_0, t_0) \in \mathbb{Z}^{m+k}, \qquad F(x) \in q^L \mathbb{Z}^e.$$

Write $S_q = \mathbb{Z}/q\mathbb{Z}$, and let the actual reduced Jacobian blocks be

$$J_x = D_Y F(x) \bmod q : S_q^m \longrightarrow S_q^e, \qquad K_x = D_T F(x) \bmod q : S_q^k \longrightarrow S_q^e.$$

Assume J_x is surjective. A vector divisibility condition below is coordinatewise.

Integer prescribed-path theorem. For every supplied path $t : \mathbb{N} \to \mathbb{Z}^k$ satisfying

$$t(0) = t_0, \qquad t(n+1) - t(n) \in q^{L+n} \mathbb{Z}^k,$$

there is a single tower $z : \mathbb{N} \to \mathbb{Z}^{m+k}$ with

$$z(0) = x, \qquad \text{free}(z(n)) = t(n),$$

$$F(z(n)) \in q^{L+n} \mathbb{Z}^e, \qquad z(n+1) - z(n) \in q^{L+n} \mathbb{Z}^{m+k}.$$

The parameter equality is exact in integers. For $a \leq b$,

$$z(b) - z(a) \in q^{L+a} \mathbb{Z}^{m+k}, \qquad DF(z(n)) \bmod q = DF(x) \bmod q.$$

Consequently $J_{z(n)} = J_x$ at every level. No later surjectivity or per-step solvability is assumed. This theorem includes positive composite bases and $q = 1$.

Arbitrary p-adic target theorem. Now let $q = p$ be prime. For every

$$\tau \in t_0 + p^L \mathbb{Z}_p^k,$$

there are a compatible integer tower z as above and $b \in \mathbb{Z}_p^{m+k}$ such that

$$z(n) \longrightarrow b, \qquad F(b) = 0, \qquad \text{free}(b) = \tau, \qquad b - z(n) \in p^{L+n} \mathbb{Z}_p^{m+k} \quad (n \geq 0).$$

A compatible integer parameter path converging to τ is constructed in the proof, with its initial representative fixed exactly. A separate theorem accepts every supplied compatible integer path with limit τ and retains its exact coordinates in the constructed tower.

Exact branching. At any stage n, put $N = L + n$. For every parameter digit $v \in \mathbb{F}_p^k$, let

$$\mathcal{L}_{n,v} = \left\{ \bar{w} \in (\mathbb{Z}/p^{N+1}\mathbb{Z})^{m+k} : \begin{array}{l} \bar{w} \equiv z(n) \pmod{p^N}, \\ F(\bar{w}) = 0, \\ \text{free}(\bar{w}) = t(n) + p^N v \pmod{p^{N+1}} \end{array} \right\}.$$

Here $p^N v$ means any integer representative of v, multiplied by p^N. The residue class does not depend on the representative. Then

$$\#\mathcal{L}_{n,v} = p^{m-e} \qquad \text{for every } n \text{ and every } v.$$

Surjectivity implies $e \le m$. This is a count of distinct actual next-level residue classes. It does not count integer representatives or entire infinite towers.

Square solved-block uniqueness. If $m = e$, every prescribed τ has exactly one root in the original ball:

$$\exists!\, b \in x + p^L \mathbb{Z}_p^{e+k} : \quad F(b) = 0, \qquad \mathrm{free}(b) = \tau.$$

Thus all valid integer parameter approximations and all lifting choices with the same target have the same endpoint. This does not assert uniqueness of the integer representatives in the tower. All prime statements include $p = 2$.

B.9.2 Proof

At depth $N \ge 1$, suppose $F(a) = q^N r$ and a desired next integer parameter target satisfies $t' - \mathrm{free}(a) = q^N w$, with $w \in \mathbb{Z}^k$. Surjectivity supplies a solved digit $u \in S_q^m$ satisfying

$$J_a u = -\bar{r} - K_a \bar{w}.$$

Choose an integer representative $\widetilde{u}$, and set

$$a' = a + q^N(\widetilde{u}, w).$$

The parameter quotient is the supplied integer w. Therefore $\mathrm{free}(a') = t'$ exactly. The checked polynomial Taylor identity gives

$$F(a') \equiv F(a) + q^N DF(a)(\widetilde{u}, w) \equiv 0 \pmod{q^{N+1}}.$$

Its quadratic remainder is divisible by q^{2N}, and $2N \ge N + 1$. Also $a' \equiv a \pmod{q}$, so evaluation of every polynomial partial derivative gives the same reduced Jacobian. Induction on the level, carrying the root, exact parameters, and fixed solved Jacobian as its state, constructs the entire integer tower. The existence proof uses ordinary classical choice. It does not supply an optimized computational lifting algorithm.

For a p-adic target τ, use $t(0) = t_0$ and, for $n \ge 1$, the canonical integer representatives of $\tau \bmod p^{L+n}$. The initial congruence hypothesis and the truncation precision imply

$$\tau - t(n) \in p^{L+n} \mathbb{Z}_p^k.$$

Subtracting successive precision relations gives compatibility in $\mathbb{Z}_p$. The checked faithful integer-divisibility theorem gives compatibility in $\mathbb{Z}$. These precision relations also give convergence to τ.

The compatible vector-tower completion theorem constructs b, proves convergence, and retains every stage precision. Continuous polynomial evaluation and the increasing root precision give $F(b) = 0$. Each parameter coordinate has both the corresponding coordinate of b and τ as its limit, so uniqueness of limits gives exact parameter equality.

For every proposed next parameter digit, the previously checked obstruction is $[\bar{r} + K_a v] \in S_p^e / \operatorname{im} J_a$. The fixed solved Jacobian is surjective, so this class vanishes for every digit at every stage. The actual lift fiber is a torsor for $\ker J_a$. Rank-nullity gives its cardinality p^{m-e}.

When $m = e$, the new solved-Jacobian definition is definitionally the existing square block used by the checked continuous parameter chart. Every root in the initial ball with the given parameters is that

chart point. Applying this to any two roots proves equality, including endpoints obtained by different constructions.

B.9.3 Scope controls

The inherited checked example $F(Y,T)=T$, $p=2$, $x=0$, $L=1$ has a surjective full Jacobian but zero solved block. Prescribing parameter digit 1 forces $T=2 \pmod 4$, so no next root exists. Full-Jacobian surjectivity cannot replace the hypothesis on the prescribed solved block.

The new checked example $F(Y_1,Y_2,T)=Y_1$ has a surjective solved block $(1,0)$. Nevertheless $(0,0,0)$ and $(0,2,0)$ are distinct exact roots in the same modulo-two ball with identical parameters. Uniqueness therefore requires the square solved case. The corresponding negative control deliberately attempts the stronger false conclusion and must be rejected by Lean.

Depth $L \geq 1$ is essential for the Taylor step used here. The general singular case can have a nonzero next obstruction after an earlier zero obstruction. Neither the finite one-step criterion nor this smooth theorem establishes unrestricted singular persistence.

B.10 Chapter IX: simultaneous coefficient and parameter deformation

The construction combines coefficient perturbation with prescribed parameter motion. The original solved Jacobian controls existence, local uniqueness, displacement and the first-order error. The formal companion identifies the four supporting modules and their recorded verification scope.

B.10.1 The theorem

Let p be any prime, $R=\mathbb{Z}_p$, and $Q=\mathbb{Q}_p$. Let

$$F,H \in R[Y_1,\dots,Y_e,T_1,\dots,T_k]^e, \qquad a=(y_0,t_0)\in R^{e+k}, \qquad F(a)=0.$$

Here $e,k\geq 0$ are arbitrary finite dimensions. There are as many solved coordinates as equations. Define the actual derivative blocks at the original root:

$$J=D_Y F(a)\in M_e(R), \qquad K=D_T F(a)\in M_{e\times k}(R).$$

Suppose, for natural numbers s,M, that

$$J\in \mathrm{GL}_e(Q), \qquad p^s J^{-1}\in M_e(R), \qquad M>2s.$$

For every $v\in R^k$, set

$$\tau=t_0+p^M v, \qquad G=F+p^M H.$$

Then there is exactly one $y\in y_0+p^{s+1}R^e$ with

$$G(y,\tau)=0.$$

It satisfies

$$y-y_0\in p^{M-s}R^e$$

and there is an integral vector $\varepsilon\in p^{2M-3s}R^e$ such that, in Q^e,

$$\boxed{y-y_0=-p^M J^{-1}\big(H(a)+Kv\big)+\varepsilon.}$$

The same original exponent s appears throughout. No inverse or rank assumption on the perturbed Jacobian is imposed. The statement includes arbitrary integral p-adic coefficients and centers, the dyadic prime, and zero dimensions.

The full-point theorem constructs $b = (y, \tau)$ and also proves

$$b - a \in p^{M-s} R^{e+k} \cap p^{s+1} R^{e+k}.$$

Parameter equality $b_T = \tau$ is exact. Uniqueness concerns every root in the stated solved-coordinate ball with these parameters, not only roots obtained by the construction. No global uniqueness is claimed.

B.10.2 Actual augmented system

Define polynomial systems with $e + k$ equations and variables by

$$\mathcal{F}(Y, T) = \big(F(Y, T), T - t_0\big), \qquad \mathcal{H}(Y, T) = \big(H(Y, T), -v\big).$$

Both are actual polynomials over R. Direct evaluation proves

$$\mathcal{F}(a) = 0, \qquad (\mathcal{F} + p^M \mathcal{H})(b) = 0 \iff F(b) + p^M H(b) = 0 \text{ and } b_T = t_0 + p^M v.$$

Actual polynomial partial differentiation gives

$$D\mathcal{F}(a) = B = \begin{pmatrix} J & K \\ 0 & I_k \end{pmatrix}.$$

These identities are proved from evaluation and partial derivatives, rather than supplied as additional hypotheses.

Choose the integral matrix $A = p^s J^{-1}$. The existing inverse-certificate equivalence gives

$$AJ = JA = p^s I_e.$$

Put $c = p^s$ and define an integral block matrix

$$C = \begin{pmatrix} A & -AK \\ 0 & cI_k \end{pmatrix}.$$

Then

$$CB = \begin{pmatrix} AJ & AK - AK \\ 0 & cI_k \end{pmatrix} = cI_{e+k},$$

$$BC = \begin{pmatrix} JA & -JAK + cK \\ 0 & cI_k \end{pmatrix} = cI_{e+k}.$$

The second equality uses $JA = cI_e$. The generic block proof works over any commutative ring. The p-adic specialization also explicitly proves that B is invertible over Q and that $p^s B^{-1}$ is integral. There is no denominator loss from appending the parameter equations.

B.10.3 Construction, error and uniqueness

Apply the previously checked weighted coefficient-perturbation construction to $\mathcal{F}, \mathcal{H}, a, C$. Its hypotheses follow from the actual augmented identities and the two-sided certificate. It constructs b, proves the

full displacement bound p^{M-s}, and proves uniqueness throughout $a + p^{s+1}R^{e+k}$. The augmented root equivalence gives the required original equations and exact parameter values.

The checked integral first-order estimate gives

$$b - a + p^{M-s}C\mathcal{H}(a) \in p^{2M-3s}R^{e+k}.$$

The decisive block action is

$$C\begin{pmatrix} H(a) \\ -v \end{pmatrix} = \begin{pmatrix} A\big(H(a) + Kv\big) \\ -p^s v \end{pmatrix}.$$

Projecting the solved coordinates therefore gives

$$y - y_0 + p^{M-s}A\big(H(a) + Kv\big) \in p^{2M-3s}R^e.$$

The existing rational-conversion theorem turns $p^{M-s}A$ into $p^M J^{-1}$ and retains an integral error vector. This proves the displayed first-order formula with the original derivative blocks.

For any competing solved-coordinate root $z \in y_0 + p^{s+1}R^e$, the joined point (z, τ) lies in the augmented uniqueness ball: $M > 2s$ implies $M \geq s + 1$, so $\tau - t_0 = p^M v \in p^{s+1}R^k$. Full-point uniqueness gives $(z, \tau) = b$, hence $z = y$. This is the additional comparison needed to obtain uniqueness in exactly the ball stated in the solved-coordinate theorem.

B.10.4 Checked controls and precision boundary

For $p = 2$, $s = 0$, $F(Y, T) = Y + T$, $H = 1$, $a = 0$, and $v = 1$, both original blocks satisfy $J = K = 1$. At $M = 1$, the exact parameter is $\tau = 2$, and the unique solved value is $y = -4$. The combined correction is $-2(1 + 1) = -4$, with zero error.

The sign controls use $M = 2$: the actual augmented root is $(y, \tau) = (-8, 4)$, and the required error ideal is $16\mathbb{Z}_2$. Omitting Kv predicts -4, with error $-4 \notin 16\mathbb{Z}_2$. Reversing its sign predicts 0, with error $-8 \notin 16\mathbb{Z}_2$. Both failures are checked. At binary depth $M = 1$, the reversed-sign difference would lie in the allowed error ideal, so that shallower example alone would not distinguish the sign.

For parameter-only motion, use

$$F(Y, T) = Y + Y^2 + T, \quad H = 0, \quad a = 0, \quad v = 1, \quad p = 2,\ s = 0,\ M = 1.$$

A checked transfer from the prior scalar quadratic root constructs an even y with

$$y + y^2 + 2 = 0, \qquad 4 \mid y + 2, \qquad 8 \nmid y + 2.$$

Thus the error exponent $2M - 3s = 2$ is attained even when only parameters move. No uniform extra error digit can be added to the general theorem. This example establishes that limitation. It does not assert optimality at every choice of p, s, M.

The inherited controls continue to record the necessity of the strict weighted threshold and other earlier scope boundaries. General rationally rank-deficient systems are outside the inverse hypothesis.

B.11 Chapter IX: analytic regularity of the local parameter solution

The argument establishes both analyticity and differentiability of the actual local polynomial solution map at a root with an invertible solved Jacobian. The statements apply to every prime, including $p = 2$. They also hold over any complete nontrivially normed field.

Let $\mathbb{K}$ be such a field, let $e, k \in \mathbb{N}$, and let

$$F \in \mathbb{K}[Y_1, \ldots, Y_e, T_1, \ldots, T_k]^e, \qquad a = (y_0, t_0) \in \mathbb{K}^e \times \mathbb{K}^k.$$

Evaluation of F means coordinatewise evaluation of its actual polynomials. Define the actual derivative blocks

$$J = D_Y F(a) \in M_e(\mathbb{K}), \qquad K = D_T F(a) \in M_{e\times k}(\mathbb{K}),$$

where each matrix entry is the corresponding formal partial derivative evaluated at a. The hypotheses are exactly

$$F(a) = 0, \qquad J \in \mathrm{GL}_e(\mathbb{K}).$$

Neither analyticity of a proposed solution nor a derivative formula is assumed.

Local analytic graph theorem. There exist a map

$$\psi : \mathbb{K}^k \longrightarrow \mathbb{K}^e$$

and open sets $U \subseteq \mathbb{K}^k$, $V \subseteq \mathbb{K}^e$ such that

$$t_0 \in U, \qquad y_0 \in V, \qquad \psi(t_0) = y_0, \qquad \psi(U) \subseteq V.$$

The map is analytic at every point of U, and its graph describes all roots in the product neighborhood:

$$\forall t \in U\ \forall y \in V, \qquad F(y, t) = 0 \iff y = \psi(t).$$

At the base parameter it has the strict Fréchet derivative

$$\boxed{D\psi(t_0) = -J^{-1}K.}$$

Consequently it is differentiable on U. The map is defined on the ambient parameter space, but its root, analyticity and uniqueness conclusions are restricted to the specified neighborhood. Uniqueness is among solved coordinates in V.

The main Lean theorem is `Komorebi.PolynomialAnalyticImplicit.exists_analytic_implicit`. The matrix in its `HasStrictFDerivAt` conclusion is the continuous linear map represented by the displayed matrix. `differentiableOn_of_analytic_graph` records the differentiability consequence.

Proof chain. The scalar polynomial derivative bridge is proved by induction on actual multivariate polynomials: constants, sums, and multiplication by a variable. For a scalar polynomial P, its strict derivative is

$$v \longmapsto \sum_j \frac{\partial P}{\partial x_j}(a) v_j.$$

Assembling the coordinates gives the strict derivative of the evaluated system as its actual Jacobian matrix. Polynomial analyticity is supplied by the pinned Mathlib theorem for multivariate polynomial evaluation, followed by finite coordinate assembly.

Consider the actual augmented polynomial map

$$\Phi(y,t) = (F(y,t),t).$$

Its derivative and inverse derivative at a are

$$D\Phi(a) = \begin{pmatrix} J & K \\ 0 & I_k \end{pmatrix}, \qquad D\Phi(a)^{-1} = \begin{pmatrix} J^{-1} & -J^{-1}K \\ 0 & I_k \end{pmatrix}.$$

The proof constructs the continuous linear equivalence from these explicit matrices and verifies both inverse identities. The strict inverse theorem gives a local inverse g of Φ, and the analytic inverse result shows that this same inverse is analytic near $\Phi(a) = (0,t_0)$. Set

$$\psi(t) = \pi_Y g(0,t).$$

The two inverse identities and a sufficiently small product neighborhood give the exact local graph statement. Composing the derivative of g with parameter insertion and solved-coordinate projection yields $-J^{-1}K$. The chosen parameter neighborhood is also restricted so that the inverse identities, analyticity and inclusion $\psi(U) \subseteq V$ hold there simultaneously.

Transfer to a supplied continuous solution. Suppose $g : \mathbb{K}^k \to \mathbb{K}^e$ is continuous at t_0, $g(t_0) = y_0$, and

$$F(g(t),t) = 0$$

for all t in some neighborhood of t_0. Under the same invertibility hypothesis at a, continuity places $g(t)$ in the uniqueness neighborhood V for all sufficiently close parameters. Hence g and ψ agree on a neighborhood of t_0. The theorem `continuous_selection_regularity` transfers both analyticity and the strict derivative formula to g.

There is also an explicit open-set version. Let U be open, let g be continuous on U, and suppose for every $t \in U$ that

$$F(g(t),t) = 0, \qquad J_t := D_Y F(g(t),t) \in \mathrm{GL}_e(\mathbb{K}).$$

Writing $K_t = D_T F(g(t),t)$, the theorem `continuous_selection_analyticOnNhd` proves

$$g \text{ is analytic at every } t \in U, \qquad Dg(t) = -J_t^{-1}K_t \quad (t \in U),$$

with a strict Fréchet derivative at each point. The invertibility hypothesis at each point is part of this theorem. This is a transfer statement for continuous local root selections satisfying its hypotheses. It does not assert equality of arbitrary global branch choices.

Integral p-adic specialization. For any prime p, let

$$F \in \mathbb{Z}_p[Y,T]^e, \qquad a \in \mathbb{Z}_p^{e+k}, \qquad F(a) = 0.$$

Let $\iota : \mathbb{Z}_p \hookrightarrow \mathbb{Q}_p$ be the coefficient inclusion, applied entrywise to points and matrices. Assume only that

$$\iota(D_Y F(a)) \in \mathrm{GL}_e(\mathbb{Q}_p).$$

The theorem `PolynomialRegularityIntegral.exists_analytic_integral_implicit` constructs the preceding analytic graph in the ambient spaces $\mathbb{Q}_p^k$ and $\mathbb{Q}_p^e$. Its root equation evaluates the original integral polynomial coefficients using ι, and its base derivative is

$$-\iota(D_Y F(a))^{-1}\,\iota(D_T F(a)).$$

The source proves that polynomial evaluation, formal partial differentiation and both Jacobian blocks commute with this inclusion. No invertibility modulo p or integral inverse is required. This permits a solved Jacobian that is singular modulo p while remaining invertible over $\mathbb{Q}_p$. The new specialization is an ambient-field theorem. It does not treat $\mathbb{Z}_p$ as a vector space over $\mathbb{Q}_p$ or assert a new explicit integral radius.

Source module	Mathematical role
`PolynomialAnalyticEvaluation.lean`	Actual polynomial analyticity and strict derivative equals the evaluated formal Jacobian.
`PolynomialAnalyticInverse.lean`	Analyticity of the same local inverse supplied by an invertible strict derivative.
`PolynomialAnalyticBlocks.lean`	Explicit augmented derivative equivalence and its solved-coordinate restriction.
`PolynomialAnalyticImplicit.lean`	Open local root graph, analyticity, base strict derivative and differentiability.
`PolynomialAnalyticSelection.lean`	Transfer to continuous root selections, including the per-point open-set theorem.
`PolynomialRegularityIntegral.lean`	Integral coefficients and centers included in the ambient p-adic field, with actual Jacobian compatibility.

This block closes the local analytic regularity obligation stated in `TARGET_CONTRACT.json`. It supplies no new uniform numerical radius. The previous weighted lifting and joint deformation results retain their own explicit radii and error estimates. It does not establish a global analytic branch or a result at a point whose solved Jacobian is singular over the fraction field. The proof uses established analytic inverse machinery and makes no novelty claim for the general implicit-function theorem.

The remaining questions include singular persistence with higher obstructions, native presentation invariance (13.2), global or completed compatibility and descent (13.3), and sharper arithmetic statements. The local regularity theorem does not settle those questions.

C Restricted native progress and complete prose proofs

This appendix presents restricted polynomial obstruction, finite reconstruction, rectangularity and topological arguments as ordinary proofs. The intrinsic commutative-algebra obstruction uses the cited Stacks specialization and its finiteness argument. These results do not complete unrestricted Native 13.2 or Native 13.3 and have no new Lean certification.

C.1 2. A complete polynomial obstruction theorem

Scope. Fix a prime p, an integer $L \geq 1$, finite natural numbers d, r, and polynomials $F_1, \ldots, F_r \in \mathbb{Z}[X_1, \ldots, X_d]$. Let $\bar{x} \in (\mathbb{Z}/p^L\mathbb{Z})^d$ satisfy every equation $F_i(\bar{x}) = 0$. Choose any integer representative $x \in \mathbb{Z}^d$. Set

$$e_i = F_i(x)/p^L \pmod{p}, \qquad J_{ij} = \frac{\partial F_i}{\partial X_j}(x) \pmod{p}.$$

The divisions are exact integer divisions. Regard J as a linear map $\mathbb{F}_p^d \to \mathbb{F}_p^r$. Define

$$O_{F,\bar{x}} = \mathbb{F}_p^r / \operatorname{im} J, \qquad o_{F,\bar{x}} = [e].$$

Theorem. For this fixed polynomial presentation, the group and distinguished class are independent of the chosen integer representative. The class vanishes if and only if $\bar{x}$ lifts to a solution modulo p^{L+1}. The obstruction group has $p^{r-\operatorname{rank} J}$ elements. When lifts exist, their set is a torsor for $\ker J$ and contains exactly $p^{d-\operatorname{rank} J}$ elements.

Proof. For every integer correction vector t, expansion of each monomial gives

$$F(x + p^L t) \equiv F(x) + p^L J(x) t \pmod{p^{L+1}}. \tag{1}$$

Indeed, each term involving at least two correction factors is divisible by p^{2L}, and $2L \geq L + 1$. Constant and linear correction terms give the two displayed summands. Adding the monomial expansions proves (1) for every polynomial, with no denominator or analytic convergence issue.

Every element reducing to $\bar{x}$ is uniquely expressible modulo p^{L+1} as $x + p^L t$ with $t \in \mathbb{F}_p^d$. By (1), it solves the equations exactly when

$$e + Jt = 0 \quad \text{in } \mathbb{F}_p^r. \tag{2}$$

Equation (2) is soluble exactly when $e \in \operatorname{im} J$: the sign makes no difference because the image is a subspace. This is equivalent to $[e] = 0$.

Another representative has the form $x' = x + p^L s$. Since $L \geq 1$, its Jacobian is the same modulo p. Dividing (1) by p^L shows that its residual digit is $e' = e + Js$, so it gives exactly the same quotient class. If t_0 solves (2), all its solutions are $t_0 + \ker J$, and no others. The finite cardinalities follow from rank-nullity. This also covers no variables, no equations, zero Jacobian and singular solutions. □

The proof is a universal mathematical argument. The accompanying Python checks are independently bounded evidence about an implementation, not a substitute for that argument. The standalone Lean specialization does not formalize multivariable polynomial expansion (1), unless its own checked source explicitly says so.

C.1.1 Necessary boundaries and exact examples

- **A failed singular lift:** $p = 3$, $L = 1$, $F(X) = X^2 - 3$, $x = 0$. Here $e = -1 \neq 0$ in $\mathbb{F}_3$ and $J = 0$. There are no lifts of zero modulo 3 to a root modulo 9.
- **Representative independence is a quotient assertion:** for $F(X) = X^2 - 1$, $p = 3$, $L = 1$, representatives 1 and 4 have residual digits 0 and 2. Their common Jacobian is 2, with full image, and both give zero obstruction. Their corrected representatives 1 and 10 are the same root modulo 9.
- **A successful step need not give indefinite continuation:** for $F(X) = X^2 - 5$, $p = 2$, the root 1 modulo 2 has zero obstruction and lifts to $1, 3$ modulo 4. Both have nonzero obstruction at the next step. There is no root modulo 8 and no compatible infinite lift.
- **The raw Jacobian cokernel need not be presentation independent:** the presentations $F = (X)$ and $G = (X, 0)$ define the same solution system. Their raw obstruction groups at zero are respectively zero and $\mathbb{F}_p$. Both actual distinguished obstructions are zero. Thus one cannot claim a canonical isomorphism of these two raw groups merely because the equations define the same seed.

C.2 3. An intrinsic finite obstruction under an algebraic restriction

Let B be a finitely presented commutative $\mathbb{Z}$-algebra, p prime and $L \geq 1$. For a ring map $f : B \to \mathbb{Z}/p^L\mathbb{Z}$, use its reduction to make $\mathbb{F}_p$ a B-module. There is a canonical class

$$o(f) \in \mathrm{Ext}^1_B(\mathrm{NL}_{B/\mathbb{Z}}, \mathbb{F}_p)$$

whose vanishing is equivalent to a lift $B \to \mathbb{Z}/p^{L+1}\mathbb{Z}$. This follows from the ring-map lifting theorem in Stacks Project, Lemma 91.2.1, tag 08S5. Specialize the source extension to $0 \to 0 \to B \to B$ and the target extension to the kernel $p^L/p^{L+1} \cong \mathbb{F}_p$. The base maps are identities of $\mathbb{Z}$. The kernel is square zero because $L \geq 1$.

The comparison in Stacks Project, Lemma 10.134.2, tag 00S1 identifies the complex from a polynomial presentation with the canonical naive cotangent complex up to homotopy. Thus this construction is intrinsic, up to the stated canonical comparison.

The group is finite. Choose a finite presentation $P = \mathbb{Z}[X_1, \ldots, X_d] \twoheadrightarrow B$ with finitely generated kernel I. The presentation description in Stacks Project, Remark 91.2.4, tag 0GPU identifies the group as

$$\mathrm{coker}\left(\mathrm{Hom}_B(\Omega_{P/\mathbb{Z}} \otimes_P B, \mathbb{F}_p) \longrightarrow \mathrm{Hom}_B(I/I^2, \mathbb{F}_p)\right).$$

If I has r chosen generators, evaluation on their classes injects the latter Hom module into $\mathbb{F}_p^r$. Hence its quotient is finite. The relation module I/I^2 retains dependencies between equations, including redundant zero equations, which the raw target $\mathbb{F}_p^r$ does not.

Status: externally proved after the exact stated specialization, with the finiteness argument above. This theorem is not independently formalized in the accompanying Lean file. Extending it to all operator/recurrence/module systems admitted by manuscript Definition 1.1 requires a specified encoding and a proof that its notion of lift is preserved. That is the missing implication for applying it to native Conjecture 13.2 without restriction.

C.3 4. A topological obstruction to the proposed spine formula

Consider the recurrence $a_{n+1} = a_n$ with integer initial value. Its global parameter space is $X = \mathbb{Z}$. Its local parameter spaces are $X_p = \mathbb{Z}_p$, and every local realization has the same prime-independent recurrence. Give the local factors their usual p-adic topologies and the product its product topology. For these integral local factors, the restricted product relative to all $\mathbb{Z}_p$ is the ordinary product. Write

$$A = \mathbb{Z}_2, \qquad B = \prod_{p>2} \mathbb{Z}_p, \qquad D = \{(n, (n)_{p>2}) : n \in \mathbb{Z}\} \subset A \times B.$$

Theorem. There are no Hausdorff space C and continuous maps $f : A \to C$, $g : B \to C$ for which the equality locus

$$\{(a, b) : f(a) = g(b)\}$$

is exactly D. Thus the canonical local realizations of global integer constant sequences cannot satisfy the manuscript's fiber-product formula in this Hausdorff topological interpretation.

Proof. The equality locus is closed: it is the inverse image of the diagonal of $C \times C$ under the continuous map $f \times g$, and a Hausdorff space has closed diagonal.

The set D is dense in $A \times B$. A nonempty basic open set prescribes congruences at only finitely many primes and finite precision at each. The moduli are pairwise coprime. The finite Chinese remainder theorem supplies an integer meeting all those congruences, so every such open set meets D.

However, D is not the whole product. The element with 2-adic coordinate zero and every odd-adic coordinate one is not diagonal. If an integer had zero 2-adic coordinate, it would be divisible by every power of two, forcing it to be zero. Its 3-adic coordinate would then be zero, not one. Consequently D is a proper dense subset and is not closed. It cannot be the equality locus above. □

This is not asserted to refute the original, underspecified sentence under every possible reading. It refutes the explicit and natural interpretation just stated. The assumptions of continuity, Hausdorffness and identification through the canonical local maps are essential to this claim.

C.3.1 A precise reconstruction that does hold

For a finite set S of primes, positive precisions L_p, and a fixed integer polynomial system F, put

$$N = \prod_{p \in S} p^{L_p}, \qquad \mathrm{Sol}_F(R) = \{x \in R^d : F(x) = 0\}.$$

Then coefficientwise CRT gives a canonical bijection

$$\mathrm{Sol}_F(\mathbb{Z}/N\mathbb{Z}) \cong \prod_{p \in S} \mathrm{Sol}_F(\mathbb{Z}/p^{L_p}\mathbb{Z}).$$

The reason is exact: the CRT ring isomorphism preserves polynomial evaluation, and zero in a finite product is equivalent to zero in every component. For F empty, passing to all compatible finite congruences identifies the profinite completion $\widehat{\mathbb{Z}}$ with $\prod_p \mathbb{Z}_p$. The same finite reconstruction

is compatible with coefficient projections and integer recurrence matrices because these operations commute with reduction and CRT.

Here the polynomial equations or recurrence matrices are fixed common data. The theorem reconstructs finite or profinite objects. It does not identify a "smallest" spine, impose additional spectral descent, or recover global $\mathbb{Z}$ from arbitrary tuples of local points. A full form of 13.3 must state exactly which object is completed and specify its universal property.

C.3.2 A finite compatibility criterion with a precise universal property

Fix finite sets A, B of local packets and an explicitly given relation $R \subseteq A \times B$. Say that R is rectangular when

$$R(a,b),\ R(a',b),\ R(a',b') \quad \Longrightarrow \quad R(a,b')$$

for all $a, a' \in A$ and $b, b' \in B$.

Theorem. The relation R can be represented exactly as

$$R(a,b) \quad \Longleftrightarrow \quad f(a) = g(b)$$

for maps from A and B to a common set if and only if R is rectangular. In that case a canonical finite choice of common set is the connected-component set C_R of the bipartite graph with vertex set $A \sqcup B$ and edges given by R.

The component maps $f_R : A \to C_R$ and $g_R : B \to C_R$ have the following universal property. For every set Y and maps $h : A \to Y$, $k : B \to Y$ satisfying $h(a) = k(b)$ whenever $R(a,b)$, there is a unique map $u : C_R \to Y$ with $u \circ f_R = h$ and $u \circ g_R = k$.

Proof. Any equality representation is rectangular, since the three assumed equalities imply $f(a) = g(b) = f(a') = g(b')$.

Conversely, suppose R is rectangular. An edge always gives equal component labels. If $a \in A$ and $b \in B$ have equal component labels, there is a finite path between them. Its length is odd. A path of length one is already an R-edge. A longer path begins with three edges $a - b_1 - a_1 - b_2$. Rectangularity gives the edge $a - b_2$. Replacing these three edges by that edge shortens the path by two. Induction therefore yields $R(a,b)$. This proves the exact equality representation. Finiteness follows because the component set is a quotient of the finite set $A \sqcup B$.

For the universal property, combine h and k into a function on $A \sqcup B$. It is constant across every edge by hypothesis, hence along every finite path. It therefore descends to a well-defined function on components. The two required factorization identities hold by construction. They determine the value on every component, proving uniqueness. □

For example, the three pairs $(a_0, b_0), (a_1, b_0), (a_1, b_1)$ without (a_0, b_1) fail rectangularity. Every equality-label representation agreeing on those three pairs also admits the fourth pair, so it cannot represent that relation exactly.

This is a precise finite gluing obligation: future arithmetic applications must define A, B and R and prove rectangularity. The universal property holds for the component quotient even when rectangularity fails, but then the equality locus strictly enlarges R. The theorem establishes neither a minimum number of labels nor a smallest spine in the manuscript's unspecified category. It carries no automatic topology, spectral information or Frobenius compatibility. **Evidence: prose proof in this note, not a Lean formalization.**

D Local polyphase constructions

The following derivations retain their stated parameter ranges. The Amice analytic pullback, depleted branches, finite-field modal minimality and unrestricted infinite polyphase claims have only the evidence identified in their source records. Their inclusion does not give them a general Lean certificate.

The figures are explanatory schematics and exact finite examples. The modulo-seven inverse plot uses the tail 6, 5, 2, 6, 5, 2, ... The divisor-branch finite-difference theorem is Theorem 3.7, with its normalization loss. Higher kernel valuations and unrestricted local-to-global questions remain open in their stated scopes.

D.1 Introduction

Euler numbers carry several kinds of local information at once. Their indices have residue addresses. Their coefficient transforms have triangular depth. Their local expansions have Mahler degree. Their congruences depend on the valuation of the transfer kernel and on the valuation of the source value in the row being reconstructed. These pieces should not be merged into one undifferentiated congruence calculation.

This article begins with the Hurwitz product

$$(a \star b)_n = \sum_{r=0}^{n} \binom{n}{r} a_r b_{n-r}.$$

Over a field of characteristic zero it is multiplication of exponential generating functions. Over a finite field it realizes the additive group algebra through the exponential modes $\epsilon_u = (u^n)_{n\geq 0}$. This finite algebra gives an exact proof of the standard window period. Hurwitz series rings are treated in [15, 7]. The finite difference and umbral background may be found in [21, 10, 13].

Fix an odd prime p, a divisor $m \mid p-1$, and put

$$h = \frac{p-1}{m}.$$

The reduced standard window inverse is defined by

$$\sum_{q=0}^{n} \binom{mn}{mq} e_q^{(m,p)} = \delta_{n0} \quad \text{in } \mathbb{F}_p.$$

We prove that

$$e_{n+h}^{(m,p)} = e_n^{(m,p)} \qquad (n \geq 1).$$

The result first follows from subgroup symmetry in the finite Hurwitz algebra. A second proof shows that the standard window operator preserves the finite space of sequences that are h periodic after their constant term. The two arguments expose different parts of the same finite character structure.

The odd and dyadic Euler formulas share a common reconstruction framework. For each prime p we define an even source series H_p and an inverse kernel K_p satisfying

$$K_p(t)H_p(t) = \operatorname{sech} t.$$

At an odd prime,

$$H_p(t) = \cosh^2(pt)\operatorname{sech} t, \qquad K_p(t) = \operatorname{sech}^2(pt).$$

At the dyadic prime,

$$H_2(t) = \frac{\sinh(2t)\sinh t}{2t^2}, \qquad K_2(t) = \frac{4t^2}{\sinh^2(2t)}.$$

The coefficient convolution is identical in form, but the kernels have different integral weights. This is the correct sense in which the local theories unify.

The dyadic kernel is substantially sharper than the separate coefficient bound alone suggests. If

$$\frac{z^2}{\sinh^2 z} = \sum_{r\geq 0} \beta_r z^{2r}$$

and

$$\kappa_{2,r} = \beta_r 2^{2r}(2r)!,$$

then

$$v_2(\kappa_{2,r}) = 4r - 1 \qquad (r \geq 1).$$

Consequently, truncation after depth M is uniformly valid modulo

$$2^{4M+3},$$

and this exponent is optimal. The rowwise estimate records the additional binary carries in the binomial coefficient. Classical congruence theory for Euler families is extensive [8, 26, 27, 24, 9]. The formulas here are stated as exact coordinate identities. Historical priority requires a separate comparison of the individual theorems.

The second expansion concerns local interpolation. The exponent of the finite unit group moves every unit mode into a principal unit neighborhood. Binomial expansion then gives a Mahler series whose depth r coefficient gains at least Lr digits when the chosen jump is the identity modulo p^L. The same argument applies to polynomial exponential modes and to invertible matrix state systems. Mahler interpolation and the Amice transform are classical [19, 6, 20]. The local unit structure and valuation tools used here are standard [16, 22, 25, 12].

The odd Euler source contains one nonunit base. Removing that base gives an analytic unit source and an interpolation of a depleted Euler sequence on every even character branch. The dyadic source is

coordinate layer	what is retained	coordinate
$n = Nk + j$	residue address	j
$u = \omega(u)\langle u\rangle$	finite character	$\omega(u)$
$f(x) = \sum c_r \binom{x}{r}$	Mahler depth	r
$KH = \operatorname{sech}$	weighted reconstruction	$v_p(\kappa_r)$

Figure 1. New reconstruction. The arithmetic coordinate chain. Residue address, local character, Mahler depth, transfer weight, and reconstruction are recorded separately.

already analytic on $\mathbb{Z}_p$ after a removable singularity is filled. It yields a direct analytic interpolation of E_{2n} on $\mathbb{Z}_2$. These branches are then refined by the substitution

$$x = Mq + s.$$

The induced Mahler coefficient transform is finite and explicit. Its kernels compose exactly. At a prime power radix, they become sparse modulo the residue prime. Every monotone valuation ladder survives the refinement.

The remaining sections treat arithmetic lift obstructions, recurrence packets, and Chinese remainder reconstruction. The lifting obstruction is the residual defect modulo the image of the declared correction map. A recurrence packet is governed by a jump matrix C^N. If one integral recurrence is fixed, all of its local realizations have one common source. These statements do not prove that arbitrary unrelated local objects have a global origin.

Four boundaries remain explicit. A period modulo p does not by itself lift to all powers of p. The full finite difference estimate for every congruential reciprocal packet still requires control of the triangular inverse. Exact higher valuations of the affine polyphase kernel are not yet known in general. Chinese remainder reconstruction and finite adelic synchronization do not prove a global source for arbitrary local systems.

D.2 Hurwitz series and finite field subgroup inversion

For the divisor-branch family, Theorem 3.7 proves the bound with the j! normalization and factorial valuation loss. No unrestricted family is asserted.

D.2.1 The Hurwitz ring

definition D.1 (Hurwitz series ring). Let R be a commutative ring with identity. The Hurwitz series ring $\mathcal{H}(R)$ is the set $R^{\mathbb{N}}$ with componentwise addition and product

$$(a \star b)_n = \sum_{r=0}^{n} \binom{n}{r} a_r b_{n-r}.$$

Its identity is

$$\delta = (1, 0, 0, \ldots).$$

When the factorials are invertible, the sequence a may be written as the exponential generating series

$$A(t) = \sum_{n \geq 0} a_n \frac{t^n}{n!},$$

and the Hurwitz product becomes ordinary multiplication. The sequence definition remains valid in every characteristic.

definition D.2 (Exponential mode). For $u \in R$, define

$$\epsilon_u = (u^n)_{n \geq 0},$$

where $0^0 = 1$.

proposition D.3 (Addition law for modes). For every $u, v \in R$,

$$\boxed{\epsilon_u \star \epsilon_v = \epsilon_{u+v}.}$$

Proof. The nth coefficient is

$$\sum_{r=0}^{n} \binom{n}{r} u^r v^{n-r} = (u + v)^n$$

by the binomial theorem. □

D.2.2 The finite additive group algebra

Let p be prime. Write $\mathbb{F}_p^+$ for the additive group of the finite field.

theorem D.4 (Finite field mode algebra). The map

$$\Theta : \mathbb{F}_p[\mathbb{F}_p^+] \longrightarrow \mathcal{H}(\mathbb{F}_p), \qquad [u] \longmapsto \epsilon_u,$$

is an injective algebra homomorphism. Its image is the p dimensional subalgebra spanned by the modes ϵ_u.

Proof. The product law follows from proposition D.3. To prove injectivity, suppose

$$\sum_{u \in \mathbb{F}_p} c_u \epsilon_u = 0.$$

Looking at the coordinates $n = 0, 1, \ldots, p-1$ gives a Vandermonde system with matrix

$$(u^n)_{0 \leq n \leq p-1,\ u \in \mathbb{F}_p}.$$

Its determinant is the product of all differences between distinct field elements, so it is nonzero. Hence every c_u vanishes. □

proposition D.5 (Augmentation criterion). Let

$$x = \sum_{u \in \mathbb{F}_p} c_u [u] \in \mathbb{F}_p[\mathbb{F}_p^+].$$

Then x is a unit if and only if

$$\operatorname{aug}(x) = \sum_u c_u$$

is nonzero. If J is the augmentation ideal, then

$$J^p = 0.$$

Proof. Choose a generator g of the cyclic additive group. Then

$$\mathbb{F}_p[\mathbb{F}_p^+] \cong \mathbb{F}_p[y]/(y^p - 1) = \mathbb{F}_p[y]/(y-1)^p.$$

The augmentation ideal is generated by $y - 1$, so its pth power is zero. Every element has the form $a + n$ with $a \in \mathbb{F}_p$ and $n \in J$. It is invertible exactly when $a \neq 0$, which is the augmentation condition. □

corollary D.6 (Finite inverse formula). If x has augmentation one and $n = x - 1$, then

$$\boxed{x^{-1} = \sum_{r=0}^{p-1} (-n)^r.}$$

Proof. By proposition D.5, $n^p = 0$. The finite geometric sum gives the inverse. □

D.2.3 Subgroup selectors

Fix a divisor m of $p - 1$. Let

$$H_m = \{\zeta \in \mathbb{F}_p^\times : \zeta^m = 1\}.$$

This group has order m.

definition D.7 (Multiple selector). Define $a^{(m)} \in \mathcal{H}(\mathbb{F}_p)$ by

$$a_n^{(m)} = \begin{cases} 1, & m \mid n, \\ 0, & m \nmid n. \end{cases}$$

lemma D.8 (Subgroup average). The multiple selector has the mode expansion

$$\boxed{a^{(m)} = \frac{1}{m} \sum_{\zeta \in H_m} \epsilon_\zeta.}$$

Proof. The nth coefficient on the right is

$$\frac{1}{m} \sum_{\zeta \in H_m} \zeta^n.$$

The character sum is one when $m \mid n$ and zero otherwise. □

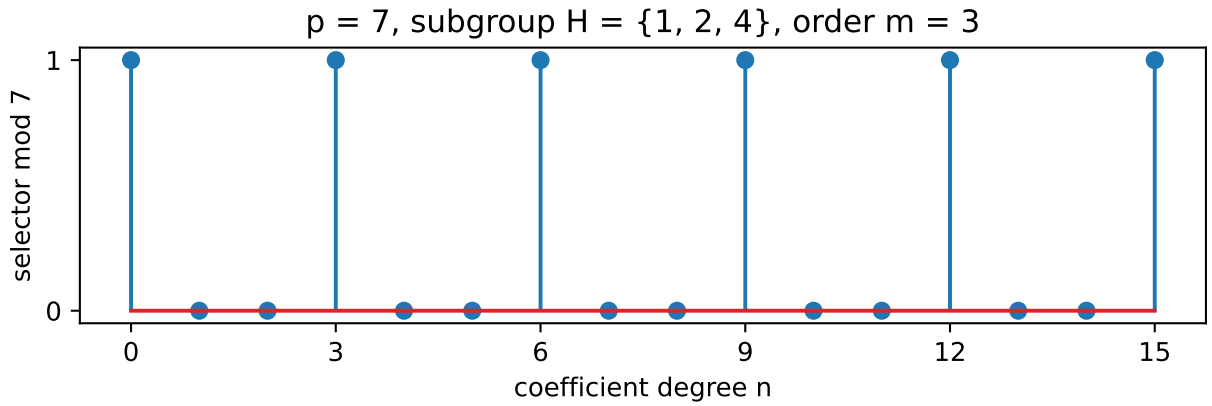

Figure 2. New reconstruction. A subgroup average in the additive group algebra. The highlighted modes select coefficient degrees divisible by the subgroup order.

Since the subgroup average has augmentation one, it has a unique Hurwitz inverse. Write

$$b^{(m,p)} = (a^{(m)})^{-1}.$$

theorem D.9 (Support and positive degree period). The inverse $b^{(m,p)}$ has the following properties.

1. $b_n^{(m,p)} = 0$ unless $m \mid n$.
2. For every positive n,

$$\boxed{b_{n+p-1}^{(m,p)} = b_n^{(m,p)}.}$$

Proof. Multiplication by an element $\eta \in H_m$ gives an automorphism of the additive group and therefore an automorphism

$$\epsilon_u \longmapsto \epsilon_{\eta u}$$

of the mode algebra. The selector $a^{(m)}$ is fixed by every such automorphism, so its unique inverse is fixed as well.

Write

$$b^{(m,p)} = \sum_{u \in \mathbb{F}_p} c_u \epsilon_u.$$

Invariance gives $c_{\eta u} = c_u$. After the change of variable $u \mapsto \eta u$,

$$b_n^{(m,p)} = \eta^n b_n^{(m,p)}$$

for every $\eta \in H_m$. If $m \nmid n$, some η satisfies $\eta^n \neq 1$, so the coefficient vanishes.

For positive n, the zero mode contributes nothing. Every nonzero mode satisfies $u^{p-1} = 1$. Hence

$$b_{n+p-1}^{(m,p)} = \sum_{u \neq 0} c_u u^{n+p-1} = \sum_{u \neq 0} c_u u^n = b_n^{(m,p)}.$$

□

definition D.10 (Compressed inverse). Set

$$e_n^{(m,p)} = b_{mn}^{(m,p)}.$$

proposition D.11 (Compressed inverse recurrence). The compressed coefficients satisfy

$$\boxed{\sum_{q=0}^{n} \binom{mn}{mq} e_q^{(m,p)} = \delta_{n0}.}$$

In particular, $e_0^{(m,p)} = 1$, and the positive coefficients are determined recursively because the diagonal is one.

Proof. Evaluate the Hurwitz identity

$$a^{(m)} \star b^{(m,p)} = \delta$$

at degree mn. Both factors vanish outside degrees divisible by m. Reindexing the surviving terms gives the displayed recurrence. □

corollary D.12 (Uniform compressed period). Let

$$h = \frac{p-1}{m}.$$

Then

$$\boxed{e_{n+h}^{(m,p)} = e_n^{(m,p)} \qquad (n \geq 1).}$$

Proof. Since $m(n+h) = mn + p - 1$, the conclusion follows from theorem D.9. □

corollary D.13 (Rational ordinary generating function). In $\mathbb{F}_p[[z]]$,

$$\boxed{\sum_{n \geq 0} e_n^{(m,p)} z^n = 1 + \frac{\sum_{r=1}^{h} e_r^{(m,p)} z^r}{1 - z^h}.}$$

Proof. Separate the constant coefficient and group the positive indices into residue classes modulo h. □

theorem D.14 (Exponential form and minimal period). Let

$$G_m = (\mathbb{F}_p^{\times})^m.$$

This cyclic group has order h. There are uniquely determined coefficients $d_v \in \mathbb{F}_p$, indexed by $v \in G_m$, such that

$$\boxed{e_n^{(m,p)} = \sum_{v \in G_m} d_v v^n \qquad (n \geq 1).}$$

The minimal positive period is the least common multiple of the orders of those v for which $d_v \neq 0$. In particular, it divides h.

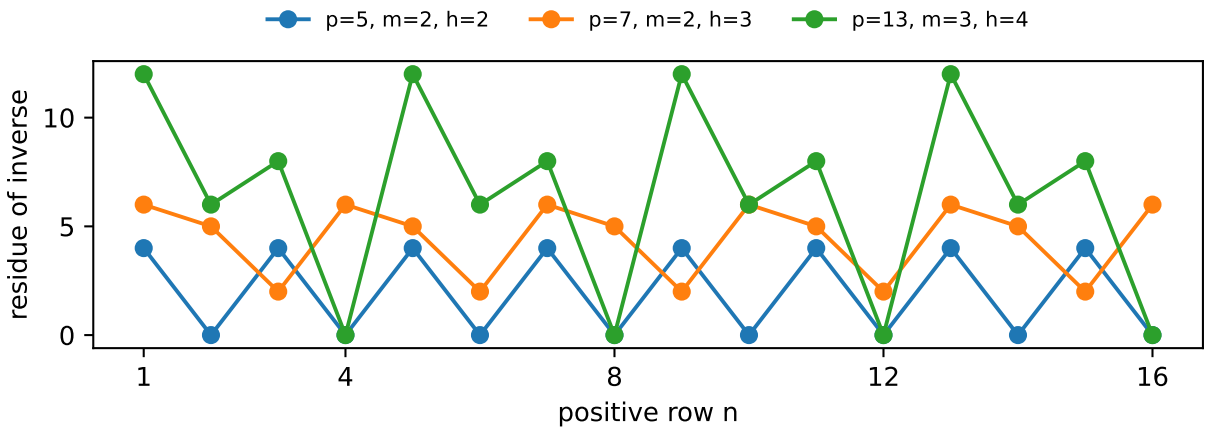

Figure 3. New reconstruction. Several compressed inverses. Every row is periodic after the constant term, as proved in corollary D.12.

Proof. The coefficients c_u in the proof of theorem D.9 are constant on the cosets of H_m. For $u \neq 0$, the value u^m depends only on the coset, and every element of G_m arises. Grouping the modes by cosets gives the displayed expansion.

Distinct elements of G_m define linearly independent functions on one full period, by the Vandermonde determinant. Therefore a positive integer r is a period exactly when $v^r = 1$ for every active mode. The least such r is the stated least common multiple. □

example D.15 (A compressed inverse modulo seven). **Editorial numerical correction.** The positive-index standard-window tail printed below is erroneous. The defining recurrence gives $e_1 = -1 \equiv 6$, $e_2 = 5$ and $e_3 = -61 \equiv 2 \pmod 7$, so the correct positive tail is $6, 5, 2, 6, 5, 2, \ldots$. The period-three conclusion remains correct. Use the recurrence-derived tail for this example.

Take $p = 7$ and $m = 2$, so $h = 3$. The recurrence gives

$$e_n^{(2,7)} = 1, 6, 4, 1, 6, 4, \ldots \qquad (n \geq 1).$$

The positive tail has exact period three.

D.3 Unit triangular coefficient transport

The examples later in the chapter use different kernels, but their coefficient algebra has one common form. This section records that form once. Let R be a commutative algebra over $\mathbb{Q}$, and take all coefficients in R.

Let

$$H(t) = \sum_{r \geq 0} h_r \frac{t^r}{r!}, \qquad h_0 = 1.$$

There is a unique inverse

$$K(t) = H(t)^{-1} = \sum_{r \geq 0} k_r \frac{t^r}{r!}.$$

theorem D.16 (Exact coefficient transport). Let

$$A(t) = \sum_{n\geq 0} A_n \frac{t^n}{n!}, \qquad S(t) = H(t)A(t).$$

Then

$$\boxed{S_n = \sum_{r=0}^{n} \binom{n}{r} h_r A_{n-r}.}$$

The inverse coordinate formula is

$$\boxed{A_n = \sum_{r=0}^{n} \binom{n}{r} k_r S_{n-r}.}$$

Both transforms are lower triangular with diagonal one.

Proof. The first identity is the coefficient rule for the product of exponential generating functions. Multiply by $K(t)$ and use $K(t)H(t) = 1$ for the inverse identity. The diagonal coefficient in each transform is the constant coefficient of its kernel, which is one. □

corollary D.17 (Composition of coefficient transports). If U_H and U_G are the triangular transforms associated with unit kernels H and G, then

$$\boxed{U_H U_G = U_{HG}.}$$

In particular, the inverse of U_H is $U_{H^{-1}}$.

Proof. Multiplication by G, followed by multiplication by H, is multiplication by HG. □

theorem D.18 (Filtered triangular reconstruction). Let p be prime. Suppose

$$A_n = \sum_{r=0}^{n} \binom{n}{r} c_r p^{w(r)} S_{n-r},$$

where $c_r \in \mathbb{Z}_p$, $S_n \in \mathbb{Z}_p$, and

$$w(r) \in \mathbb{N}.$$

For every precision $L \geq 1$,

$$\boxed{A_n \equiv \sum_{\substack{0\leq r\leq n \\ w(r)<L}} \binom{n}{r} c_r p^{w(r)} S_{n-r} \pmod{p^L}.}$$

When the omitted set is nonempty, the tail has valuation at least

$$\boxed{\min_{\substack{0\leq r\leq n \\ w(r)\geq L}} \left(w(r) + v_p\binom{n}{r} + v_p(S_{n-r}) \right).}$$

Proof. Every omitted summand belongs to $p^L\mathbb{Z}_p$. The sharper statement follows by taking the minimum of the exact lower bounds for the summands and applying the nonarchimedean triangle inequality. □

remark D.19. An arbitrary invertible triangular matrix can encode an arbitrary sequence. The transforms retained here have an explicit generating kernel and a visible filtration. Those two features make exact inversion and uniform truncation possible.

D.4 Congruential reciprocal packets

D.4.1 Residue sections of the exponential series

For integers $N \geq 1$ and $0 \leq j < N$, define

$$\mathcal{E}_{N,j}(t) = \sum_{n \geq 0} \frac{t^{Nn+j}}{(Nn+j)!}.$$

The forced factor t^j may be removed without changing the residue address.

definition D.20 (Congruential reciprocal packet). Define

$$\boxed{\mathcal{C}_{N,j}(t) = \frac{t^j/j!}{\mathcal{E}_{N,j}(t)} = \sum_{n \geq 0} C_{N,j}(n) \frac{t^{Nn}}{(Nn)!}.}$$

theorem D.21 (Triangular inverse system). The coefficients satisfy $C_{N,j}(0) = 1$ and

$$\boxed{\sum_{q=0}^{n} \binom{Nn+j}{Nq} C_{N,j}(q) = \delta_{n0}.}$$

For $n \geq 1$,

$$\boxed{C_{N,j}(n) = -\frac{\sum_{q=0}^{n-1} \binom{Nn+j}{Nq} C_{N,j}(q)}{\binom{Nn+j}{Nn}}.}$$

Proof. Multiply $\mathcal{C}_{N,j}(t)$ by $\mathcal{E}_{N,j}(t)$ and compare the coefficient of $t^{Nn+j}/(Nn+j)!$. The last summand is the diagonal term, which is nonzero over $\mathbb{Q}$. □

proposition D.22 (A denominator bound). Let

$$D_{N,j}(n) = \prod_{r=1}^{n} \binom{Nr+j}{Nr}, \qquad D_{N,j}(0) = 1.$$

Then

$$\boxed{D_{N,j}(n) C_{N,j}(n) \in \mathbb{Z}.}$$

For every prime p,

$$v_p(C_{N,j}(n)) \geq -\sum_{r=1}^{n} v_p \binom{Nr+j}{Nr}.$$

Proof. Use induction on n in the recurrence of theorem D.21. Every earlier denominator divides $D_{N,j}(n-1)$, while the new diagonal denominator is the final factor of $D_{N,j}(n)$. The valuation statement follows. □

example D.23 (Euler and Bernoulli boundaries). For $(N, j) = (2, 0)$,

$$\mathcal{C}_{2,0}(t) = \operatorname{sech} t,$$

so

$$C_{2,0}(n) = E_{2n}.$$

For $(N, j) = (2, 1)$,

$$\mathcal{C}_{2,1}(t) = \frac{t}{\sinh t},$$

and

$$C_{2,1}(n) = 2\left(1 - 2^{2n-1}\right) B_{2n}.$$

The usual convention $B_1 = -1/2$ is used. Euler and Bernoulli number conventions are reviewed in [10, 23].

D.4.2 Standard windows

Fix a prime p, an integer $m \geq 1$, and an address $0 \leq j < p$. Put

$$N = mp.$$

For arbitrary m, let $\widetilde{e}_n^{(m,p)} \in \mathbb{F}_p$ be the unique sequence satisfying

$$\boxed{\sum_{q=0}^{n} \binom{mn}{mq} \widetilde{e}_q^{(m,p)} = \delta_{n0}.}$$

When $m \mid p - 1$, this sequence agrees with the compressed Hurwitz inverse in proposition D.11.

standard fact D.24 (Lucas congruence). If $a = a_0 + a_1 p + \cdots$ and $b = b_0 + b_1 p + \cdots$ are base p expansions, then

$$\binom{a}{b} \equiv \prod_r \binom{a_r}{b_r} \pmod{p}.$$

This is the classical theorem of Lucas [18].

theorem D.25 (Standard window reduction). For $0 \leq q \leq n$,

$$\boxed{\binom{mpn + j}{mpq} \equiv \binom{mn}{mq} \pmod{p}.}$$

The diagonal coefficient is a unit modulo p:

$$\binom{mpn + j}{mpn} \equiv 1 \pmod{p}.$$

Proof. Write

$$mpn + j = p(mn) + j, \qquad mpq = p(mq).$$

Lucas reduction separates the lowest base p digit and gives

$$\binom{mpn+j}{mpq} \equiv \binom{j}{0}\binom{mn}{mq} \pmod{p}.$$

The diagonal case is obtained by setting $q = n$. □

corollary D.26 (Standard window integrality). Every coefficient $C_{mp,j}(n)$ belongs to $\mathbb{Z}_p$.

Proof. The recurrence in theorem D.21 starts with a p integral constant term. The binomial coefficients are integers, and every diagonal term is a p adic unit by theorem D.25. Induction gives the result. □

corollary D.27 (Address independence modulo the prime). Let $\widetilde{e}_n^{(m,p)}$ be the reduced standard inverse above. Then

$$\boxed{C_{mp,j}(n) \equiv \widetilde{e}_n^{(m,p)} \pmod{p}}$$

for every $0 \le j < p$.

Proof. Modulo p, the recurrence in theorem D.21 becomes

$$\sum_{q=0}^{n} \binom{mn}{mq} C_{mp,j}(q) = \delta_{n0}.$$

This is the defining recurrence for $\widetilde{e}_n^{(m,p)}$. The diagonal is one, so the solution is unique. □

theorem D.28 (Uniform standard window period). Assume that p is odd and $m \mid p-1$. Put

$$h = \frac{p-1}{m}.$$

Then for every standard window address $0 \le j < p$,

$$\boxed{C_{mp,j}(n+h) \equiv C_{mp,j}(n) \pmod{p} \qquad (n \ge 1).}$$

Proof. By corollary D.27, every address reduces to the same reduced standard inverse. Under the divisibility assumption, that inverse agrees with the compressed Hurwitz inverse by proposition D.11. Its positive tail has period h by corollary D.12. □

corollary D.29 (Rational residual generating function). Under the hypotheses of theorem D.28, for every standard address j,

$$\sum_{n\ge 0} \left(C_{mp,j}(n) \bmod p\right) z^n = 1 + \frac{\sum_{r=1}^{h} \widetilde{e}_r^{(m,p)} z^r}{1 - z^h}.$$

Proof. Combine corollaries D.13 and D.27. □

theorem D.30 (Fourier invariance of the standard window operator). Let p be odd, let $m \mid p-1$, and let $h = (p-1)/m$. Define

$$(T_{m,p} f)_n = \sum_{q=0}^{n} \binom{mn}{mq} f_q \quad \text{in } \mathbb{F}_p.$$

Let V_h be the vector space of sequences satisfying

$$f_{n+h} = f_n \qquad (n \geq 1).$$

Then

$$\boxed{T_{m,p}(V_h) = V_h.}$$

The restriction of $T_{m,p}$ to V_h is an automorphism.

Proof. Choose $d_0 = f_h$ and $d_n = f_n$ for $n \geq 1$. Then d is fully h periodic and $f = d + c\delta_0$ for $c = f_0 - f_h$. Since $T_{m,p}\delta_0$ is the constant sequence one, it is enough to treat d. Expand

$$d_q = \sum_{\chi \in \mu_h} c_\chi \chi^q.$$

The mth power map on $\mathbb{F}_p^\times$ has image μ_h. Choose y with $y^m = \chi$. The root filter gives

$$T_{m,p}(\chi^\bullet)_n = \frac{1}{m} \sum_{\zeta \in \mu_m} (1 + \zeta y)^{mn}.$$

If $1 + \zeta y = 0$, the corresponding term vanishes for positive n. Otherwise

$$((1 + \zeta y)^m)^h = (1 + \zeta y)^{p-1} = 1.$$

Every summand is therefore h periodic for positive n. Thus $T_{m,p}$ preserves V_h. It is unit lower triangular on every finite initial segment. Its restriction to the finite dimensional space determined by $f_0, f_1, \ldots, f_h$ is injective and hence bijective. □

corollary D.31 (A second proof of the standard window period). The reduced inverse $e^{(m,p)}$ and every standard address satisfy the period in theorem D.28.

Proof. The sequence $\delta = (1, 0, 0, \ldots)$ belongs to V_h. Its inverse image under the automorphism in theorem D.30 also belongs to V_h. Address independence modulo p gives the statement for every standard address. □

remark D.32. The theorem gives a period modulo p. A period modulo higher powers requires additional control of the triangular inverse and cannot be inferred from the finite field argument alone.

D.5 One local Euler source and kernel calculus

The odd and dyadic reconstructions have one convolutional form. Their sources, kernels, and valuation profiles are different. We first construct each chart and then state the common theorem.

D.5.1 The odd source and its inverse

Let q be a positive odd integer. Define

$$S_n(q) = \sum_{a=0}^{q-1} (-1)^a (2a + 1)^n.$$

p = 7, m = 2, h = 3	root filter	mode at row n
$\chi = 2,\ y = 3$	input character	2^{n}
$(1+y)^{2} = 2$	first output mode	$4\,2^{n}$
$(1-y)^{2} = 4$	second output mode	$4\,4^{n}$
$T(2^{\bullet})_{n}$	sum modulo 7	$4(2^{n}+4^{n})$

Figure 4. New reconstruction. Finite field Fourier transfer for a standard window. Each character becomes a finite sum of positive index modes with period dividing h.

Let the signed Euler numbers and Euler zigzag numbers be defined by

$$\operatorname{sech} t = \sum_{n \geq 0} E_{n} \frac{t^{n}}{n!}$$

and

$$\sec t + \tan t = \sum_{n \geq 0} Z_{n} \frac{t^{n}}{n!}.$$

lemma D.33 (Odd source generating function). For every positive odd q,

$$\boxed{\sum_{n \geq 0} S_{n}(q) \frac{t^{n}}{n!} = \mathrm{e}^{qt} \cosh(qt) \operatorname{sech} t.}$$

Its even part is

$$\boxed{\sum_{n \geq 0} S_{2n}(q) \frac{t^{2n}}{(2n)!} = \cosh^{2}(qt) \operatorname{sech} t.}$$

Proof. The finite geometric sum gives

$$\sum_{a=0}^{q-1} (-1)^{a} \mathrm{e}^{(2a+1)t} = \mathrm{e}^{t} \frac{1+\mathrm{e}^{2qt}}{1+\mathrm{e}^{2t}} = \mathrm{e}^{qt} \cosh(qt) \operatorname{sech} t.$$

Averaging at t and $-t$ gives the even part. □

lemma D.34 (Zigzag inverse kernel).

$$\boxed{\operatorname{sech}^{2} t = \sum_{r \geq 0} (-1)^{r} Z_{2r+1} \frac{t^{2r}}{(2r)!}.}$$

Proof. The identity $\tanh t = -i \tan(it)$ gives the odd zigzag expansion of $\tanh t$. Differentiate. □

n / q	0	1	2	3	4	5	6	7	8
0	1	0	0	0	0	0	0	0	0
1	1	1	0	0	0	0	0	0	0
2	1	6	1	0	0	0	0	0	0
3	1	1	1	1	0	0	0	0	0
4	1	0	0	0	1	0	0	0	0
5	1	3	0	0	3	1	0	0	0
6	1	3	5	0	5	3	1	0	0
7	1	0	0	0	0	0	0	1	0
8	1	1	0	0	4	0	0	1	1

Figure 5. New reconstruction. The standard window matrix for $p = 7$, $m = 2$, and $0 \le j < 7$. Reduction removes the address and retains diagonal one.

theorem D.35 (Odd modulus Euler coordinate pair). For every positive odd q and every even $n \ge 0$,

$$\boxed{E_n = \sum_{r=0}^{n/2} (-1)^r Z_{2r+1} \binom{n}{2r} q^{2r} S_{n-2r}(q).}$$

The inverse transform is

$$\boxed{S_n(q) = E_n + \sum_{r=1}^{n/2} 2^{2r-1} \binom{n}{2r} q^{2r} E_{n-2r}.}$$

Both transforms are lower triangular with diagonal one.

Proof. The even source identity gives

$$\operatorname{sech} t = \operatorname{sech}^2(qt) \sum_{n \ge 0} S_{2n}(q) \frac{t^{2n}}{(2n)!}.$$

Insert lemma D.34 and compare coefficients. For the inverse, multiply $\operatorname{sech} t$ by

$$\cosh^2(qt) = 1 + \sum_{r \ge 1} 2^{2r-1} q^{2r} \frac{t^{2r}}{(2r)!}.$$

□

corollary D.36 (Odd modulus truncation). For every $M \ge 0$, every positive odd q, and every even n,

$$\boxed{E_n \equiv \sum_{r=0}^{\min(M, n/2)} (-1)^r Z_{2r+1} \binom{n}{2r} q^{2r} S_{n-2r}(q) \pmod{q^{2M+2}}.}$$

If $p \mid q$ and $a = v_p(q)$, the same truncation is valid modulo $p^{2a(M+1)}$.

Proof. Every omitted term contains q^{2r} with $r \geq M+1$. The local statement follows by taking the p adic valuation. □

proposition D.37 (Odd row weight). For an odd prime p, the rth nonzero term in the reconstruction has valuation

$$\boxed{W_p(n,r) = 2r + v_p(Z_{2r+1}) + v_p\binom{n}{2r} + v_p\big(S_{n-2r}(p)\big).}$$

The binomial contribution is

$$\boxed{v_p\binom{n}{2r} = \frac{s_p(2r) + s_p(n-2r) - s_p(n)}{p-1},}$$

where s_p is the base p digit sum.

Proof. The first identity separates the valuation of every factor. The second is Legendre's formula, equivalently Kummer's carry theorem [14]. □

D.5.2 The dyadic source and its inverse

For even $n \geq 0$, define

$$\boxed{R_n = \frac{3^{n+2} - 1}{4(n+1)(n+2)}.}$$

Its even exponential generating function is

$$\boxed{\sum_{n \text{ even}} R_n \frac{t^n}{n!} = \frac{\sinh(2t)\sinh t}{2t^2}.}$$

Define β_r by

$$\boxed{\frac{z^2}{\sinh^2 z} = \sum_{r \geq 0} \beta_r z^{2r}.}$$

proposition D.38 (Dyadic inverse coefficients). For $r \geq 1$,

$$\boxed{\beta_r = -\frac{2^{2r}(2r-1)B_{2r}}{(2r)!}.}$$

Consequently,

$$\boxed{v_2(\beta_r) = s_2(r) - 1.}$$

Every R_n is a dyadic unit.

Proof. Differentiate the Bernoulli expansion of $\coth z$ and use $-(\coth z)' = \sinh(z)^{-2}$. The von Staudt and Clausen theorem gives $v_2(B_{2r}) = -1$. Legendre's formula gives

$$v_2((2r)!) = 2r - s_2(r).$$

For R_n, put $k = n + 2$. Since k is even,

$$v_2(3^k - 1) = 2 + v_2(k).$$

The denominator has the same valuation because $n + 1$ is odd. □

theorem D.39 (Dyadic Euler coordinate pair). For every even $n \geq 0$,

$$\boxed{E_n = \sum_{r=0}^{n/2} \beta_r 2^{2r} (n)_{2r} R_{n-2r}.}$$

The inverse transform is

$$\boxed{R_n = \sum_{r=0}^{n/2} \frac{2^{4r+1}}{(2r+2)!} (n)_{2r} E_{n-2r}.}$$

Proof. Substitute $z = 2t$ in the inverse series and multiply

$$\frac{4t^2}{\sinh^2(2t)} \frac{\sinh(2t)\sinh t}{2t^2} = \operatorname{sech} t.$$

Coefficient extraction gives the forward transform. The inverse follows from

$$\left(\frac{\sinh(2t)}{2t}\right)^2 = \sum_{r \geq 0} \frac{2^{4r+1}}{(2r+2)!} t^{2r}.$$

□

D.5.3 The common source and kernel law

For a prime p, define

$$A_{p,n} = \begin{cases} S_n(p), & p \text{ odd}, \\ R_n, & p = 2 \text{ and } n \text{ even}, \\ 0, & p = 2 \text{ and } n \text{ odd}, \end{cases}$$

and

$$\kappa_{p,r} = \begin{cases} (-1)^r Z_{2r+1} p^{2r}, & p \text{ odd}, \\ \beta_r 2^{2r} (2r)!, & p = 2. \end{cases}$$

theorem D.40 (Unified local Euler transfer). For every prime p and every even $n \geq 0$,

$$\boxed{E_n = \sum_{r=0}^{n/2} \binom{n}{2r} \kappa_{p,r} A_{p,n-2r}.}$$

If

$$H_p(t) = \sum_{m \geq 0} A_{p,2m} \frac{t^{2m}}{(2m)!}$$

and

$$K_p(t) = \sum_{r \geq 0} \kappa_{p,r} \frac{t^{2r}}{(2r)!},$$

then

$$\boxed{K_p(t) H_p(t) = \operatorname{sech} t.}$$

For odd p,

$$H_p(t) = \cosh^2(pt) \operatorname{sech} t, \qquad K_p(t) = \operatorname{sech}^2(pt).$$

For $p = 2$,

$$H_2(t) = \frac{\sinh(2t) \sinh t}{2t^2}, \qquad K_2(t) = \frac{4t^2}{\sinh^2(2t)}.$$

Proof. The two source and kernel products were proved in theorems D.35 and D.39. Their divided power coefficient laws have the displayed common form. □

theorem D.41 (Unified inverse local transfer). Define

$$\lambda_{p,r} = \begin{cases} 1, & p \text{ odd and } r = 0, \\ 2^{2r-1} p^{2r}, & p \text{ odd and } r \geq 1, \\ \dfrac{2^{4r+1}}{(2r+1)(2r+2)}, & p = 2. \end{cases}$$

Then for every prime p and every even $n \geq 0$,

$$\boxed{A_{p,n} = \sum_{r=0}^{n/2} \binom{n}{2r} \lambda_{p,r} E_{n-2r}.}$$

Equivalently, if

$$L_p(t) = K_p(t)^{-1},$$

then

$$\boxed{H_p(t) = L_p(t) \operatorname{sech} t,}$$

where

$$L_p(t) = \cosh^2(pt)$$

for odd p, and

$$L_2(t) = \left(\frac{\sinh(2t)}{2t} \right)^2$$

for $p = 2$.

Proof. For odd p, this is the inverse identity in theorem D.35. For $p = 2$, rewrite the inverse identity in theorem D.39 by using

$$(n)_{2r} = (2r)! \binom{n}{2r}.$$

Table 3. The common local Euler architecture and the parts that remain prime dependent.

Feature	Odd prime chart	Dyadic chart
Finite torsion address	Modulo $p-1$	Sign address modulo two
Principal units	$1+p\mathbb{Z}_p$	$1+4\mathbb{Z}_2$
Source	Alternating odd power sum $S_n(p)$	Weighted source R_n
Kernel	$\operatorname{sech}^2(pt)$	$4t^2/\sinh^2(2t)$
Positive depth weight	At least $2r$, with zigzag and row factors	Exactly $4r-1$, before the binomial carry
Analytic branch	Depleted unit source	Direct integral source
Natural refined step	$(p-1)p^a$	2^{a+1}

The coefficient becomes

$$\frac{2^{4r+1}(2r)!}{(2r+2)!}=\frac{2^{4r+1}}{(2r+1)(2r+2)}.$$

The generating functions are the inverses of the kernels in theorem D.40. □

corollary D.42 (Exact change between local source charts). **Editorial range correction.** This comparison holds for the even source subsequences, equivalently the evenized generating functions H_p. It does not identify their full odd-degree source values. For $p=3$, the original odd source has $A_{3,1}=S_1(3)=3$, whereas every odd dyadic source coefficient is zero. The even kernel L_3K_2 cannot change that odd coefficient. Read the coefficient consequence below only at even indices. The displayed identity $H_p=L_pK_\ell H_\ell$ and its proof remain valid.

For any two primes p and ℓ, the source sequences $A_{p,n}$ and $A_{\ell,n}$ are related by an exact unit lower triangular transformation obtained by composing the inverse kernel L_p with the reconstruction kernel K_ℓ.

Proof. Both source series reconstruct $\operatorname{sech} t$. Hence

$$H_p(t)=L_p(t)K_\ell(t)H_\ell(t).$$

The multiplier has constant coefficient one, so theorem D.16 gives an exact unit lower triangular coordinate change. □

example D.43 (The first odd reconstruction). For $p=3$ and $n=2$,

$$S_2(3)=1-9+25=17.$$

Since $Z_1=1$, $Z_3=2$, and $S_0(3)=1$, the odd coordinate formula gives

$$E_2=17-2\cdot 9=-1.$$

The large source value and the depth one correction are both necessary.

example D.44 (The first nontrivial dyadic row). For $n=4$,

$$R_4=\frac{91}{15},\qquad R_2=\frac{5}{3},\qquad R_0=1.$$

The exact kernel coefficients are

$$\kappa_{2,1} = -\frac{8}{3}, \qquad \kappa_{2,2} = \frac{128}{5}.$$

Therefore

$$E_4 = \frac{91}{15} - \frac{8}{3}\binom{4}{2}\frac{5}{3} + \frac{128}{5} = 5.$$

The rational source values are dyadic units, while the transfer depth is carried by the kernel.

remark D.45. The common convolution does not identify the integral charts. At an odd prime the finite character coordinate has order $p-1$. At the dyadic prime it begins with the sign coordinate, and the principal unit subgroup begins at $1+4\mathbb{Z}_2$.

D.5.4 Exact dyadic transfer depth

For $r \geq 1$, write

$$\kappa_{2,r} = \beta_r 2^{2r}(2r)! = -2^{4r}(2r-1)B_{2r}.$$

theorem D.46 (Exact dyadic kernel weight). **Editorial index conventions.** The standalone kernel valuation holds for all $r \geq 1$. Its reconstruction-term formula requires even $n \geq 0$ and $1 \leq r \leq n/2$. In the following truncation formulas only terms with $r \leq n/2$ occur. Terms that would use R_{n-2r} at a negative index are omitted. An empty tail is exactly zero, and the minimum over an empty set of term valuations is $+\infty$. These conventions include $M \geq n/2$.

For every $r \geq 1$,

$$\boxed{v_2(\kappa_{2,r}) = 4r - 1.}$$

The rth reconstruction term has exact valuation

$$\boxed{v_2\left(\kappa_{2,r}\binom{n}{2r}R_{n-2r}\right) = 4r - 1 + v_2\binom{n}{2r}.}$$

Equivalently,

$$\boxed{W_2(n,r) = 4r - 1 + s_2(r) + s_2(n-2r) - s_2(n).}$$

Proof. The Bernoulli formula gives $v_2(B_{2r}) = -1$. The source value is a unit. Kummer's binary carry formula gives the last expression. □

theorem D.47 (Optimal dyadic truncation). Let

$$T_{2,M}(n) = \sum_{r=0}^{\min(M,n/2)} \kappa_{2,r}\binom{n}{2r}R_{n-2r}.$$

Then

$$\boxed{E_n \equiv T_{2,M}(n) \pmod{2^{4M+3}}.}$$

More precisely,

$$\boxed{v_2\big(E_n - T_{2,M}(n)\big) \geq \min_{M+1\leq r\leq n/2}\left(4r - 1 + v_2\binom{n}{2r}\right).}$$

The uniform exponent $4M+3$ is best possible.

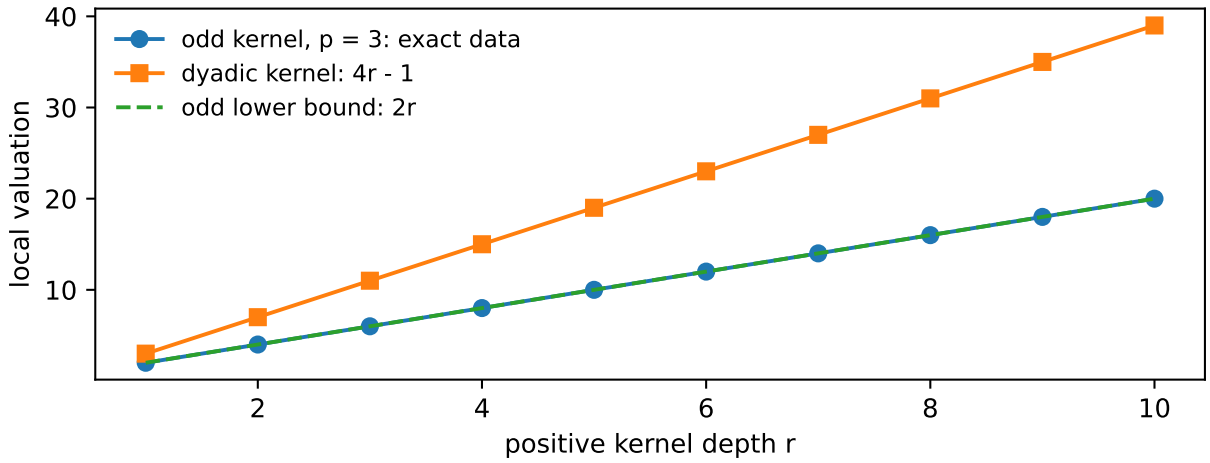

Figure 6. New reconstruction. Odd and dyadic kernels share one convolution law but have different valuation profiles. The positive depth dyadic kernel has exact slope four and offset minus one.

local coordinate	odd p	p = 2
finite torsion	modulo p - 1	sign modulo 2
principal units	$1 + p\mathbb{Z}_p$	$1 + 4\mathbb{Z}_2$
source choice	depleted unit branch	direct dyadic source
kernel floor	$2r$	$4r - 1$

Figure 7. New reconstruction. The local Euler charts share source and kernel reconstruction. Their torsion addresses, principal unit depths, source corrections, and precision growth remain different.

Proof. Every omitted term has valuation at least $4(M+1)-1$. For optimality, take $n = 2M+2$. There is one omitted term. Its binomial coefficient and source value are one, so its valuation is exactly $4M+3$. □

The first three sharp truncations are

$$E_n \equiv R_n \pmod 8,$$

$$E_n \equiv R_n - \frac{8}{3}\binom{n}{2} R_{n-2} \pmod{128},$$

$$E_n \equiv R_n - \frac{8}{3}\binom{n}{2} R_{n-2} + \frac{128}{5}\binom{n}{4} R_{n-4} \pmod{2048}.$$

D.6 Mahler transfer and local analytic branches

The finite character coordinate resolves the torsion part of a local unit. A sufficiently long arithmetic jump moves the remaining unit into a principal unit neighborhood. The coarse variable then has a convergent Mahler expansion with an explicit valuation slope.

D.6.1 Finite Mahler coordinates

For a function f on the nonnegative integers, define

$$\Delta f(n) = f(n+1) - f(n).$$

theorem D.48 (Finite Mahler reconstruction). Given $f(0), \dots, f(N)$, put $c_r = \Delta^r f(0)$. Then

$$\boxed{f(n) = \sum_{r=0}^{n} c_r \binom{n}{r} \qquad (0 \le n \le N).}$$

For every s with $0 \le s \le N$,

$$\boxed{\Delta^s f(n) = \sum_{r=s}^{N} c_r \binom{n}{r-s} \qquad (0 \le n \le N-s).}$$

Proof. Let

$$P(x) = \sum_{r=0}^{N} c_r \binom{x}{r}.$$

Newton interpolation gives $P(n) = f(n)$ for $0 \le n \le N$. Iterating

$$\Delta \binom{x}{r} = \binom{x}{r-1}$$

gives

$$\Delta^s P(n) = \sum_{r=s}^{N} c_r \binom{n}{r-s}.$$

When $0 \le n \le N-s$, every value used in $\Delta^s f(n)$ lies among the prescribed data, so $\Delta^s f(n) = \Delta^s P(n)$. □

corollary D.49 (Mahler valuation ledger). If $c_r \in \mathbb{Z}_p$ and $v_p(c_r) \ge w(r)$, then

$$\boxed{v_p(\Delta^s f(n)) \ge \min_{r \ge s} \left(w(r) + v_p \binom{n}{r-s} \right).}$$

Proof. Apply the nonarchimedean triangle inequality to theorem D.48. □

The infinite interpolation theorem states that every continuous function on $\mathbb{Z}_p$ has a unique convergent Mahler expansion [19, 20]. We use that theorem as a standard input when the local variable is allowed to range over all of $\mathbb{Z}_p$.

D.6.2 Carmichael and Mahler transfer for unit modes

standard fact D.50 (Local unit decomposition). For odd p, every unit has a unique factorization

$$u = \omega(u)\langle u\rangle, \qquad \omega(u)^{p-1} = 1, \qquad \langle u\rangle \in 1 + p\mathbb{Z}_p.$$

Every dyadic unit has a unique factorization

$$u = (-1)^{\epsilon(u)}\langle u\rangle, \qquad \epsilon(u) \in \{0,1\}, \qquad \langle u\rangle \in 1 + 4\mathbb{Z}_2.$$

The first factor gives the finite character address. The second factor admits logarithmic and Mahler coordinates.

For odd p and $L \geq 1$, put

$$\Lambda_{p,L} = (p-1)p^{L-1}.$$

For $p = 2$ and $L \geq 3$, put

$$\Lambda_{2,L} = 2^{L-2}.$$

These are exponents of the unit groups modulo the declared prime powers.

theorem D.51 (One unit mode). Let $u \in \mathbb{Z}_p^\times$, let $H = \Lambda_{p,L}$, and put

$$q_{u,L} = u^H - 1 \in p^L\mathbb{Z}_p.$$

For every integer address j and every $x \in \mathbb{Z}_p$,

$$\boxed{u^{Hx+j} = u^j \sum_{r\geq 0} q_{u,L}^r \binom{x}{r}.}$$

The rth Mahler coefficient has valuation at least Lr.

Proof. Write $u^{Hx+j} = u^j(1+q_{u,L})^x$ and use the convergent binomial series on $\mathbb{Z}_p$. □

example D.52 (Paired principal unit expansions). At the odd prime three,

$$2^{2x+j} = 2^j 4^x = 2^j \sum_{r\geq 0} 3^r \binom{x}{r}.$$

At the dyadic prime,

$$3^{2x+j} = 3^j 9^x = 3^j \sum_{r\geq 0} 8^r \binom{x}{r}.$$

The formal expansions are identical. Their first local slopes are one and three because $4 - 1 = 3$ while $9 - 1 = 8$.

corollary D.53 (Basic odd and dyadic difference gains). For odd p,

$$\boxed{\Delta^r_{(p-1)p^a} u^n = u^n \left(u^{(p-1)p^a} - 1\right)^r, \qquad v_p\left(\Delta^r_{(p-1)p^a} u^n\right) \geq (a+1)r.}$$

For odd $u \in \mathbb{Z}_2^\times$,

$$\boxed{\Delta^r_{2^{a+1}} u^n = u^n \left(u^{2^{a+1}} - 1\right)^r, \qquad v_2\left(\Delta^r_{2^{a+1}} u^n\right) \geq (a+3)r.}$$

Proof. One step difference multiplies a unit mode by $u^H - 1$. Fermat reduction and lifting the exponent give the odd estimate. For odd u,

$$v_2\left(u^{2^{a+1}} - 1\right) = v_2(u^2 - 1) + a \geq a + 3.$$

□

D.6.3 Polynomial exponential modes

theorem D.54 (Polynomial exponential Mahler transfer). Let

$$f(n) = P(n)u^n$$

with $P \in \mathbb{Z}_p[n]$ of degree d. Let $H = \Lambda_{p,L}$, fix an address j, and write

$$Q_j(x) = P(Hx + j), \qquad y = u^H, \qquad q = y - 1.$$

Then

$$\boxed{f(Hx + j) = \sum_{r \geq 0} c_{j,r} \binom{x}{r},}$$

where

$$\boxed{c_{j,r} = u^j \sum_{k=0}^{\min(d,r)} \binom{r}{k} \Delta^k Q_j(0) y^k q^{r-k}.}$$

Consequently,

$$\boxed{v_p(c_{j,r}) \geq L \max(r - d, 0).}$$

For $R \geq d$, truncation at depth R is valid modulo $p^{L(R+1-d)}$ uniformly on $\mathbb{Z}_p$.

Proof. On the polynomial factor the difference operator acts as $q + y\Delta$. The two terms commute. Expand $(q + y\Delta)^r$ and evaluate at zero. Since $\Delta^k Q_j = 0$ for $k > d$, every surviving term contains at least q^{r-d}. □

D.6.4 Matrix state systems and finite adelic synchronization

Let

$$v_{n+1} = Cv_n, \qquad a_n = w^T C^n v_0,$$

with $C \in M_d(\mathbb{Z}_p)$ invertible modulo p.

theorem D.55 (Matrix Carmichael and Mahler transfer). **Editorial hypothesis correction.** The original displayed statement leaves the vectors untyped. Its integrality conclusion requires $v_0, w \in \mathbb{Z}_p^d$, $L \geq 1$, and $H, j, n \in \mathbb{N}$ with $H > 0$. The value at $Hx + j$ for $x \in \mathbb{Z}_p$ means the matrix-binomial interpolation. With $p = 3$, $C = 4$, $L = 1$, $w = 1$ and $v_0 = 1/3$, one has $\Delta_1 a_0 = 1$, which is not in $3\mathbb{Z}_3$. The printed claim without these restrictions is therefore not a certificate as written. The full original proof follows under the corrected hypotheses.

Assume

$$C^H = I + p^L B$$

with $B \in M_d(\mathbb{Z}_p)$. For every address j and every $x \in \mathbb{Z}_p$,

$$\boxed{a_{Hx+j} = \sum_{r \geq 0} p^{Lr} \binom{x}{r} w^T C^j B^r v_0.}$$

The series converges on $\mathbb{Z}_p$, and

$$\boxed{\Delta_H^r a_n \equiv 0 \pmod{p^{Lr}}.}$$

Proof. Use

$$C^{Hx+j} = C^j (I + p^L B)^x$$

and the matrix binomial series. One difference in the coarse variable multiplies the series by $p^L B$. □

theorem D.56 (Finite adelic transfer). **Editorial hypothesis correction.** Read this statement with $v_0, w \in \mathbb{Z}^d$, $H > 0$ and $j, n, r \in \mathbb{N}$, and positive integer L_p. These restrictions make the integral congruences and powers well typed. Allowing $v_0 = 1/3$ in the one-prime example above loses the advertised digit. Invertibility of C alone does not restore it. The original proof is retained under these hypotheses.

Let

$$Q = \prod_{p \in S} p^{L_p}$$

for a finite set of primes. Let $C \in M_d(\mathbb{Z})$ be invertible modulo Q, and choose H such that

$$C^H = I + QB$$

with $B \in M_d(\mathbb{Z})$. Then for every nonnegative integer x,

$$\boxed{a_{Hx+j} = \sum_{r=0}^{x} Q^r \binom{x}{r} w^T C^j B^r v_0.}$$

For every r,

$$\boxed{\Delta_H^r a_n \equiv 0 \pmod{Q^r}.}$$

Proof. Apply the integer matrix binomial theorem and reduce at every selected prime. □

example D.57 (A simultaneous Fibonacci jump). Let

$$C = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}.$$

The matrix C is invertible modulo twenty four, and

$$C^{24} - I = 24 \begin{pmatrix} 3126 & 1932 \\ 1932 & 1194 \end{pmatrix}.$$

For every scalar coordinate of the state sequence $C^n v_0$,

$$\boxed{\Delta_{24}^r a_n \equiv 0 \pmod{24^r}.}$$

One integral jump therefore gives simultaneous congruence ladders at the primes two and three.

D.6.5 Amice pullback

definition D.58 (Amice pullback). For a formal exponential generating series

$$F(z) = \sum_{n \geq 0} a_n \frac{z^n}{n!},$$

define

$$\widehat{F}(T) = F(\log(1+T)).$$

theorem D.59 (Derivative conjugacy).

$$\boxed{\widehat{F}'(T) = (1+T)\frac{d}{dT}\widehat{F}(T).}$$

Proof. Differentiate the composition $F(\log(1+T))$. □

proposition D.60 (Weighted convergence). If

$$\widehat{F}(T) = \sum_{r \geq 0} c_r T^r$$

and

$$v_p(c_r) + r\alpha \longrightarrow +\infty,$$

then the series converges whenever $v_p(T) \geq \alpha$.

Proof. The valuation of the rth term is $v_p(c_r) + r v_p(T)$, which tends to positive infinity. □

D.6.6 Odd prime depletion

For an odd prime p, the source $S_n(p)$ contains one nonunit base. Put

$$\sigma_p = (-1)^{(p-1)/2}$$

and

$$S_n^{\times}(p) = S_n(p) - \sigma_p p^n.$$

theorem D.61 (Depleted odd prime reconstruction). For every even n,

$$\boxed{\left(1 - \sigma_p p^n\right) E_n = \sum_{r=0}^{n/2} (-1)^r Z_{2r+1} \binom{n}{2r} p^{2r} S_{n-2r}^{\times}(p).}$$

Proof. The removed source mode contributes $\sigma_p \cosh(pt)$. Multiplication by $\operatorname{sech}^2(pt)$ gives $\sigma_p \operatorname{sech}(pt)$. Subtract it from the full source and kernel product. □

Fix an even address $j \in \{0, 2, \dots, p-3\}$. For $x \in \mathbb{Z}_p$, define

$$\mathscr{E}^{\times}_{p,j}(x) = \sum_{r \geq 0} (-1)^r Z_{2r+1} p^{2r} \binom{(p-1)x + j}{2r} \times \sum_{\substack{0 \leq a < p \\ 2a+1 \neq p}} (-1)^a (2a+1)^{j-2r} \left((2a+1)^{p-1}\right)^x.$$

theorem D.62 (Odd prime analytic Euler branch). The series defining $\mathscr{E}^{\times}_{p,j}$ converges in the Tate algebra on $\mathbb{Z}_p$. For every nonnegative integer x,

$$\boxed{\mathscr{E}^{\times}_{p,j}(x) = \left(1 - \sigma_p p^{(p-1)x+j}\right) E_{(p-1)x+j}.}$$

Proof. Every retained base is a unit, and its $(p-1)$st power lies in $1 + p\mathbb{Z}_p$. The polynomial

$$p^{2r} \binom{(p-1)x + j}{2r}$$

has Gauss norm at most

$$p^{-2r+v_p((2r)!)}.$$

This tends to zero because p is odd. The remaining factors have bounded Gauss norm. Thus the series converges in the Tate algebra. At a nonnegative integer x, the binomial factor vanishes for large r, and theorem D.61 gives the value. □

remark D.63. The analytic function is defined by its unit source series. The expression $p^{(p-1)x+j}$ in the interpolation identity is evaluated only at nonnegative integers. No analytic function $x \mapsto p^x$ on all of $\mathbb{Z}_p$ is used.

D.6.7 Direct dyadic interpolation

For $x \in \mathbb{Z}_2$, define

$$\boxed{\mathscr{R}(x) = \frac{9^{x+1} - 1}{8(x+1)(2x+1)}.}$$

The apparent singularity at $x = -1$ is removable, with value $-\log(9)/8$.

lemma D.64 (Analytic dyadic source). The function $\mathscr{R}$ belongs to the dyadic Tate algebra and takes values in $\mathbb{Z}_2$. For every nonnegative integer n,

$$\boxed{\mathscr{R}(n) = R_{2n}.}$$

Proof. Put $y = x + 1$ and let $\ell = \log 9$. Since $v_2(\ell) = 3$,

$$\frac{9^y - 1}{8y} = \frac{\ell}{8} \sum_{m \geq 0} \frac{\ell^m}{(m+1)!} y^m.$$

The coefficient of y^m has valuation

$$3m - v_2((m+1)!),$$

which is nonnegative and tends to positive infinity. The quotient therefore belongs to $\mathbb{Z}_2\langle y\rangle$. The factor $2x+1 = 1+2x$ is a unit in $\mathbb{Z}_2\langle x\rangle$, with inverse $\sum_{m\geq 0}(-2x)^m$. Hence $\mathscr{R}$ is integral and analytic. The integer values follow from the definition of R_{2n}. □

Define

$$\boxed{\mathscr{E}_2(x) = \sum_{r\geq 0} \kappa_{2,r}\binom{2x}{2r}\mathscr{R}(x-r).}$$

theorem D.65 (Direct dyadic Euler interpolation). The series defining $\mathscr{E}_2$ converges in the dyadic Tate algebra. For every nonnegative integer n,

$$\boxed{\mathscr{E}_2(n) = E_{2n}.}$$

Truncation after depth M is uniformly valid modulo 2^{4M+3} on $\mathbb{Z}_2$.

Proof. The monomial Gauss norm of $\binom{2x}{2r}$ is at most $2^{v_2((2r)!)}$. Since

$$v_2(\kappa_{2,r}) = 4r-1,$$

the product tends to zero in Gauss norm. Translation by the integer r preserves the unit disc, so $\mathscr{R}(x-r)$ remains an integral analytic function with uniformly bounded supremum norm. The series therefore converges in the Tate algebra.

At a nonnegative integer n, every term with $r > n$ vanishes and theorem D.39 remains. For arbitrary $x \in \mathbb{Z}_2$, the integer valued polynomial $\binom{2x}{2r}$ and the source value $\mathscr{R}(x-r)$ lie in $\mathbb{Z}_2$. Every omitted term after depth M is therefore divisible by 2^{4M+3}. This proves the uniform truncation statement. □

theorem D.66 (Unified local interpolation statement). The odd branch $\mathscr{E}^{\circ\times}_{p,j}$ and the dyadic branch $\mathscr{E}_2$ are analytic local realizations of the source and kernel law in theorem D.40. At integer arguments they recover, respectively,

$$\left(1-\sigma_p p^n\right) E_n$$

on each even odd prime character branch and

$$E_{2n}$$

on the dyadic even branch. The two realizations have distinct source corrections and distinct kernel valuation slopes.

Proof. Combine theorems D.62 and D.65 with the source and kernel definitions in theorem D.40. □

D.7 Polyphase refinement of local Mahler coordinates

Polyphase refinement replaces one local branch by finitely many digit branches while preserving exact synthesis. For sequences it is residue analysis. For local functions it is the digit tree of $\mathbb{Z}_p$. In Mahler coordinates it becomes a finite triangular kernel.

D.7.1 Discrete analysis and exact synthesis

For a sequence $a = (a_n)_{n\geq 0}$ and $M \geq 2$, define

$$a_r^{[M]}(q) = a_{Mq+r} \qquad (0 \leq r < M).$$

The analysis map is

$$\mathcal{P}_M a = \left(a_0^{[M]}, \ldots, a_{M-1}^{[M]}\right).$$

Synthesis interleaves the branches by the rule

$$a_{Mq+r} = a_r^{[M]}(q).$$

theorem D.67 (Exact discrete polyphase reconstruction). The analysis map $\mathcal{P}_M$ is a bijection between sequences and ordered families of M sequences. If

$$A(z) = \sum_{n\geq 0} a_n z^n$$

and

$$A_r^{[M]}(w) = \sum_{q\geq 0} a_{Mq+r} w^q,$$

then

$$\boxed{A(z) = \sum_{r=0}^{M-1} z^r A_r^{[M]}(z^M).}$$

Proof. Every nonnegative integer has a unique expression $Mq + r$ with $0 \leq r < M$. Group the terms of the ordinary generating function by this residue. □

theorem D.68 (Nested discrete refinement). For positive integers M, N,

$$\boxed{\left(a_r^{[M]}\right)_s^{[N]} = a_{r+Ms}^{[MN]}.}$$

For a mixed radix path $(M_1, \ldots, M_\ell)$ with digits $0 \leq s_i < M_i$, the final address is

$$\boxed{r(\boldsymbol{s}) = s_1 + M_1 s_2 + \cdots + \left(\prod_{i=1}^{\ell-1} M_i\right) s_\ell.}$$

Only the product radix and accumulated address determine the final branch.

Proof. Direct substitution gives

$$\left(a_r^{[M]}\right)_s^{[N]}(q) = a_{M(Nq+s)+r}.$$

Iterate this identity along the mixed radix path. □

D.7.2 Carry convolution and the shift matrix

Let $c = a * b$ be the ordinary Cauchy convolution. Write A_r, B_r, and C_r for the phase ordinary generating functions.

proposition D.69 (One carry convolution law). For every residue r,

$$\boxed{C_r(w) = \sum_{u+v=r} A_u(w)B_v(w) + w \sum_{u+v=r+M} A_u(w)B_v(w).}$$

The first sum has no phase carry. The second has one coarse index carry.

Proof. Write the input indices as $Mq+u$ and $Mq'+v$. Since $0 \le u, v < M$, their sum has residue $u+v$ when $u+v < M$, and residue $u+v-M$ with one additional coarse index when $u+v \ge M$. □

theorem D.70 (Polyphase shift matrix). Let E be the scalar shift $(Ea)_n = a_{n+1}$, and let E_q shift the coarse index. Then

$$\boxed{\mathcal{P}_M(Ea) = \mathsf{S}_M(E_q)\mathcal{P}_M a,}$$

where

$$\mathsf{S}_M(E_q) = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ E_q & 0 & 0 & \cdots & 0 \end{pmatrix}.$$

It also satisfies

$$\boxed{\mathsf{S}_M(E_q)^M = E_q I_M.}$$

Proof. For $r < M-1$,

$$(Ea)_{Mq+r} = a_{Mq+r+1} = a_{r+1}^{[M]}(q).$$

For $r = M-1$,

$$(Ea)_{Mq+M-1} = a_{M(q+1)} = E_q a_0^{[M]}(q).$$

After M shifts every phase has advanced by one coarse index. □

D.7.3 Local branches and digit reconstruction

For $a \ge 1$ and $0 \le s < p^a$, define

$$f_{a,s}(x) = f(p^a x + s).$$

theorem D.71 (Exact local branch reconstruction). The family $\{f_{a,s}\}_{0 \le s < p^a}$ determines f uniquely on $\mathbb{Z}_p$. More precisely, if $y \in s + p^a\mathbb{Z}_p$, then

$$\boxed{f(y) = f_{a,s}\left(\frac{y-s}{p^a}\right).}$$

For $a, b \ge 1$,

$$\boxed{(f_{a,s})_{b,t} = f_{a+b,s+p^a t}.}$$

Thus local refinement is exactly the p adic digit tree.

Proof. The cosets $s + p^a\mathbb{Z}_p$ form a disjoint partition of $\mathbb{Z}_p$. The first formula is the inverse affine change of variables on one coset. The second follows from

$$p^a(p^b x + t) + s = p^{a+b}x + p^a t + s.$$

□

D.7.4 The affine Mahler kernel

Let

$$\Phi_M(z) = (1+z)^M - 1.$$

For $M \geq 1$, $s \geq 0$, and $r, k \geq 0$, define

$$\boxed{\Theta_{M,s}(r,k) = [z^r](1+z)^s \Phi_M(z)^k.}$$

Equivalently,

$$\boxed{\Theta_{M,s}(r,k) = \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} \binom{Mj+s}{r}.}$$

It vanishes unless

$$k \leq r \leq Mk + s.$$

proposition D.72 (Edge coefficients of the affine kernel). For every $M \geq 1$, $s \geq 0$, and $k \geq 0$,

$$\boxed{\Theta_{M,s}(k,k) = M^k, \qquad \Theta_{M,s}(Mk+s,k) = 1.}$$

For binary radix and zero address,

$$\boxed{\Theta_{2,0}(k+j,k) = 2^{k-j}\binom{k}{j} \qquad (0 \leq j \leq k).}$$

Hence

$$\boxed{v_2\left(\Theta_{2,0}(k+j,k)\right) = k - j + v_2\binom{k}{j}.}$$

Proof. The lowest degree term of $\Phi_M(z)$ is Mz, and its highest degree term is z^M. Multiplication by $(1+z)^s$ gives the two edge coefficients. When $M = 2$ and $s = 0$,

$$\Phi_2(z)^k = (2z + z^2)^k = z^k(2+z)^k.$$

Taking the coefficient of z^{k+j} gives the binary formula. □

theorem D.73 (Mahler polyphase transfer). Let

$$f(x) = \sum_{r \geq 0} c_r \binom{x}{r}$$

be a convergent Mahler expansion. For

$$g_s(q) = f(Mq + s),$$

one has

$$\boxed{g_s(q) = \sum_{k\geq 0} d_{s,k} \binom{q}{k},}$$

where

$$\boxed{d_{s,k} = \sum_{r=k}^{Mk+s} c_r \Theta_{M,s}(r,k).}$$

Every refined coefficient uses a finite window of the original Mahler coefficients.

Proof. Use

$$(1+z)^{Mq+s} = (1+z)^s \, (1+\Phi_M(z))^q = \sum_{k\geq 0} \binom{q}{k} (1+z)^s \Phi_M(z)^k.$$

Taking the coefficient of z^r gives the affine expansion of $\binom{Mq+s}{r}$. Since $c_r \to 0$ and every $d_{s,k}$ uses indices $r \geq k$, the transformed coefficients also tend to zero. □

theorem D.74 (Kernel composition). For positive integers M, N,

$$\boxed{\sum_{k\geq 0} \Theta_{M,s}(r,k)\Theta_{N,t}(k,\ell) = \Theta_{MN,Mt+s}(r,\ell).}$$

The sum is finite.

Proof. Apply theorem D.73 first to $x = Mq + s$ and then to $q = Ny + t$. The composite substitution is $x = MNy + Mt + s$. Uniqueness of Mahler coefficients gives the identity. □

D.7.5 Valuation transport

theorem D.75 (Polyphase valuation ledger). For every refined coefficient,

$$\boxed{v_p(d_{s,k}) \geq \min_{k\leq r\leq Mk+s} \left(v_p(c_r) + v_p(\Theta_{M,s}(r,k))\right).}$$

If $v_p(c_r) \geq w(r)$ for a nondecreasing function w, then

$$\boxed{v_p(d_{s,k}) \geq w(k).}$$

Thus every monotone Mahler precision ladder survives arbitrary polyphase refinement.

Proof. Apply the nonarchimedean triangle inequality to the finite coefficient formula. Since $r \geq k$, monotonicity gives $w(r) \geq w(k)$, and the affine kernel is integral. □

theorem D.76 (Prime power sparsification). **Editorial hypothesis correction.** The affine-kernel congruence below needs no change, but its consequence for transformed Mahler coefficients requires $c_r \in \mathbb{Z}_p$ for every r. Convergence of a $\mathbb{Q}_p$-valued Mahler expansion alone is insufficient. For $p = 2$,

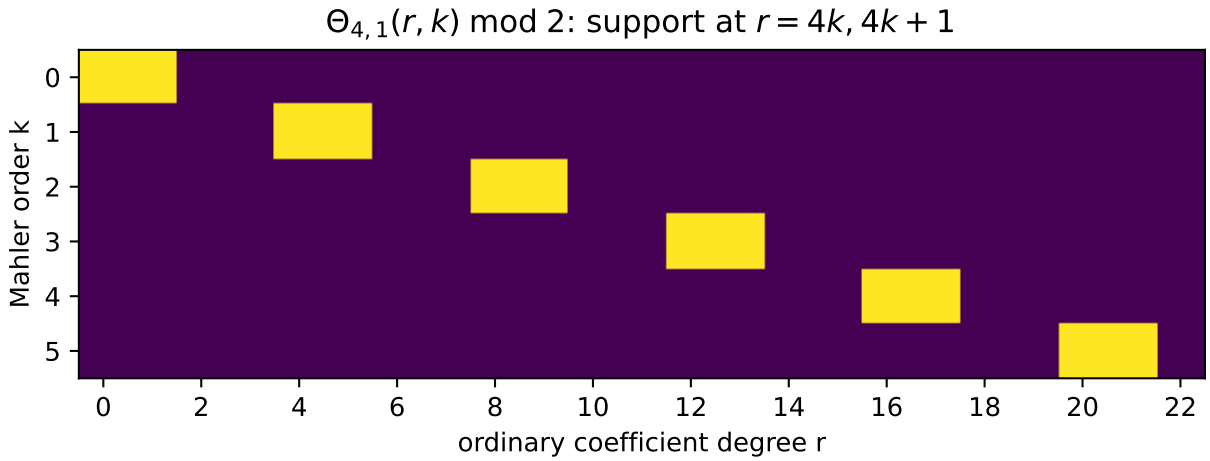

Figure 8. New reconstruction. The affine Mahler kernel has finite triangular support. At a prime power radix, its reduction is confined to a short Frobenius window.

$M = 2$, $s = 0$ and $f(x) = x/2$, one has $c_1 = 1/2$, $c_2 = 0$, while $g(q) = q$ has $d_1 = 1$. Thus $d_1 \not\equiv c_2 \pmod 2$. The coefficient consequence is read with integral original coefficients.

Let $M = p^a$. Then

$$\boxed{\Theta_{p^a,s}(r,k) \equiv \binom{s}{r - p^a k} \pmod p,}$$

where the binomial coefficient is zero outside its natural range. Consequently,

$$\boxed{d_{s,k} \equiv \sum_{u=0}^{s} \binom{s}{u} c_{p^a k+u} \pmod p.}$$

In particular,

$$\boxed{d_{0,k} \equiv c_{p^a k} \pmod p.}$$

Proof. In characteristic p,

$$(1+z)^{p^a} - 1 \equiv z^{p^a}.$$

Substitute this congruence in the definition of $\Theta_{p^a,s}$. □

D.7.6 Precision amplification

theorem D.77 (Scalar polyphase precision amplification). Let $u \in \mathbb{Z}_p^\times$, let $a, r \geq 0$, and put

$$H_a = \begin{cases} (p-1)p^a, & p \text{ odd}, \\ 2^{a+1}, & p = 2. \end{cases}$$

Then

$$\boxed{\Delta_{H_a}^r u^n = u^n \left(u^{H_a} - 1\right)^r.}$$

For odd p,

$$\boxed{v_p\left(\Delta_{H_a}^r u^n\right) \geq (a+1)r.}$$

For $p = 2$ and odd u,

$$\boxed{v_2\left(\Delta_{H_a}^r u^n\right) \geq (a+3)r.}$$

Equivalently, every additional prime power digit increases the certified Mahler slope by one.

Proof. One difference with step H_a multiplies the unit mode by $u^{H_a} - 1$. Iterate. The valuation estimates are those of corollary D.53. □

lemma D.78 (Matrix power amplification). **Editorial hypothesis correction.** Require $L \geq 1$. At $L = 0$ the standalone claim is false: for $p = 3$, $d = 1$ and $X = 2 = 1 + B$, one has $X^3 - 1 = 7 \notin 3\mathbb{Z}_3$. With $L \geq 1$, every higher binomial term in the retained proof has the required valuation, including $p = 2$.

If

$$X = I + p^L B$$

with $B \in M_d(\mathbb{Z}_p)$, then for every $a \geq 0$ there is $B_a \in M_d(\mathbb{Z}_p)$ such that

$$\boxed{X^{p^a} = I + p^{L+a} B_a.}$$

Proof. Induct on a. Expand the pth power of $I + p^{L+a} B_a$. The linear term has valuation at least $L + a + 1$, and every higher term has at least that valuation. □

theorem D.79 (Matrix polyphase precision amplification). **Editorial hypothesis correction.** Require $L \geq 1$, $C, B \in M_d(\mathbb{Z}_p)$, $v_0, w \in \mathbb{Z}_p^d$, $H > 0$, and $a, j, n, r \in \mathbb{N}$. These are the hypotheses of the two corrected matrix statements used by the retained proof. Without integral observation vectors or positive L, the preceding counterexamples invalidate the claimed precision.

Assume

$$C^H = I + p^L B.$$

Put $H_a = Hp^a$. Then

$$C^{H_a} = I + p^{L+a} B_a$$

for an integral matrix B_a. Every refined packet

$$b_{a,j}(x) = a_{H_a x + j}$$

has Mahler coefficients satisfying

$$\boxed{v_p(c_{a,j,r}) \geq (L+a)r.}$$

Equivalently,

$$\boxed{\Delta_{H_a}^r a_n \equiv 0 \pmod{p^{(L+a)r}}.}$$

Proof. Combine lemma D.78 and theorem D.55. □

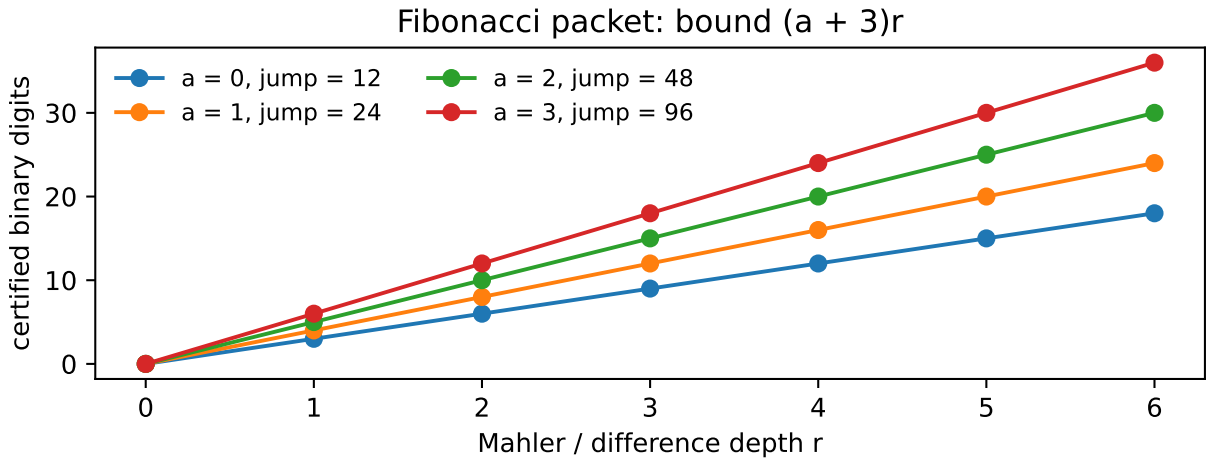

Figure 9. New reconstruction. Every additional prime power refinement digit increases the certified Mahler slope of a principal unit matrix packet by one.

example D.80 (Refined dyadic Fibonacci ladder). For the Fibonacci companion matrix

$$C = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix},$$

one has

$$C^{12} = I + 8 \begin{pmatrix} 29 & 18 \\ 18 & 11 \end{pmatrix}.$$

Therefore

$$\boxed{\Delta^{r}_{12\cdot 2^{a}} F_n \equiv 0 \pmod{2^{(a+3)r}}.}$$

Every dyadic refinement doubles the step and adds one guaranteed binary digit at each Mahler depth.

D.7.7 Character and polyphase coordinates

For odd p, write

$$\boxed{n = j + (p-1)(s + p^{a} q),}$$

with $0 \le j < p-1$ and $0 \le s < p^{a}$. The address j records the finite character. The address s records the principal unit digit. The variable q carries the remaining Mahler expansion.

At the dyadic prime, write

$$\boxed{n = j + 2(s + 2^{a} q),}$$

with $j \in \{0, 1\}$ and $0 \le s < 2^{a}$. The sign coordinate replaces the odd prime character coordinate.

proposition D.81 (Local phase lattice). For a unit mode u^{n}, the odd prime coordinate gives

$$\boxed{u^{n} = u^{j+(p-1)s} \left(u^{(p-1)p^{a}}\right)^{q}.}$$

The dyadic coordinate gives

$$\boxed{u^{n} = u^{j+2s} \left(u^{2^{a+1}}\right)^{q}.}$$

Thus finite character phase, local digit address, and Mahler depth are separate coordinates.

Proof. Substitute the two displayed decompositions of n. □

corollary D.82 (Polyphase refinement of the Euler branches). The analytic branches in theorems D.62 and D.65 admit exact refinements under $x = p^a q + s$. Their refined Mahler coefficients are obtained from $\Theta_{p^a,s}$. The original monotone valuation ladders are preserved, and unit mode or invertible matrix representations gain one certified digit per refinement level.

Proof. Apply theorems D.73, D.75 and D.79 and corollary D.53. □

remark D.83. Exact refinement does not imply that every branch is simpler. A simplification theorem requires an additional invariant, such as Frobenius sparsity, valuation gain, spectral collision, or a vanishing transfer block.

D.8 Arithmetic lift obstructions

A congruence class may solve an equation to one precision and fail at the next. The correct obstruction is not an arbitrary residual vector. It is the residual vector modulo the image of the declared correction map.

D.8.1 Linear lifting

Let p be a prime. Let

$$M \in M_{r,d}(\mathbb{Z}_p), \qquad b \in \mathbb{Z}_p^r.$$

Suppose that $x_L \in \mathbb{Z}_p^d$ satisfies

$$Mx_L \equiv b \pmod{p^L}$$

for some $L \geq 1$. Define the reduced residual

$$\rho_L(x_L) = \frac{Mx_L - b}{p^L} \pmod{p} \in \mathbb{F}_p^r.$$

Write $\overline{M}$ for the reduction of M modulo p.

definition D.84 (Linear lift obstruction). The linear obstruction at depth L is

$$\boxed{\mathrm{Ob}_L^{\mathrm{lin}}(x_L) = [\rho_L(x_L)] \in \mathrm{coker}(\overline{M}).}$$

theorem D.85 (One level linear lifting). A class represented by x_L lifts to a solution modulo p^{L+1} if and only if

$$\boxed{\mathrm{Ob}_L^{\mathrm{lin}}(x_L) = 0.}$$

More precisely, a correction $y \in \mathbb{F}_p^d$ gives a lift

$$x_{L+1} = x_L + p^L y \pmod{p^{L+1}}$$

if and only if

$$\boxed{\overline{M}y = -\rho_L(x_L).}$$

When one correction exists, the set of all correction classes is a coset of $\ker \overline{M}$.

Proof. Modulo p^{L+1},

$$M(x_L + p^L y) - b = Mx_L - b + p^L My.$$

After division by p^L and reduction modulo p, the lift condition becomes

$$\rho_L(x_L) + \overline{M}y = 0.$$

This equation is solvable exactly when the residual lies in the image of $\overline{M}$. If y_0 is one solution, every solution is $y_0 + z$ with $z \in \ker \overline{M}$. □

proposition D.86 (Representative independence). The class $\mathrm{Ob}_L^{\mathrm{lin}}(x_L)$ depends only on the solution class of x_L modulo p^L.

Proof. Replace x_L by $x_L + p^L z$. The reduced residual changes by $\overline{M}z$. Its class in the cokernel is unchanged. □

corollary D.87 (Exact number of linear children). If $\rho = \mathrm{rank}_{\mathbb{F}_p} \overline{M}$, then a solvable depth L class has exactly

$$\boxed{p^{d-\rho}}$$

children modulo p^{L+1}.

Proof. The correction set is a coset of a vector space of dimension $d - \rho$. □

example D.88 (A visible linear obstruction). Take $p = 3$, $L = 1$, and

$$M = \begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}.$$

The class $x_1 = (0, 0)$ solves

$$Mx_1 \equiv b \pmod 3$$

for both

$$b_1 = (-3, 0) \qquad \text{and} \qquad b_2 = (0, -3).$$

For b_1, the reduced residual is $(1, 0)$, which belongs to the image of $\overline{M}$. There are three correction classes, given by

$$y_1 + y_2 = 2 \pmod 3.$$

For b_2, the residual is $(0, 1)$, whose cokernel class is nonzero. No lift modulo nine exists because the second row of M remains zero.

D.8.2 Polynomial lifting

Let

$$F = (F_1, \dots, F_r) : \mathbb{Z}_p^d \longrightarrow \mathbb{Z}_p^r$$

be a polynomial map.

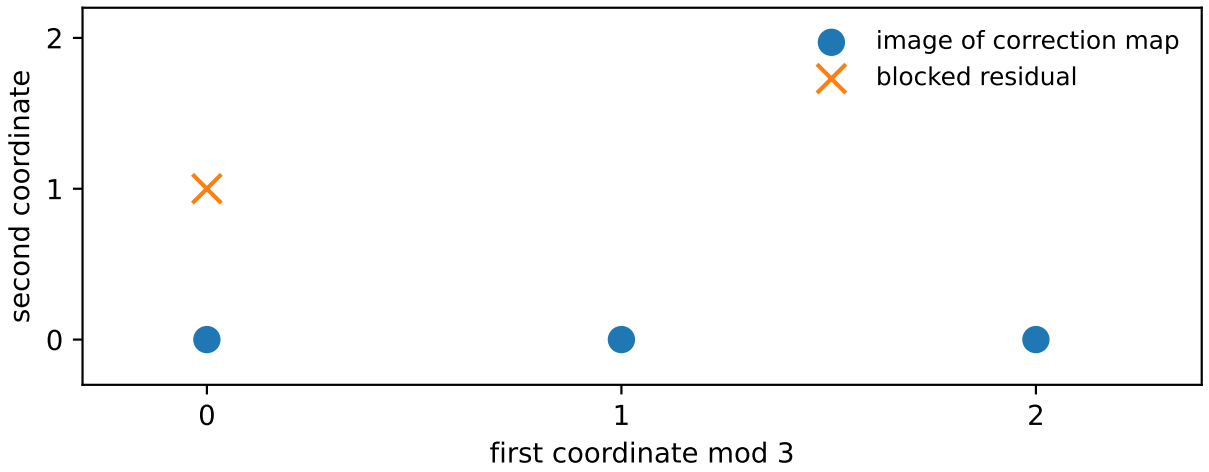

Figure 10. New reconstruction. A residual vector lifts precisely when its class vanishes in the cokernel of the reduced correction map.

Editorial coefficient clarification. Here polynomial means $F_i \in \mathbb{Z}_p[X_1, \dots, X_d]$, not merely an integer-valued polynomial with coefficients in $\mathbb{Q}_p$. This makes the Jacobian and Taylor remainder integral and their reduction well typed.

Suppose

$$F(x_L) \in p^L \mathbb{Z}_p^r.$$

Define

$$\rho_L^F(x_L) = \frac{F(x_L)}{p^L} \pmod{p}.$$

Let $J_F(x_L)$ denote the Jacobian matrix and write $\overline{J}_F(x_L)$ for its reduction modulo p.

definition D.89 (Polynomial lift obstruction). The polynomial obstruction at depth L is

$$\boxed{\mathrm{Ob}_L^F(x_L) = [\rho_L^F(x_L)] \in \operatorname{coker}(\overline{J}_F(x_L)).}$$

theorem D.90 (One level polynomial lifting). Let $L \geq 1$. A class represented by x_L lifts to a zero of F modulo p^{L+1} if and only if

$$\boxed{\mathrm{Ob}_L^F(x_L) = 0.}$$

A correction $y \in \mathbb{F}_p^d$ gives a lift if and only if

$$\boxed{\overline{J}_F(x_L) y = -\rho_L^F(x_L).}$$

When a correction exists, the correction classes form a coset of

$$\ker \overline{J}_F(x_L).$$

Proof. The polynomial Taylor expansion gives

$$F(x_L + p^L y) \equiv F(x_L) + p^L J_F(x_L) y \pmod{p^{L+1}}.$$

Every term of degree at least two in the increment contains p^{2L}, which is divisible by p^{L+1}. Divide by p^L, reduce modulo p, and apply the same cokernel criterion as in theorem D.85. □

proposition D.91 (Polynomial representative independence). The class $\mathrm{Ob}_L^F(x_L)$ depends only on the class of x_L modulo p^L.

Proof. If x_L is replaced by $x_L + p^L z$, Taylor expansion shows that the reduced residual changes by an element of the image of $\bar{J}_F(x_L)$. The reduced Jacobian itself is unchanged because $L \geq 1$. □

corollary D.92 (Simple root lifting). Assume $r = d$ and

$$\det J_F(x_L) \not\equiv 0 \pmod{p}.$$

Then the depth L solution has exactly one child modulo p^{L+1}. Iterating gives a unique p adic zero above the initial class.

Proof. The reduced Jacobian is invertible, so every residual has one correction. The resulting compatible sequence is Cauchy in $\mathbb{Z}_p^d$, and continuity of F gives a zero in the limit. Uniqueness holds at every depth. □

example D.93 (A singular polynomial obstruction). Let $p = 3$ and consider the class $x_1 = 0$ modulo three. For

$$F_0(x) = x^2,$$

the residual and the reduced derivative both vanish. Every correction $y \in \mathbb{F}_3$ gives

$$F_0(3y) \equiv 0 \pmod{9},$$

so the class has three children. For

$$F_1(x) = x^2 + 3,$$

the reduced derivative is still zero, but the reduced residual is one. Its class in the cokernel is nonzero, so no lift modulo nine exists.

This is the usual simple root mechanism behind Hensel lifting. The obstruction formulation also covers singular Jacobians, where some residual classes lift and others do not [22, 12, 20].

D.8.3 Packetwise obstruction splitting

theorem D.94 (Packet decomposition of a lift obstruction). Suppose

$$\mathbb{F}_p^d = \bigoplus_{a \in A} U_a, \qquad \mathbb{F}_p^r = \bigoplus_{a \in A} V_a,$$

and suppose a linear correction map $D : \mathbb{F}_p^d \to \mathbb{F}_p^r$ satisfies

$$D(U_a) \subseteq V_a$$

for every a. Write $D_a = D|_{U_a}$. Then

$$\boxed{\operatorname{coker} D \cong \bigoplus_{a \in A} \operatorname{coker} D_a.}$$

address j	k = 0	k = 1	k = 2	k = 3	k = 4
0	0	2	8	34	144
1	1	3	13	55	233
2	1	5	21	89	377

Figure 11. New reconstruction. Fibonacci residues F_{3k+j}, with $F_0 = 0$ and $F_1 = 1$. Each packet evolves by the same jump matrix C^3 and has a different initial address.

A residual lifts if and only if every packet obstruction vanishes.

Proof. The image of D is the direct sum of the images of the maps D_a. Taking the quotient of the codomain packet decomposition gives the stated cokernel decomposition. □

remark D.95. The obstruction theorems solve one declared local lifting step. They do not prove that a compatible branch exists across unrelated primes, that a global Diophantine point exists, or that an arithmetic representation is automorphic.

D.9 Recurrence packets and a common integral spine

Linear recurrences provide a setting where residue subsequences, local completions, and a common global source can all be described exactly. Background on recurrence sequences may be found in [11, 23].

D.9.1 Companion jumps

Let R be a commutative ring. Let

$$v_{n+1} = Cv_n, \qquad C \in M_d(R).$$

For a positive integer N and an address $j \in \{0, \dots, N-1\}$, define the residue state packet

$$u_k^{(j)} = v_{Nk+j}.$$

theorem D.96 (Companion jump recurrence). Every residue state packet satisfies

$$\boxed{u_{k+1}^{(j)} = C^N u_k^{(j)}.}$$

More explicitly,

$$\boxed{u_k^{(j)} = C^j (C^N)^k v_0.}$$

Proof. The state relation gives $v_n = C^n v_0$. Substitute $n = Nk + j$. □

Fibonacci state matrix	characteristic polynomial	roots
C = [[1, 1], [1, 0]]	$x^2 - x - 1$	α, β
C^3 = [[3, 2], [2, 1]]	$x^2 - 4x - 1$	α^3, β^3

Figure 12. New reconstruction. Passing to every Nth term raises each characteristic root to its Nth power.

We use the resultant convention

$$\operatorname{Res}_y(f, g) = \prod_{f(\alpha)=0} g(\alpha)$$

when f is monic, with roots counted with multiplicity.

theorem D.97 (Characteristic polynomial of the jump). Let

$$\chi_C(y) = \det(yI - C).$$

Then

$$\boxed{\chi_{C^N}(x) = \operatorname{Res}_y\bigl(\chi_C(y), x - y^N\bigr).}$$

The identity holds over the coefficient ring after interpreting the resultant universally.

Proof. After passage to an algebraic closure, let $\alpha_1, \dots, \alpha_d$ be the eigenvalues of C, counted with algebraic multiplicity. The resultant is

$$\prod_{i=1}^{d} (x - \alpha_i^N),$$

which is the characteristic polynomial of C^N. Both sides are polynomial expressions with integer coefficients in the entries of C, so the identity descends to every commutative coefficient ring. □

D.9.2 Second order recurrences

theorem D.98 (Residue subsequences of a second order recurrence). Suppose

$$x_{n+2} = P x_{n+1} - Q x_n$$

over a commutative ring. Define $V_0 = 2$, $V_1 = P$, and

$$V_{n+2} = P V_{n+1} - Q V_n.$$

For every positive integer N and every address j, the subsequence

$$u_k = x_{Nk+j}$$

satisfies

$$\boxed{u_{k+2} = V_N u_{k+1} - Q^N u_k.}$$

Proof. The companion matrix

$$C = \begin{pmatrix} P & -Q \\ 1 & 0 \end{pmatrix}$$

has trace P and determinant Q. The trace of C^N is V_N, while its determinant is Q^N. Cayley Hamilton applied to C^N gives

$$(C^N)^2 - V_N C^N + Q^N I = 0.$$

Apply this identity to the residue state packet and take its scalar coordinate. □

corollary D.99 (Fibonacci residue packets). Let $F_0 = 0$, $F_1 = 1$, and $F_{n+2} = F_{n+1} + F_n$. Let L_N denote the Lucas number. For every $N \geq 1$ and every address j,

$$\boxed{F_{N(k+2)+j} = L_N F_{N(k+1)+j} - (-1)^N F_{Nk+j}.}$$

Proof. Apply theorem D.98 with $P = 1$ and $Q = -1$. Then $V_N = L_N$. □

D.9.3 Finite and local periodicity

theorem D.100 (Periodicity of an invertible recurrence modulo a prime power). Let

$$C \in M_d(\mathbb{Z}), \qquad p \nmid \det C.$$

For every $L \geq 1$, every state orbit modulo p^L is purely periodic. Its period divides the order of C in

$$\mathrm{GL}_d(\mathbb{Z}/p^L\mathbb{Z}).$$

If $p \mid \det C$, every orbit is still eventually periodic.

Proof. When $p \nmid \det C$, multiplication by C is a permutation of the finite state set $(\mathbb{Z}/p^L\mathbb{Z})^d$. Every orbit of a permutation is periodic, and applying the group order relation for C gives the divisibility statement. Without invertibility, repeated application of a map on a finite set eventually repeats a state, after which the orbit is periodic. □

corollary D.101 (Residue packet periods). Under the invertibility hypothesis of theorem D.100, every residue packet with jump N has period dividing the order of C^N modulo p^L.

Proof. Use the jump matrix from theorem D.96. □

D.9.4 The common integral spine

theorem D.102 (Base change of an integral recurrence). Let

$$C \in M_d(\mathbb{Z}), \qquad v_0 \in \mathbb{Z}^d.$$

The integral orbit

$$v_n = C^n v_0$$

determines, by base change, compatible orbits in every ring R equipped with a homomorphism $\mathbb{Z} \to R$. In particular, the reductions modulo every positive integer and the orbits in every $\mathbb{Z}_p^d$ share the same companion matrix, characteristic polynomial, and integer recurrence relations.

Proof. Every coordinate of $C^n v_0$ is an integer polynomial in the entries of C and v_0. Applying a ring homomorphism commutes with matrix multiplication and preserves every polynomial relation with integer coefficients. □

corollary D.103 (Prime independent recurrence spine). An integral companion system gives a canonical common source for all of its local realizations. No choice of coefficient prime is required to define the recurrence or its residue packets.

Proof. Apply theorem D.102 to the companion matrix and its initial state. □

remark D.104. This theorem supplies a prime independent spine for integral linear recurrences. It does not prove that every unrelated family of local arithmetic packets arises from one global object.

D.10 Chinese remainder packet refinement

The Chinese remainder theorem gives an exact factorization of residue addresses. We state it at the level of sequence projectors so that it can be combined directly with the earlier coordinate systems.

definition D.105 (Residue projector). For a sequence $a = (a_n)_{n \geq 0}$, a positive integer N, and an address r modulo N, define

$$(P_{N,r}a)_n = \begin{cases} a_n, & n \equiv r \pmod{N}, \\ 0, & n \not\equiv r \pmod{N}. \end{cases}$$

proposition D.106 (Complete residue packet system). For fixed N, the projectors $P_{N,r}$ satisfy

$$P_{N,r}P_{N,s} = \delta_{rs}P_{N,r}$$

and

$$\boxed{\sum_{r \bmod N} P_{N,r} = I.}$$

Proof. Every nonnegative integer belongs to exactly one residue class modulo N. □

theorem D.107 (Coprime packet factorization). Let A and B be coprime positive integers. Let r_A be an address modulo A and r_B an address modulo B. Let r be the unique address modulo AB satisfying

$$r \equiv r_A \pmod{A}, \qquad r \equiv r_B \pmod{B}.$$

Then

$$\boxed{P_{AB,r} = P_{A,r_A}P_{B,r_B} = P_{B,r_B}P_{A,r_A}.}$$

Proof. The product retains exactly the indices satisfying both congruences. By the Chinese remainder theorem, those indices form one residue class modulo AB [14]. □

corollary D.108 (Several coprime moduli). Let $N_1, \dots, N_s$ be pairwise coprime and put

$$N = \prod_{j=1}^{s} N_j.$$

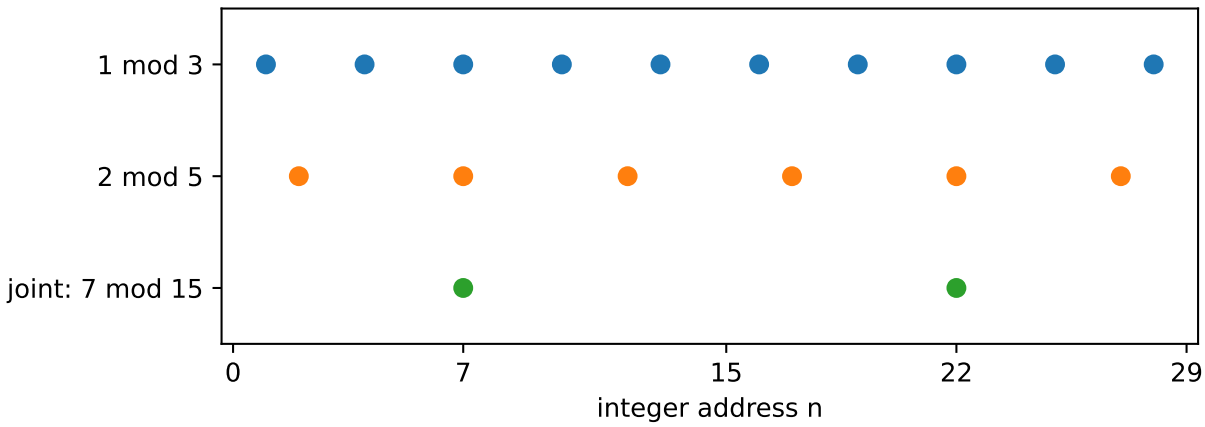

Figure 13. New reconstruction. A residue modulo a product of coprime moduli is the exact intersection of its local residue packets.

For compatible addresses r_j,

$$\boxed{P_{N,r} = \prod_{j=1}^{s} P_{N_j,r_j},}$$

where r is the unique combined address modulo N.

Proof. Iterate theorem D.107. □

standard fact D.109 (Finite local reconstruction). Let

$$N = \prod_{j=1}^{s} p_j^{a_j}$$

be the prime power factorization of a positive integer. The map

$$\mathbb{Z}/N\mathbb{Z} \longrightarrow \prod_{j=1}^{s} \mathbb{Z}/p_j^{a_j}\mathbb{Z}$$

is a ring isomorphism. Thus a compatible collection of prime power residues reconstructs one residue modulo N [14].

proposition D.110 (Dyadic and odd residue refinement). Let $N = 2^a m$ with m odd. Every residue packet modulo N factors uniquely as the product of one dyadic packet modulo 2^a and one odd packet modulo m.

Proof. The moduli 2^a and m are coprime. Apply theorem D.107. □

remark D.111. The residue address factors exactly, but valuation weights do not become identical across primes. The odd coordinate system of appendix D.5 and the dyadic coordinate system of appendix D.5 remain genuinely different integral charts.

Table 4. Status of the principal local arithmetic blocks.

Block	Status	Main boundary
Standard window period	Proved modulo the residue prime	Higher prime powers require inverse estimates
Unified local Euler transfer	Proved for every prime	Odd and dyadic integral charts remain different
Dyadic kernel and truncation	Exact weight and optimal uniform modulus proved	Row cancellation may give stronger values
Carmichael and Mahler transfer	Proved for scalar, polynomial exponential, matrix, and finite adelic systems	A jump congruence must first be available
Local Euler interpolation	Proved for depleted odd branches and the direct dyadic branch	The odd nonunit factor is only evaluated at integer interpolation points
Affine polyphase transfer	Exact analysis, synthesis, carry law, kernel composition, residual sparsity, and valuation preservation proved	General exact kernel valuations remain open
Lift obstruction and recurrence spine	Proved for the declared local problems and integral recurrences	Unrestricted global gluing is not proved

D.11 Verification and exact boundaries

The proofs in the article are symbolic. Exact computation tests formulas, finite ranges, and the source implementation. It does not replace a uniform proof.

D.11.1 The remaining congruential difference problem

Let $C_{mp,j}(n)$ be a congruential reciprocal coefficient and let

$$h = \frac{p-1}{m}.$$

The unit mode calculations suggest bounds for

$$v_p\left(\Delta_h^s C_{mp,j}(n)\right).$$

The theorems of appendices D.6 and D.7 determine the gain before the congruential triangular inverse is applied. They do not yet determine every valuation loss introduced by that inverse. The full family bound therefore remains open.

scope	conclusion or boundary
standard windows	finite periods and inverse coordinates
declared correction map	one-step cokernel obstruction
fixed integral recurrence	common source for its local images
arbitrary local families	global source NOT supplied
affine kernel valuations	general sharp higher laws remain open

Figure 14. New reconstruction. The proved local coordinate theory and the remaining inverse valuation, affine kernel, and global gluing problems.

D.11.2 Higher valuations of the affine kernel

The residual formula

$$\Theta_{p^a,s}(r,k) \equiv \binom{s}{r-p^a k} \pmod{p}$$

is exact. A closed formula for

$$v_p\left(\Theta_{p^a,s}(r,k)\right)$$

in terms of base p carries and the three digit addresses is not proved here. Such a formula would sharpen the min plus valuation ledger and could distinguish optimal refinement trees.

D.11.3 The remaining global gluing problem

The finite adelic theorem synchronizes a finite set of primes when one integral state system is already fixed. The recurrence theorem gives a common local source under the same assumption. Chinese remainder projectors reconstruct finite residue addresses. None of these results proves that an arbitrary collection of local analytic branches has a common global arithmetic origin.

D.11.4 Scope

The article uses classical work on Euler congruences, finite differences, local fields, Hurwitz series, Mahler interpolation, Lucas congruences, and recurrence sequences [8, 26, 27, 24, 9, 18, 17, 11]. The exact formulas and local transfer statements should be compared individually with that literature before any historical priority claim is made.

D.12 Conclusion

The local arithmetic theory now has one common architecture. The finite character coordinate identifies the torsion phase. The source and kernel product reconstructs the Euler coefficient. The kernel valuation records certified precision. Carmichael and Mahler coordinates describe the remaining principal unit

motion. Polyphase analysis resolves additional local digits, records carries and shifts exactly, and transports Mahler coefficients through a finite affine kernel.

The odd and dyadic cases agree at the level of convolution and differ at the level of integral geometry. At odd primes the source must be depleted before it becomes a unit mode interpolation. At the dyadic prime the source extends directly to an analytic integral function. The dyadic kernel has exact weight $4r - 1$, giving the optimal uniform modulus 2^{4M+3} after depth M.

Three tasks remain outside the proved region. The first is a complete finite difference estimate after the congruential triangular inverse. The second is an exact higher valuation theory for the affine Mahler kernel. The third is a global existence theorem for local systems that do not already arise from one integral source.

For the divisor-branch family, Theorem 3.7 proves the bound with the j! normalization and factorial valuation loss. No unrestricted family is asserted.

E Supplementary derivations

These supplements give the arithmetic derivations, examples and formal interfaces. The scope of each result is stated in the main text and the formal companion. A restricted intermediate construction is not the full conclusion of the chapter.

E.1 Coefficient coordinates

Scope and result

The following arguments develop the initial formal interfaces for the arithmetic constructions.

Seven of 24 named items proved in the manuscript now have Lean coverage in the stated scopes. Seventeen remain pending. Three classical inputs and two conjectures are registered separately. The development contains **89 explicit theorem declarations and 22 definitions across eight modules**. Supporting lemmas and concrete instances are included. These are not 89 independent discoveries.

Item	Covered mathematical content
1.2	Residue reconstruction and divisor refinement
2.1	Actual unit-EGF coordinate equivalence and transported projectors
2.2	Filtered finite coefficient reconstruction, including $\mathbb{Z}_p$
3.2	Constructed unique triangular inverse and original section identity
3.3	Universal denominator clearing
8.2	Lucas standard-window reduction and the diagonal unit
13.1	Exact normalization counterexample and sharp factorial loss

The correction is preserved

The normalized packet is not the same object as the packet multiplied by $j!$. The checked recurrence gives

$$C_{6,3}(1) = -\frac{1}{84}, \qquad C_{6,3}(2) = \frac{703}{5460},$$

$$C_{6,3}(2) - C_{6,3}(1) = \frac{64}{455}, \qquad v_3\left(\frac{64}{455}\right) = 0.$$

Thus the unrestricted normalized no-loss claim fails already at a valid one-step parameter instance. Multiplication by $3!$ restores one factor of three in this instance. The general corrected finite-difference theorem is **not** inferred from this calculation and is not yet formalized here.

1. Residue packets and actual EGF coordinates

Source items 1.2 and 2.1

For a sequence $a : \mathbb{N} \to R$, define the actual selector

$$(P_{N,j}a)(n) = \begin{cases} a(n), & n \bmod N = j, \\ 0, & \text{otherwise.} \end{cases}$$

The source proves idempotence for every selector, orthogonality for distinct standard residue labels, and, when $N > 0$,

$$\sum_{j=0}^{N-1} P_{N,j}a = a.$$

If $N \mid M$ and $M > 0$, it also proves

$$P_{N,j}a = \sum_{\substack{0 \le r < M \\ r \bmod N = j}} P_{M,r}a.$$

The formal power-series versions are proved coefficientwise for actual `PowerSeries` objects. There is no finite truncation of the sequence domain in these theorems.

A constructed inverse, not an inverse hypothesis

Let K be a characteristic-zero field. Define

$$\mathcal{E}(a) = \sum_{n \ge 0} \frac{a_n}{n!} t^n, \qquad \mathcal{D}(A)_n = n![t^n]A.$$

Both inverse laws $\mathcal{D}\mathcal{E} = I$ and $\mathcal{E}\mathcal{D} = I$ are proved. The ordinary power-series product then yields the binomial convolution

$$\mathcal{D}\big(\mathcal{E}(h)\mathcal{E}(a)\big)_n = \sum_{r=0}^{n} \binom{n}{r} h_r a_{n-r}.$$

For $h_0 = 1$, the formal inverse of $H = \mathcal{E}(h)$ is used to construct a sequence equivalence

$$U_H a = \mathcal{D}(H\mathcal{E}(a)), \qquad U_H^{-1} a = \mathcal{D}(H^{-1}\mathcal{E}(a)).$$

The equivalence has proved left and right inverse laws. The inverse's constant coefficient is proved to be one. The associated lower-triangular entries have diagonal one and vanish above the diagonal.

For the actual conjugated selectors

$$\widehat{P}_{N,j} = U_H P_{N,j} U_H^{-1},$$

idempotence, orthogonality, and finite reconstruction are proved from the constructed maps. No projector identity for the conjugates is inserted as an assumption.

Formal boundary. These are formal series and coefficient identities. They do not establish convergence for an analytic EGF. The characteristic-zero field assumption is explicit. Unrestricted factorial division in an arbitrary ring is not asserted.

2. Triangular inversion and denominator control

Source items 3.2 and 3.3

For a general lower-triangular coefficient array T over a field with nonzero diagonal, the code defines forward substitution by well-founded recursion:

$$a_n = \frac{b_n - \sum_{q<n} T_{nq} a_q}{T_{nn}}.$$

It proves that this constructed sequence solves every row and that every sequence solving those rows equals it. No existence or uniqueness premise is used.

The congruential coefficients

Over $\mathbb{Q}$, specialize to

$$T_{nq} = \binom{Nn+j}{Nq}, \qquad b_n = \delta_{n0}.$$

The diagonal is positive as an integer, hence nonzero. The resulting sequence $C_{N,j}(n)$ satisfies

$$C_{N,j}(0) = 1, \qquad \sum_{q=0}^{n} \binom{Nn+j}{Nq} C_{N,j}(q) = \delta_{n0}.$$

The displayed recurrence in the manuscript and the unique-solution theorem are consequences of this definition.

The formalization does not stop at a recurrence. In the variable $z = t^N$, construct

$$K_{N,j}(z) = \sum_{n\geq 0} \frac{j!}{(Nn+j)!} z^n, \qquad F_{N,j}(z) = \sum_{n\geq 0} \frac{C_{N,j}(n)}{(Nn)!} z^n.$$

It proves the factorial coefficient identity, then $F_{N,j} K_{N,j} = 1$ and therefore $F_{N,j} = K_{N,j}^{-1}$.

For $N > 0$ and $0 \leq j < N$, the independently defined original exponential section is

$$E_{N,j}(t) = \sum_{d \equiv j \pmod N} \frac{t^d}{d!}.$$

Using the actual power-series expansion homomorphism $z \mapsto t^N$, the code proves

$$E_{N,j}(t) = \frac{t^j}{j!} K_{N,j}(t^N), \qquad \boxed{F_{N,j}(t^N) E_{N,j}(t) = \frac{t^j}{j!}.}$$

Thus the recurrence is connected back to the original normalized EGF definition. The section vanishes at zero when $j > 0$. No inverse of that nonunit section is assumed.

Universal clearing

Define

$$D_{N,j}(n) = \prod_{r=1}^{n} \binom{Nr+j}{Nr}, \qquad D_{N,j}(0) = 1.$$

For every n, the code proves $D_{N,j}(n)C_{N,j}(n) \in \mathbb{Z}$. The general proof promotes each earlier clearing denominator to the common product, then cancels the new nonzero diagonal. This is a denominator bound, not a claim that every normalized coefficient is integral.

3. Filtered tails and the standard window

Source items 2.2 and 8.2

Filtration at a finite coefficient row

Let R be any commutative ring. For $w \in \mathbb{N} \cup \{\infty\}$ define

$$p^{[w]} = \begin{cases} p^w, & w < \infty, \\ 0, & w = \infty. \end{cases}$$

The infinity convention expresses a vanishing coefficient, not an infinite exponent operation. For any finite index set, every term with weight at least L is divisible by p^L. A finite-sum proof yields

$$\boxed{p^L \mid \sum_{r=0}^{n} \binom{n}{r} c_r p^{[w(r)]} S_{n-r} - \sum_{\substack{0 \le r \le n \\ w(r) < L}} \binom{n}{r} c_r p^{[w(r)]} S_{n-r}.}$$

The result is specialized to actual p-adic integers $R = \mathbb{Z}_p$ for prime p. Divisibility there is precisely the asserted membership in $p^L\mathbb{Z}_p$.

For an individual row the sum is finite, so the proof does not require $w(r) \to \infty$. This is a stronger coefficient-row scope, not a theorem about an infinite limiting process. A supporting lemma also proves a p^{2M+2} tail bound for a sum with visible factors p^{2m}. It is not counted as either Euler supercongruence theorem: their generating-function reconstruction identities remain pending.

Actual Lucas reduction

For prime p, all $m, n, q \in \mathbb{N}$, and $0 \le j < p$, the checked binomial congruence is

$$\boxed{\binom{mpn+j}{mpq} \equiv \binom{mn}{mq} \pmod{p}.}$$

The proof applies Mathlib's Lucas low-digit reduction to the actual natural binomial coefficients. It does not assume a pre-reduced row. The statement also permits $q > n$. If $m > 0$, both binomial coefficients then vanish.

Taking $q = n$ gives

$$\binom{mpn+j}{mpn} \equiv 1 \pmod{p}.$$

Nondivisibility by p and invertibility of that diagonal in $\mathbb{Z}/p\mathbb{Z}$ are proved. The separate supporting lemma $p \nmid j!$ for $j < p$ establishes the standard-window factorial-unit condition.

Dependency boundary. Lucas' theorem is a named classical input in the manuscript and is reused from the pinned Mathlib library. This block does not independently reconstruct Lucas' full digit theorem. The residue-independence result (8.3), uniform standard-window period (8.5), and the global finite-difference theorem (7.5) remain pending.

Principal targets.

`StandardWindow.factorial_valuation_zero`

4. Sharp normalization boundary

Source item 13.1

The construction fixes the two coefficient conventions:

$$C_{N,j}(n), \qquad \widetilde{C}_{N,j}(n) = j!\, C_{N,j}(n).$$

The witness uses $p = 3$, $m = 2$, $N = mp = 6$, $j = 3$, $n = 1$ and difference step $h = (p-1)/m = 1$. The parameter conditions are checked explicitly, including odd primality, $m \mid p - 1$ and $j < N$.

The first row gives $84C_{6,3}(1) + 1 = 0$. The second row, evaluated by the same recursive definition, gives $C_{6,3}(2) = 703/5460$. Therefore

$$\Delta_1 C_{6,3}(1) = \frac{64}{455} \neq 0.$$

Neither numerator nor denominator is divisible by three, so its actual rational 3-adic valuation is zero. A further theorem negates the universal one-step no-loss statement by applying it to this valid tuple and deriving $1 \leq 0$.

For the unnormalized convention,

$$\Delta_1 \widetilde{C}_{6,3}(1) = 3!\,\frac{64}{455} = \frac{384}{455}, \qquad v_3\left(\frac{384}{455}\right) = 1.$$

The factorial's valuation is also proved:

$$v_3(3!) = 1, \qquad v_3\big(\Delta_1 C_{6,3}(1)\big) = 1 - v_3(3!) = 0.$$

This proves sharpness at the displayed normalization boundary. It does not establish the corrected global inequality for all parameters, and does not assert that every nonunit-factorial parameter tuple must violate every no-loss specialization. All valuation calculations here concern nonzero rationals.

Work remaining in the named proved register

Items	Pending mathematical content
4.1–4.3	Odd-power generating function, Euler reconstruction, odd-prime ladder
5.1–5.4	Dyadic inverse and source integrality, reconstruction, weighted ladder
6.2	Finite unit-decomposition certificates
7.2–7.5	Finite Mahler reconstruction, weighted differences, unit modes, global odd-prime differences
8.3, 8.5	Standard-window residue independence and uniform period
9.1, 9.2	Companion jumps and Fibonacci packet recurrence
10.1	Arithmetic CRT packet factorization

The two conjectures, 13.2 and 13.3, remain unproved and outside the 24-item register. The 17 pending entries are manuscript proof claims awaiting this project's Lean verification, not conjectures newly created by the formalization process.

E.2 Odd Euler reconstruction

Scope and result

This supplement gives the formal constructions for Lemma 4.1, Theorem 4.2 and Corollary 4.3.

Ten of 24 named items proved in the manuscript are now covered in their recorded scopes. Fourteen remain pending. Three classical inputs and two conjectures are tracked separately. The cumulative corpus has **163 named theorem declarations and 37 explicit definitions in 13 modules**. The 74 new theorems include auxiliary identities and concrete examples. They are not 74 independent discoveries.

Item	New formal coverage	Theorems
4.1	Literal odd-power EGF and its even part	18
4.2	Integral Euler and signed zigzag coefficient bridges	29
4.2, 4.3	Exact reconstruction, matrix rows and truncation	16
Example	Exact scalar anchors and sharpness controls	11
	Total added across five modules	74

The five added modules are:

`OddPowerSeries`, `EulerCoefficients`, `ZigzagCoefficients`, `OddEulerReconstruction` and `OddEulerExamples`.

A useful scope strengthening

The algebraic proof needs *oddness*, not primality. The exact reconstruction and the integer divisibility statement are therefore checked for every positive odd length p, including $p = 1$ and odd composites. The manuscript's odd-prime statement follows as a specialization. This is a sharpening of assumptions in this development, not a historical-priority claim. Even lengths are not included. A checked row-zero counterexample shows why.

What is not completed

The weighted dyadic theory and general odd-prime finite-difference theorem lie outside this argument. No continuum convergence or analytic summability theorem follows from the formal power-series identities.

1. The actual odd-power generating function

Lemma 4.1; manuscript page 10

Work in the rational formal power-series ring $\mathbb{Q}[[t]]$. Define

$$S_n(p) = \sum_{a=0}^{p-1} (-1)^a (2a+1)^n \in \mathbb{Z}, \qquad F_p(t) = \sum_{n \geq 0} S_n(p) \frac{t^n}{n!}.$$

The formal exponential is Mathlib's `PowerSeries.exp`. Scalar substitution is its actual `rescale` homomorphism. We define

$$\exp_a(t) = e^{at}, \qquad \cosh_a(t) = \frac{e^{at} + e^{-at}}{2}, \qquad \operatorname{sech}(t) = \cosh_1(t)^{-1}.$$

The constant term of $\cosh_a$ is proved to be one, so the reciprocal used here is a unit inverse.

From finite sums to a series identity

Coefficient extraction proves

$$F_p(t) = \sum_{a=0}^{p-1} (-1)^a e^{(2a+1)t}.$$

An induction on the actual finite summation length establishes the telescoping identity

$$F_p(t) \cosh t = \frac{1 - (-1)^p e^{2pt}}{2}.$$

For odd p this gives, without a geometric-series convergence assumption,

$$\boxed{F_p(t) = \frac{1 + e^{2pt}}{2} \operatorname{sech} t.}$$

This is an equality of complete formal series, not a fixed-degree polynomial check.

Even projection is identified coefficientwise

For any formal series f, let $\mathrm{EvenPart}(f) = (f(t) + f(-t))/2$. Its nth coefficient is proved to be the coefficient of f when n is even and zero otherwise. Rescaling the inverse law proves $\operatorname{sech}(-t) = \operatorname{sech}(t)$. The exponential multiplication identity then gives

$$\cosh^2(pt) = \frac{2 + e^{2pt} + e^{-2pt}}{4},$$

and hence

$$\boxed{\sum_{r \geq 0} S_{2r}(p) \frac{t^{2r}}{(2r)!} = \cosh^2(pt) \operatorname{sech} t.}$$

Both the full and even EGF formulas are derived from the original integer sum. Neither is supplied as a hypothesis.

Principal targets.

`OddPower.source_as_exponentials`

`OddPower.source_times_cosh`

`OddPower.odd_source_egf`, `OddPower.odd_source_even_egf`

2. Integral Euler coefficients and the zigzag bridge

Coefficient foundations for Theorem 4.2

The first block already constructed $C_{N,j}(r)$ by the manuscript's triangular recurrence. At $(N, j) = (2, 0)$, every diagonal binomial coefficient equals one. Its denominator-clearing product is therefore one, and $C_{2,0}(r)$ is an integer.

The source defines E_{2r} as the integer numerator of that rational coefficient and proves that its rational cast equals $C_{2,0}(r)$. Set $E_{2r+1} = 0$. The actual exponential-section identity from the first block proves

$$\boxed{\sum_{n\geq 0} E_n \frac{t^n}{n!} = \operatorname{sech} t.}$$

Thus the integer sequence is connected to the intended signed Euler family, rather than merely assigned the name Euler.

The inverse coefficients are integral by construction

Define the integer binomial convolution

$$B_n = \sum_{r=0}^{n} \binom{n}{r} E_r E_{n-r}, \qquad b_m = B_{2m}.$$

The product formula for actual EGFs gives

$$\sum_{n\geq 0} B_n \frac{t^n}{n!} = \operatorname{sech}^2 t.$$

Odd coefficients vanish by parity. In particular, every b_m is an integer. This is the integrality required by the later congruence.

Connecting to the chapter's Z_n convention

The chapter defines Z_n through $\sec t + \tan t$. The Lean construction uses Mathlib's actual formal sine and cosine series and defines

$$\sec t = (\cos t)^{-1}, \quad \tan t = (\sin t)\sec t, \quad Z_n = n![t^n](\sec t + \tan t).$$

It proves the sine and cosine derivative identities, $\sin^2 t + \cos^2 t = 1$, and

$$(\tan t)' = \sec^2 t.$$

Sign substitution in the squared variable carries the hyperbolic cosine kernel to the actual cosine kernel. The same homomorphism carries their inverses and their squares. Extracting the even coefficient in the derivative of tangent yields

$$\boxed{b_m = (-1)^m Z_{2m+1}.}$$

This formula is *proved*, not assumed as an input to reconstruction. The formalization follows the generating-function definition of zigzag numbers. It does not additionally formalize their interpretation as counts of alternating permutations.

Principal targets.

`EulerCoefficients.euler_egf`, `EulerCoefficients.inverse_coeff_cast`

`Zigzag.derivative_tan,Zigzag.inverse_is_signed_zigzag`

3. Exact reconstruction and the triangular matrix

Theorem 4.2; manuscript page 11

For odd p, rescaling the already proved inverse law gives

$$\operatorname{sech}(pt)\cosh(pt) = 1.$$

Multiplying the even-source identity by $\operatorname{sech}^2(pt)$ therefore proves

$$\operatorname{sech}^2(pt)\left(\sum_{r\geq 0} S_{2r}(p)\frac{t^{2r}}{(2r)!}\right) = \operatorname{sech} t.$$

Actual EGF multiplication now gives the integer coefficient formula

$$\boxed{E_{2r} = \sum_{m=0}^{r}\binom{2r}{2m} b_m p^{2m} S_{2(r-m)}(p).}$$

The formal proof first extracts the sum over all indices and then proves that the odd summands vanish. A checked even-index summation identity supplies the displayed change of variables.

Substituting the independently proved signed-zigzag identity recovers the manuscript's notation. For every even degree n,

$$\boxed{E_n = \sum_{m=0}^{n/2}(-1)^m Z_{2m+1}\binom{n}{2m} p^{2m} S_{n-2m}(p).}$$

The Lean version uses $n = 2r$ to avoid ambiguous natural-number division. Every even natural degree has that form. Primality is not used in this equality.

The row action is connected to the matrix entries

Reversing the finite sum and using binomial symmetry gives the actual source-index row action

$$E_{2r} = \sum_{q=0}^{r} U_{r,q}(p) S_{2q}(p),$$

where

$$U_{r,q}(p) = \begin{cases}\binom{2r}{2q} b_{r-q} p^{2(r-q)}, & q \leq r,\\ 0, & q > r.\end{cases}$$

The row-action equality, the diagonal identity $U_{r,r} = 1$, and vanishing above the diagonal are all checked. The arithmetic weight is also explicit:

$$p^{2(r-q)} \mid U_{r,q}(p) \quad \text{in } \mathbb{Z}, \qquad 0 \leq q \leq r.$$

No inverse-coordinate identity, unit diagonal or weight bound is assumed for these rows.

4. Uniform truncation and a sharp exact example

Corollary 4.3 and Example 4.4

For row $2r$ and depth M, the actual truncation is

$$T_M(p,2r) = \sum_{m=0}^{\min(M,r)} \binom{2r}{2m} b_m p^{2m} S_{2(r-m)}(p).$$

Every omitted term has $m \geq M+1$. Its other factors are integers, so the first-block omitted-tail theorem, now applied to the *proved Euler identity*, gives

$$\boxed{p^{2M+2} \mid E_{2r} - T_M(p,2r) \quad \text{in } \mathbb{Z}.}$$

This is not divisibility in $\mathbb{Q}$, where a nonzero divisor would make the assertion vacuous. The statement holds for every row and depth. For an odd prime it is precisely the claimed supercongruence. If $M \geq r$, complete retention is proved exact.

The displayed manuscript row is kernel-checked

The scalar anchors are derived from the same general coefficient recurrence:

$$(E_0, E_2, E_4, E_6, E_8) = (1, -1, 5, -61, 1385),$$

$$(b_0, b_1, b_2, b_3, b_4) = (1, -2, 16, -272, 7936).$$

The literal source sums at $p = 5$ give

$$(S_0, S_2, S_4, S_6, S_8) = (1, 49, 4705, 428689, 37665985).$$

Consequently,

$$T_2(5,8) = 2\,731\,001\,385, \qquad E_8 - T_2(5,8) = -2\,731\,000\,000.$$

The source proves both

$$5^6 \mid E_8 - T_2(5,8), \qquad 5^7 \nmid E_8 - T_2(5,8).$$

Thus the guaranteed power is attained in this example. No stronger uniform exponent is inferred.

Oddness cannot be silently dropped

For length two, $S_0(2) = 1 - 1 = 0$, whereas $E_0 = 1$. The row-zero reconstruction already fails. The source proves the failure of
the even-length identity.

Principal targets.

E.3 Dyadic reconstruction

Scope and result

This supplement develops the stated forms of Lemmas 5.1 and 5.2, Theorem 5.3 and Corollary 5.4.

Fourteen of 24 named items proved in the manuscript now have formal coverage. Ten remain pending. Three classical inputs and two conjectures are tracked separately. The cumulative corpus has **219 named theorem declarations and 53 explicit definitions in 17 modules**. The 56 added theorems include supporting identities and exact examples, not 56 independent discoveries.

New module	Scope	Theorems	Defs.
`DyadicIntegrality`	5.1, 5.2	21	8
`DyadicSeries`	5.1, 5.3	11	4
`DyadicReconstruction`	5.3, 5.4	10	4
`DyadicExamples`	Exact controls	14	0
Total added	Four named items	56	16

The completed mathematical chain

The inverse coefficients are defined from a genuine unit power series and connected to $z^2/\sinh^2 z$. The source is the chapter's explicit rational formula, not an abstract integral input. Its valuation calculation proves the stronger statement that *every even source coefficient is a* 2*-adic unit*. Formal-series multiplication and coefficient extraction then yield the Euler identity with the correct falling factorial. The omitted-tail theorem gives divisibility in the actual completed integer ring $\mathbb{Z}_2$.

Completion boundary

The Bernoulli closed form for the inverse coefficients has no dedicated universal formalization here. Formal-series identities do not establish analytic convergence. The global odd-prime finite-difference theorem is developed separately.

1. Integral coefficients and an exact unit source

Lemmas 5.1 and 5.2; manuscript page 14

Define the rational subring

$$\mathcal{O}_2 = \{q \in \mathbb{Q} : |q|_2 \le 1\}.$$

Its ring laws follow from the actual nonarchimedean norm. For every $q \in \mathcal{O}_2$, the code constructs its element in Mathlib's completed ring $\mathbb{Z}_2$, and proves that the underlying value in $\mathbb{Q}_2$ is the rational cast of q. No integrality claim is hidden in a coercion.

The unit kernel and its reciprocal

Use a squared formal variable u and define

$$k_m = \frac{2^{2m+1}}{(2m+2)!}, \qquad K(u) = \sum_{m\geq 0} k_m u^m, \qquad \beta_m = [u^m]K(u)^{-1}.$$

The constant term is proved to be one. The factorial valuation bound gives

$$v_2(k_m) = 2m + 1 - v_2((2m+2)!) \geq 0.$$

Thus every k_m belongs to $\mathcal{O}_2$. A general coefficientwise subring theorem is proved by strong induction using the actual unit-inverse coefficient formula. Applied to K, it establishes

$$\boxed{\beta_m \in \mathcal{O}_2 \quad \text{for every } m \geq 0.}$$

The reciprocal's coefficients are therefore proved integral. The proof does not assume them integral in order to obtain the final congruence. Their connection to the intended hyperbolic function is proved on the next page.

The source has valuation exactly zero

At even degree $2r$, define the literal rational source

$$R_{2r} = \frac{3^{2r+2} - 1}{4(2r+1)(2r+2)}.$$

Both numerator and denominator are nonzero. The pinned Mathlib lifting-the-exponent theorem gives

$$v_2(3^{2r+2} - 1) = 2 + v_2(2r+2).$$

Because $2r+1$ is odd, the denominator has the same valuation. Consequently,

$$\boxed{v_2(R_{2r}) = 0, \qquad |R_{2r}|_2 = 1.}$$

The code proves actual `IsUnit` status for the constructed $\mathbb{Z}_2$ element. This strengthens the manuscript's integrality conclusion without changing its source. The argument applies at $r = 0$, where $R_0 = 1$, as well as at every later row.

2. Connecting the definitions to actual formal series

Generating-function foundations for Theorem 5.3

Work in $\mathbb{Q}[[t]]$. The formal exponential and rescaling homomorphism are the same checked objects used in the second block. Define

$$\sinh_a(t) = \frac{e^{at} - e^{-at}}{2}, \qquad \cosh_a(t) = \frac{e^{at} + e^{-at}}{2}.$$

Let $B(t) = K(t^2)^{-1} = \sum_{m\geq 0} \beta_m t^{2m}$ and let

$$F(t) = \sum_{r\geq 0} R_{2r} \frac{t^{2r}}{(2r)!}.$$

These series are constructed independently from the definitions on the preceding page.

No inverse of a zero-constant series is assumed

Coefficient extraction proves the cleared identity

$$t^2 K(t^2) = \frac{\cosh(2t) - 1}{2}.$$

A separate identity from the formal exponential gives

$$\sinh^2 t = \frac{\cosh(2t) - 1}{2}.$$

Since $K(t^2)$ has constant term one, its reciprocal exists as a unit. Multiplication then proves

$$\boxed{B(t)\sinh^2 t = t^2.}$$

This is the precise formal meaning of $B(t) = t^2/\sinh^2 t$. The forced quadratic zero is removed first. The proof does not claim that $\sinh t$ itself is an invertible formal power series.

The explicit rational source supplies its own identity

From the formula for R_{2r}, coefficient arithmetic proves

$$\boxed{t^2 F(t) = \frac{\cosh(3t) - \cosh t}{4}.}$$

The product relation for the formal hyperbolic cosines yields

$$F(t)\cosh t = K(4t^2).$$

This equality is proved after multiplication by t^2 and cancellation of that monomial in the formal-series ring. It is not an assumed source-transform relation.

Rescale the reciprocal by $t \mapsto 2t$. The unit inverse law and the preceding identity now give

$$\boxed{B(2t)F(t) = \operatorname{sech} t.}$$

The right side uses the same integral signed Euler sequence. These are equalities of full formal series, not fixed-degree experiments.

Principal targets.

`DyadicSeries.beta_original_generating_function`

`DyadicSeries.source_shift_identity,DyadicSeries.source_times_cosh`

`DyadicSeries.dyadic_reconstruction_series`

3. Exact reconstruction and genuine dyadic congruence

Theorem 5.3 and Corollary 5.4; manuscript pages 14–15

The reciprocal coefficients β_m use an *ordinary* power expansion. In contrast, the source and Euler series use exponential coefficients. Extracting degree $2r$ from $B(2t)F(t) = \operatorname{sech} t$ therefore gives

$$\boxed{E_{2r} = \sum_{m=0}^{r} \beta_m 2^{2m} (2r)_{2m} R_{2(r-m)},} \qquad (2r)_{2m} = \frac{(2r)!}{(2r-2m)!}.$$

The formal proof uses the actual natural-number descending factorial and proves its factorial-quotient identity for $2m \le 2r$. The odd coefficient terms vanish by a proved parity argument. The binomial EGF product then supplies the falling factorial, rather than treating it as an extra assumed factor.

Both row indexing by r and the literal even-degree version with hypothesis $\mathrm{Even}(n)$ are checked. All rows include degree zero. The exact identity is a rational equality with the Euler coefficient's integer-to-rational cast made explicit.

The finite truncation

For $M \ge 0$, define

$$T_M(2r) = \sum_{m=0}^{\min(M,r)} \beta_m 2^{2m} (2r)_{2m} R_{2(r-m)}.$$

The integral rational factors are embedded into $\mathbb{Z}_2$ using their proved witnesses. The cast of this $\mathbb{Z}_2$ truncation into $\mathbb{Q}_2$ is proved to equal the cast of the literal rational truncation.

Each omitted term has $m \ge M+1$. Its remaining factors lie in $\mathbb{Z}_2$, so the checked weighted-tail theorem proves

$$\boxed{2^{2M+2} \mid E_{2r} - T_M(2r) \quad \text{in } \mathbb{Z}_2.}$$

This is not divisibility in $\mathbb{Q}$ or $\mathbb{Q}_2$, where division by any nonzero scalar would make the claim vacuous. A second theorem supplies the equivalent rational statement

$$\boxed{\frac{E_{2r} - T_M(2r)}{2^{2M+2}} \in \mathcal{O}_2.}$$

It follows from actual $\mathbb{Z}_2$ divisibility and the proved rational/completed-field bridge. No precision assertion is passed in as a hypothesis.

Endpoints and scope

When $M \ge r$, the sum retains every term and $T_M(2r) = E_{2r}$ exactly, in both rational and dyadic coordinates. The zero-error case is included. No finite valuation of zero is used. This is a separate dyadic construction, not substitution of $p = 2$ into the odd-length theorem.

Principal targets.

`DyadicReconstruction.dyadic_reconstruction`

`DyadicReconstruction.dyadic_supercongruence`

`DyadicReconstruction.normalized_error_integral`

4. Exact examples and adversarial checks

Example 5.5 and controls against incorrect normalizations

The actual reciprocal recurrence gives

$$(\beta_0, \beta_1, \beta_2, \beta_3, \beta_4) = \left(1, -\frac{1}{3}, \frac{1}{15}, -\frac{2}{189}, \frac{1}{675}\right).$$

These values are obtained from the general formal-series definition. They are not substituted as independent input data for the reconstruction theorem. The source formula gives

$$(R_0, R_2, R_4, R_6, R_8) = \left(1, \frac{5}{3}, \frac{91}{15}, \frac{205}{7}, \frac{7381}{45}\right).$$

Using the retained Euler anchor $E_8 = 1385$, Lean checks the literal decomposition

$$E_8 = \frac{7381}{45} - \frac{6560}{3} + \frac{163072}{15} - \frac{204800}{9} + \frac{229376}{15} = 1385.$$

Truncations and actual valuations

Depth M	$T_M(8)$	Guaranteed exponent $2M+2$
0	7381/45	2
1	−91019/45	4
2	398197/45	6
3	−208601/15	8
4	1385	10

The checked nonzero error valuations are

$$E_8 - T_0(8) = \frac{54944}{45}, \qquad v_2(E_8 - T_0(8)) = 5,$$

$$E_8 - T_3(8) = \frac{229376}{15}, \qquad v_2(E_8 - T_3(8)) = 15.$$

They exceed the uniform guarantees. These two examples do not establish a universally stronger exponent.

What the negative controls rule out

Omitting the rescaling 2^{2m} already breaks the degree-two identity: the altered sum is 1, whereas $E_2 = -1$. Confusing ordinary beta coefficients with EGF coefficients would replace $\beta_1 = -1/3$ by $-2/3$. A checked inequality excludes that normalization. A deliberately false claim that the depth-zero degree-eight error has valuation at least six is rejected.

These three negative proof files are separate from the active mathematical modules. The verifier also retains the five earlier invalid controls, including the normalized all-residue counterexample. Rejection of an attempted proof is an engineering control. The actual counterexample theorems establish the mathematical failures.

Principal targets.

E.4 Mahler interpolation

Scope and result

This supplement develops the stated forms of Theorem 7.2, Corollary 7.3 and Theorem 7.4.

Seventeen of 24 named items proved in the manuscript now have formal coverage. Seven remain pending. Three classical inputs and two conjectures are tracked separately. The cumulative project contains **272 named theorem declarations and 60 explicit definitions across 21 modules**.

New module	Scope	Theorems	Defs.
`FiniteMahler`	7.2	19	3
`PadicDifferenceBounds`	7.3	12	2
`UnitModeDifferences`	7.4	9	0
`MahlerExamples`	Exact controls	13	2
Total added	Three items	53	7

The 53 additions include supporting lemmas and examples, not 53 independent discoveries. The classical Gregory–Newton and binomial-difference results are reused from pinned Mathlib. The new modules connect those results to the actual Paper IX coefficient definitions, interpolation scopes, valuation bounds and unit modes.

Two explicit specification boundaries

A finite sample through N determines $\Delta^s f(n)$ only when $n + s \le N$. For arbitrary orders, the finite-coefficient identity describes the constructed interpolant, not every unknown continuation of the sample. All three versions are separately checked.

The additive valuation is extended to $\mathrm{ord}_p(0) = \infty$. This avoids incorrectly applying Mathlib's finite-valued default at zero to an inequality that must also cover cancellation and identically zero differences.

1. Reconstruction and finite-data scope

Theorem 7.2; manuscript page 17

Let R be any commutative ring. The implementation uses the actual forward-difference operator

$$\Delta_h f(n) = f(n+h) - f(n), \qquad c_r = \Delta_1^r f(0).$$

For a full sequence $f : \mathbb{N} \to R$, pinned Mathlib's Gregory–Newton formula gives

$$\boxed{f(n) = \sum_{r=0}^{n} c_r \binom{n}{r}.}$$

The source applies the theorem to these exact definitions. A separate explicit formula relates an s-th difference to its original sampled values, so the data dependence is inspectable:

$$\Delta_h^s f(n) = \sum_{j=0}^{s} (-1)^{s-j} \binom{s}{j} f(n + jh).$$

Applying Newton reconstruction to $\Delta_1^s f$ and composing the iterated operators proves

$$\boxed{\Delta_1^s f(n) = \sum_{j=0}^{n} c_{s+j} \binom{n}{j}.}$$

The apparently infinite coefficient sum is finite at each natural argument. Neither continuity nor convergence is needed for these identities.

An independently defined interpolant

For a finite coefficient list, define

$$I_N(c)(n) = \sum_{r=0}^{N} c_r \binom{n}{r}.$$

The source proves exact coefficient extraction:

$$\Delta_1^s I_N(c)(0) = \begin{cases} c_s, & s \le N, \\ 0, & s > N. \end{cases}$$

It follows that $I_N(c)$ has the stated shifted-coefficient formula at every order, with zero coefficients beyond N. Every difference of order greater than N vanishes. Its coefficients are uniquely determined by its values at $0, \dots, N$.

What the finite sample does and does not determine

For $c_r = \Delta_1^r f(0)$ with $r \le N$, the source proves

$$I_N(c)(n) = f(n) \quad (n \le N), \qquad \Delta_1^s I_N(c)(n) = \Delta_1^s f(n) \quad (n + s \le N).$$

The condition is essential. The sequences $f(n) = n$ and $g(n) = 0$ agree on the sample $\{0\}$, but $\Delta f(0) = 1$ and $\Delta g(0) = 0$. This is a checked counterexample to unrestricted inference outside the observed stencil.

Principal targets.

`Mahler.difference_from_coefficients`, `Mahler.finite_sample_difference`

2. Weighted bounds in the actual ring $\mathbb{Z}_p$

Corollary 7.3; manuscript page 18

Let p be prime. For $x \in \mathbb{Z}_p$, define

$$\operatorname{ord}_p(x) = \begin{cases} \infty, & x = 0, \\ v_p(x), & x \neq 0. \end{cases}$$

The nonzero branch uses Mathlib's actual p-adic valuation. The implementation proves its connection to genuine integral divisibility:

$$\boxed{L \leq \operatorname{ord}_p(x) \quad \Longleftrightarrow \quad p^L \mid x \text{ in } \mathbb{Z}_p, \qquad L \in \mathbb{N}.}$$

This is not divisibility in $\mathbb{Q}_p$, where a nonzero scalar can divide any field element. The zero case is proved separately, so zero does not spuriously violate a positive lower bound.

The source also proves multiplicativity of this extended order, the nonarchimedean lower bound for addition, and its finite-sum consequence. The natural-number cast is connected to the actual integer binomial valuation.

The binomial valuation is retained

Let $f : \mathbb{N} \to \mathbb{Z}_p$, let $c_r = \Delta_1^r f(0)$, and suppose

$$w(s+j) \leq \operatorname{ord}_p(c_{s+j}) \quad (0 \leq j \leq n), \qquad w : \mathbb{N} \to \mathbb{N} \cup \{\infty\}.$$

Set

$$B_p(w; n, s) = \min_{0 \leq j \leq n} \left\{ w(s+j) + v_p\binom{n}{j} \right\}.$$

Every binomial in this range is nonzero. The code proves

$$\boxed{B_p(w; n, s) \leq \operatorname{ord}_p(\Delta_1^s f(n)).}$$

This is the manuscript minimum after the substitution $r = s + j$. Coefficients outside this range have zero binomial multiplier. Weights equal to infinity are allowed, and a completely vanishing difference has order infinity.

For a uniform coefficient hypothesis, the simpler conclusion follows:

$$\boxed{\inf_{j \geq 0} w(s+j) \leq \operatorname{ord}_p(\Delta_1^s f(n)).}$$

For each finite $L \leq B_p(w; n, s)$, a separate theorem yields $p^L \mid \Delta_1^s f(n)$ inside $\mathbb{Z}_p$. Another specialization handles arbitrary finite interpolants with infinite weights beyond their degree.

Principal targets.

`PadicBounds.nat_le_order_iff`, `PadicBounds.weighted_difference_bound`

`PadicBounds.weighted_difference_divisibility`

`PadicBounds.coefficient_tail_bound`, `PadicBounds.interpolant_weighted_bound`

3. Unit modes and residue-field reduction

Theorem 7.4; manuscript page 18

For u in any commutative ring, and every natural step h, iteration proves

$$\boxed{\Delta_h^s(u^n) = u^n(u^h - 1)^s.}$$

The proof unfolds the actual forward-difference operator and uses the power multiplication law. No valuation premise or geometric-difference identity is assumed. More generally, a proved divisibility $p^k \mid u^h - 1$ implies

$$p^{ks} \mid \Delta_h^s(u^n).$$

Why a p-adic unit supplies one factor of p

Now let $u \in \mathbb{Z}_p^\times$. The actual ring homomorphism

$$\pi : \mathbb{Z}_p \longrightarrow \mathbb{F}_p$$

sends u to a nonzero unit. Fermat's finite-field theorem therefore gives

$$\pi(u)^{p-1} = 1, \qquad \pi(u^{p-1} - 1) = 0.$$

Using the proved kernel identity $\ker \pi = p\mathbb{Z}_p$, the source derives

$$\boxed{p \mid u^{p-1} - 1 \quad \text{inside } \mathbb{Z}_p.}$$

The conclusion is not supplied as an abstract certificate. It follows from the unit hypothesis and the standard residue-field construction.

Combining it with the geometric identity establishes

$$\boxed{p^s \mid \Delta_{p-1}^s(u^n), \qquad s \le \operatorname{ord}_p(\Delta_{p-1}^s(u^n)).}$$

These statements hold for every prime, including $p = 2$ with step one. Zero differences and order zero are included. Every multiple of the Fermat step satisfies the same lower bound.

Finite integral linear combinations

For any finite index set S, coefficients $a_i \in \mathbb{Z}_p$ and units $u_i \in \mathbb{Z}_p^\times$, linearity of the actual iterated operator gives

$$\Delta_h^s\left(\sum_{i\in S} a_i u_i^n\right) = \sum_{i\in S} a_i u_i^n (u_i^h - 1)^s.$$

At $h = p - 1$, the result is divisible by p^s. The empty sum is permitted. This does not prove that the general congruential Euler packets of Theorem 7.5 admit such a representation.

Principal targets.

`UnitModes.geometric_difference`, `UnitModes.unit_fermat_divisibility`

`UnitModes.unit_mode_valuation_gain`

`UnitModes.finite_unit_modes_valuation_gain`

4. Exact examples and adversarial checks

The examples use the same definitions as the general results

A polynomial anchor

The actual difference table for $f(n) = n^2$ yields

$$(c_0, c_1, c_2, c_3) = (0, 1, 2, 0).$$

The finite interpolant therefore reconstructs $I_2(c)(7) = 49$. This checks the sign and indexing conventions, not just the names of the defined objects.

A sharp binomial-weight improvement

Let

$$F(n) = 81\binom{n}{1} + 3\binom{n}{2} + 3\binom{n}{3} + 81\binom{n}{4}.$$

At $n = 3$ and $s = 1$, the four coefficient valuations are $(4, 1, 1, 4)$, while the binomial valuations are $(0, 1, 1, 0)$. Thus the refined bound is

$$B_3(w; 3, 1) = \min(4, 2, 2, 4) = 2,$$

stronger than the coefficient-only lower bound one. The source checks both the minimum and the actual result:

$$\boxed{\Delta F(3) = 180, \qquad \operatorname{ord}_3(180) = 2.}$$

The valuation equality is proved in the actual completed ring $\mathbb{Z}_3$, with an independent exact integer divisibility check as well.

A sharp unit-mode gain

For $p = 5$ and $u = 2$,

$$\Delta_4^2(u^n)\big|_{n=0} = (2^4 - 1)^2 = 225.$$

The source proves $5^2 \mid 225$ and $5^3 \nmid 225$. This example attains the guaranteed gain. No additional uniform power of p is claimed.

What fails when hypotheses or conventions are dropped

The nonunit $u = 3$ at $p = 3$ gives $\Delta_2(u^n)|_{n=0} = 8$, with no factor of three. A constant unit has every positive-order difference zero, hence infinite extended valuation. The finite-sample counterexample on page 2 distinguishes a true interpolant identity from an unsupported claim about unknown continuation.

Source. The module `MahlerExamples` contains these exact certificates. Principal target names are listed in the fourth-block ledger.

5. Verification record and remaining work

Evidence is retained separately from conclusions

E.5 Finite units and CRT

Scope and result

This supplement develops Proposition 6.2, Corollary 8.3 and Theorem 10.1 in the scopes stated below.

Twenty of 24 named items proved in the manuscript now have formal coverage. Four remain pending. Three classical inputs and two conjectures are tracked separately. The cumulative project contains **333 named theorem declarations and 77 explicit definitions across 28 modules**.

New module	Scope	Theorems	Defs.
`UnitTriangular`	Integral solver	5	1
`WindowIndependence`	8.3	11	3
`FiniteUnits`	6.2, prime powers	13	4
`DyadicUnits`	6.2, sign branch	10	4
`UnitRefinement`	Finite compatibility	4	2
`CRTPackets`	10.1	5	1
`FiniteArithmeticExamples`	Exact controls	13	2
Total added	Three items	61	17

The 61 new theorems include supporting lemmas and examples, not 61 independent discoveries. Pinned Mathlib supplies finite-field, unit-group, ideal-power, p-adic residue and Chinese-remainder results. The new modules connect these to the actual packet coefficients, explicit finite lifts and existing selectors.

The specification matters

Rational coefficients are not reduced through an imaginary map $\mathbb{Q} \to \mathbb{F}_p$. The proof first constructs their integral lifts in $\mathbb{Z}_p$ and establishes equality in $\mathbb{Q}_p$. Root representatives are actual units at the requested precision, not unchanged residues that need not satisfy the root equation modulo p^ℓ.

1. Integral reduction of the original coefficients

Corollary 8.3; manuscript pages 19–20

Fix a prime p, an integer $m \geq 1$ and a window address $0 \leq j < p$. The earlier project defines the rational packet coefficients by the actual recurrence

$$\sum_{q=0}^{n} \binom{mpn+j}{mpq} C_{mp,j}(q) = \delta_{n0}.$$

The previous Lucas theorem proves

$$\binom{mpn+j}{mpq} \equiv \binom{mn}{mq} \pmod{p}, \qquad \binom{mpn+j}{mpn} \equiv 1 \pmod{p}.$$

The last congruence makes each diagonal entry a unit in the actual completed ring $\mathbb{Z}_p$.

First construct the integral solution

For a ring R, a triangular row system T, right-hand side b, and proved unit pivots $d_n = T_{nn}$, define

$$s_n = d_n^{-1} \left(b_n - \sum_{q<n} T_{nq} s_q \right).$$

The new ring-level solver uses well-founded recursion. Its row identities and unique-solution property are proved. The source also proves compatibility of this solver with ring homomorphisms into fields.

Specializing to $R = \mathbb{Z}_p$ constructs $c_{m,j}^{(p)}(n)$. Mapping to $\mathbb{Q}_p$ and comparing with the original rational forward substitution gives

$$\boxed{c_{m,j}^{(p)}(n) = C_{mp,j}(n) \quad \text{in } \mathbb{Q}_p.}$$

Thus every original standard-window coefficient is p-integral, for every row. Integrality is a conclusion, not an additional hypothesis on the coefficients.

Then apply the residue map

Independently define $e^{(m,p)}$ over $\mathbb{F}_p$ by the unit-diagonal system

$$\sum_{q=0}^{n} \binom{mn}{mq} e_q^{(m,p)} = \delta_{n0}.$$

Its recurrence and uniqueness are checked. Applying the actual homomorphism $\pi : \mathbb{Z}_p \to \mathbb{F}_p$ to the integral row, and then Lucas reduction, proves

$$\boxed{\pi(c_{m,j}^{(p)}(n)) = e_n^{(m,p)}.}$$

For $j, k < p$, a separate ideal statement gives

$$p \mid c_{m,j}^{(p)}(n) - c_{m,k}^{(p)}(n) \quad \text{inside } \mathbb{Z}_p.$$

The formal solver also covers $m = 0$. The manuscript uses $m \geq 1$. No global finite-difference theorem or period assertion enters this proof.

2. Explicit finite prime-power decomposition

Proposition 6.2; odd-prime branch

Let p be prime, $\ell \geq 1$, and

$$a \in (\mathbb{Z}/p^{\ell}\mathbb{Z})^{\times}.$$

Define actual units in the same ring by

$$\boxed{\omega_{\ell}(a) = a^{p^{\ell-1}}, \qquad \langle a \rangle_{\ell} = a\,\omega_{\ell}(a)^{-1}.}$$

The Lean source writes $\ell = L + 1$, so zero precision is excluded without truncated natural-number subtraction.

The root equation and residue are derived

Euler's unit-group exponent gives

$$\omega_{\ell}(a)^{p-1} = a^{p^{\ell-1}(p-1)} = a^{\varphi(p^{\ell})} = 1.$$

Reduction to the actual field $\mathbb{F}_p$ commutes with powers. Its Frobenius identity gives

$$\overline{\omega_{\ell}(a)} = \bar{a}^{p^{\ell-1}} = \bar{a}.$$

Consequently,

$$\boxed{a = \omega_{\ell}(a)\langle a \rangle_{\ell}, \quad \omega_{\ell}(a)^{p-1} = 1, \quad \overline{\langle a \rangle_{\ell}} = 1.}$$

The manuscript's finite existence conclusion is obtained directly. The proof does not assume a Hensel lift or an already supplied root representative.

Uniqueness requires a lifting argument

The source proves the actual kernel statement

$$\bar{x} = 0 \quad \Longleftrightarrow \quad p \mid x \quad \text{in } \mathbb{Z}/p^{\ell}\mathbb{Z}.$$

For $x \equiv y \pmod{p}$, the checked ideal-power lifting theorem gives

$$x^{p^{\ell-1}} - y^{p^{\ell-1}} \in (p)^{\ell} = (0).$$

If $w^{p-1} = 1$, then $w^{p} = w$ and hence $w^{p^{k}} = w$ for every k. Therefore two roots with the same residue are equal. The decomposition is unique whenever its second factor reduces to one. Multiplicativity of both factors is also proved.

For $p = 3, \ell = 2, a = 2$, the checked values are

$$\omega_2(2) = 8, \qquad \langle 2 \rangle_2 = 7, \qquad 8^2 = 1, \quad 8 \cdot 7 = 2 \quad \text{in } \mathbb{Z}/9\mathbb{Z}.$$

The unlifted representative 2 is not a square root of one modulo nine.

`FiniteUnits.omega_unique,.decomposition_unique`

`FiniteUnits.omega_mul,.principal_mul`

3. Precision compatibility and the dyadic sign

Finite refinements and Proposition 6.2's dyadic branch

For $1 \le k \le \ell$, let

$$\rho_{\ell,k} : \mathbb{Z}/p^{\ell}\mathbb{Z} \longrightarrow \mathbb{Z}/p^{k}\mathbb{Z}$$

be the actual reduction homomorphism. It induces a map on units. The explicit construction satisfies

$$\boxed{\rho_{\ell,k}(\omega_\ell(a)) = \omega_k(\rho_{\ell,k}(a)),}$$

$$\boxed{\rho_{\ell,k}(\langle a\rangle_\ell) = \langle \rho_{\ell,k}(a)\rangle_k.}$$

The proof uses the exponent factorization $p^{\ell-1} = p^{k-1}p^{\ell-k}$ and the already proved Frobenius invariance of a lifted root. Principal factors also satisfy

$$\langle a\rangle_\ell^{\,p^{\ell-1}} = 1.$$

At precision one the principal factor is exactly one. These are coherent finite certificates. No infinite inverse limit or topological unit-group equivalence is constructed here.

Why the mod-four branch is separate

Now let $\ell \ge 2$ and $a \in (\mathbb{Z}/2^{\ell}\mathbb{Z})^{\times}$. The actual units of $\mathbb{Z}/4\mathbb{Z}$ are exhausted by 1 and -1. Define

$$\varepsilon_\ell(a) = \begin{cases} 1, & a \equiv 1 \pmod 4, \\ -1, & a \equiv 3 \pmod 4, \end{cases} \qquad \langle a\rangle_{2,\ell} = \varepsilon_\ell(a)a.$$

The source uses $\ell = L + 2$. It proves

$$\boxed{a = \varepsilon_\ell(a)\langle a\rangle_{2,\ell}, \quad \varepsilon_\ell(a) \in \{1,-1\}, \quad \langle a\rangle_{2,\ell} \equiv 1 \pmod 4.}$$

The sign is uniquely determined by the residue modulo four, and cancellation gives uniqueness of the principal factor.

The checked example $a = 3$ modulo eight has sign $7 = -1$ and principal factor 5:

$$7 \cdot 5 = 3 \pmod 8, \qquad 5 = 1 \pmod 4.$$

The code separately proves $1 = -1$ in $\mathbb{Z}/2\mathbb{Z}$ but $1 \ne -1$ in $\mathbb{Z}/4\mathbb{Z}$. Modulo two alone cannot identify the sign. The generic prime-power construction at $p = 2$ only asks for a principal residue modulo two and is not silently substituted for this stronger mod-four factorization.

Principal targets.

`DyadicUnits.dyadic_unit_decomposition,.decomposition_unique`

4. CRT addresses and the actual packet selectors

Theorem 10.1; manuscript page 22

Let $a \geq 0$, let M be odd, and put $N = 2^a M$. Coprimality is derived from oddness:

$$\gcd(2^a, M) = 1.$$

The construction uses the actual Chinese-remainder ring equivalence

$$\boxed{\mathbb{Z}/N\mathbb{Z} \;\simeq\; \mathbb{Z}/2^a\mathbb{Z} \times \mathbb{Z}/M\mathbb{Z}.}$$

Its bijectivity and component formula are checked. On a natural representative r, the components are precisely its reductions modulo the two factors, not arbitrary coordinate labels.

The algebraic bridge to projectors

For natural indices n, r, the source proves

$$n \equiv r \pmod{2^a M} \quad\Longleftrightarrow\quad \big(n \equiv r \pmod{2^a} \text{ and } n \equiv r \pmod{M}\big).$$

For the original coefficient selector

$$(P_{N,r} f)(n) = \begin{cases} f(n), & n \bmod N = r, \\ 0, & \text{otherwise}, \end{cases}$$

take the canonical label $0 \leq r < N$. The logical equivalence yields the actual equality of sequence operators

$$\boxed{P_{N,r} f = P_{2^a,\, r \bmod 2^a}\big(P_{M,\, r \bmod M} f\big).}$$

This statement holds for coefficients in any type with zero. A separate theorem lifts the equality coefficientwise to the existing formal power-series selectors over any semiring.

The cases $a = 0$ and $M = 1$ are included. The corresponding one-element residue ring is not excluded. Oddness of M already implies positivity.

What is not asserted

CRT factors addresses, not the visibility weights or valuation filtrations associated with those addresses. Nothing in this proof gives an equal-weight decomposition at every prime or an additional analytic convergence theorem.

Coprimality cannot be discarded. The distinct classes 0 and 2 modulo four both map to $(0, 0)$ when both components are reduced modulo two. The source checks this counterexample. It also checks a composite-modulus failure of the Fermat exponent and a coefficient outside the standard window that is not 3-adically integral.

E.6 Recurrence packets

Scope and result

This supplement develops Theorem 9.1 and Corollary 9.2.

Twenty-two of 24 named items proved in the manuscript now have formal coverage. Two remain pending. Three classical inputs and two conjectures are tracked separately. The cumulative corpus has **382 named theorem declarations and 84 explicit definitions across 31 modules**.

New module	Scope	Theorems	Defs.
`CompanionPackets`	General jump and recurrence	17	2
`FibonacciPackets`	Actual Fibonacci specialization	18	4
`RecurrenceExamples`	Examples and boundary cases	14	1
Total added	Two named items	49	7

These counts include supporting lemmas and examples, not 49 independent mathematical discoveries. The principal statements are universal over their explicit inputs, not finite numerical observations.

The main mathematical connection

A sampled state $u_k = v_{Nk+j}$ evolves by the actual jump matrix C^N. Its recurrence is derived from the characteristic polynomial of that matrix. No scalar recurrence or spectral decomposition is supplied as a substitute for the desired conclusion.

For Fibonacci numbers, the state is independently defined from Mathlib's actual sequence. The Lucas sequence is independently defined by its initial values and recurrence. The trace and determinant of C^N are then proved to supply the sampled recurrence coefficients.

Important qualification

A d-dimensional state system supplies a recurrence of **order at most** d. Its minimal recurrence need not have order d. The original statement is read as the characteristic-polynomial recurrence, not a minimal-order claim. The formal equations also handle singular matrices, zero-dimensional spaces and zero step.

1. Actual matrix orbits and arithmetic jumps

Theorem 9.1; manuscript page 22

Let R be a commutative ring, I a finite coordinate type and $d = |I|$. For $C \in M_I(R)$ and $v_0 \in R^I$, define

$$\operatorname{orbit}(C, v_0, n) = C^n v_0, \qquad u_k = \operatorname{packet}(C, v_0, N, j, k) = C^{Nk+j} v_0.$$

The implementation uses actual matrix powers and matrix–vector multiplication. A separately supplied sequence v with

$$v_{n+1} = Cv_n$$

is proved by induction to equal this power orbit. Thus the source-sequence formulation is connected to the construction.

The jump formula

Associativity and the laws for powers of one matrix give

$$\boxed{u_k = C^j (C^N)^k v_0 = (C^N)^k (C^j v_0).}$$

Only powers of the same matrix are interchanged. The argument does not assume that arbitrary matrices commute. In particular,

$$u_{k+1} = C^N u_k, \qquad u_{k+a} = (C^N)^a u_k.$$

The step matrix is C^N, not C. A checked example with the Fibonacci matrix and $N = 2$ rejects replacing the jump with a single original step.

Refinement of an arithmetic address

Taking another subsequence with step M and offset s yields

$$u_{Mk+s} = v_{(NM)k+(Ns+j)}.$$

The formal proof establishes this identity for the actual packet function by checking the index arithmetic. It is not inferred from a diagram or a naming convention.

Endpoints and interpretation

The algebraic identities allow $N = 0$, in which case $u_k = v_j$ is constant. Positive-modulus residue packets are the special case $N > 0$ and $0 \le j < N$. The formula also permits offsets beyond that standard range. No inverse matrix, diagonalization, eigenvalue, or characteristic-zero assumption is needed.

2. From the characteristic polynomial to a recurrence

Theorem 9.1, continued

Put $D = C^N$ and let

$$\chi_D(X) = \det(XI - D) = X^d + \sum_{a=0}^{d-1} c_a X^a$$

be its actual characteristic polynomial. The implementation reuses the pinned Mathlib Cayley–Hamilton theorem, expands polynomial evaluation into a finite sum and proves

$$\sum_{a=0}^{d} \chi_D[a] D^a = 0, \qquad \chi_D[d] = 1.$$

Here $\chi_D[a]$ denotes the coefficient at index a. The identities hold over any commutative coefficient ring. The zero-ring case is handled explicitly by the proof's subsingleton branch.

The complete vector recurrence

Apply the matrix identity to the actual state u_k. The already proved advance identity identifies each $D^a u_k$ with u_{k+a}. Consequently,

$$\sum_{a=0}^{d} \chi_D[a] u_{k+a} = 0, \qquad \boxed{u_{k+d} = -\sum_{a=0}^{d-1} c_a u_{k+a}.}$$

This is the desired recurrence, with its monic leading coefficient and all earlier coefficients supplied by χ_D. It is not an assumption on the packet sequence.

Every coordinate and every R-linear scalar observation $\lambda : R^I \to R$ satisfies the corresponding equation:

$$\lambda(u_{k+d}) = -\sum_{a=0}^{d-1} c_a \lambda(u_{k+a}).$$

A separate source-sequence theorem transports the recurrence back to the original v_{Nk+j} notation.

Order versus minimal order

The characteristic polynomial gives a recurrence of order at most d. For example, $C = I_2$ gives a degree-two characteristic polynomial, but every orbit is constant and obeys $u_{k+1} = u_k$. Both statements are checked. No minimal-polynomial classification is claimed.

For $d = 0$, the unique empty vector is zero and the formula remains valid. For singular matrices, Cayley–Hamilton still applies: invertibility is irrelevant. The nilpotent example $C = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ has $C^2 = 0$ and $\chi_C = X^2$.

3. Fibonacci and Lucas coefficients are derived

Corollary 9.2; manuscript page 22

Define the actual integer matrix and state

$$C = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}, \qquad v_n = \begin{pmatrix} F_{n+1} \\ F_n \end{pmatrix}, \qquad v_0 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}.$$

The values F_n are Mathlib's `Nat.fib`, cast into $\mathbb{Z}$. Its basic recurrence proves $v_{n+1} = Cv_n$. The second coordinate of the packet state is therefore proved to be the intended F_{Nk+j}, not a newly assumed sequence.

An independent Lucas sequence

Define

$$L_0 = 2, \quad L_1 = 1, \quad L_{n+2} = L_n + L_{n+1}.$$

Direct finite matrix arithmetic proves $C^2 = C + I$. Multiplication by C^n gives $C^{n+2} = C^n + C^{n+1}$. Taking traces shows that $\operatorname{tr}(C^n)$ satisfies the same recurrence and initial values as L_n. Induction yields

$$\boxed{\operatorname{tr}(C^N) = L_N.}$$

The implementation separately proves

$$\det C = -1, \qquad \det(C^N) = (-1)^N, \qquad L_N = 2F_{N+1} - F_N.$$

No Binet roots or diagonalizability argument is needed.

The sampled Fibonacci recurrence

The actual two-by-two characteristic-polynomial formula gives

$$\chi_{C^N}(X) = X^2 - L_N X + (-1)^N.$$

Insert these coefficients into the general packet recurrence and take the second coordinate:

$$\boxed{F_{N(k+2)+j} = L_N F_{N(k+1)+j} - (-1)^N F_{Nk+j}.}$$

The full two-coordinate state satisfies the same equation. All subtraction is in $\mathbb{Z}$, not truncated natural-number subtraction. The result holds for all natural N, j, k, including zero step and zero initial values.

4. Exact examples and meaningful boundary checks

Example 9.3 and supporting results

The independently defined Lucas recurrence gives

$$(L_0, L_1, L_2, L_3, L_4, L_5) = (2, 1, 3, 4, 7, 11).$$

For $N = 3$, the general theorem therefore specializes to

$$u_{k+2} = 4u_{k+1} + u_k.$$

The implementation proves this for every offset j and every k, not only the displayed sample. At $j = 2$, direct evaluation of the actual Fibonacci sequence gives

$$(F_2, F_5, F_8, F_{11}, F_{14}, F_{17}) = (1, 5, 21, 89, 377, 1597).$$

This is the exact manuscript example.

The parity sign cannot be removed

For $N = 2$, the recurrence is

$$u_{k+2} = 3u_{k+1} - u_k.$$

At $j = 1, k = 0$, the correct equation is $5 = 3 \cdot 2 - 1$. Replacing the minus sign with a plus would assert $5 = 7$. The source proves the inequality, and a separate invalid-proof control attempts and rejects the false equation.

At $N = 1$ the ordinary Fibonacci recurrence is recovered. At $N = 0$, $L_0 = 2$ and the packet is constant, so the same formula becomes $u = 2u - u$.

Uniqueness from the first two packet values

For a fixed N, j, any integer sequence satisfying the proved sampled recurrence and starting at F_j, F_{N+j} agrees with F_{Nk+j} for all k. This is proved by two-step induction. It is a consequence of the established coefficients and recurrence, not a premise used to identify Fibonacci values initially.

Independent finite mirrors

A pure-Python exact-arithmetic implementation computes characteristic polynomials by the permutation determinant and states by repeated matrix application. It checks 280 matrix systems over integers, rationals and several modular rings, including composite moduli and the zero ring. Separately it computes sampled Fibonacci sequences recursively and compares them with direct Fibonacci evaluation. These are useful regression checks, not Lean extraction or universal proofs.

E.7 Periods and difference bounds

Scope and result

This block completes Corollary 8.5 of the unchanged status-corrected manuscript by an independent finite-field argument. It does **not** assume the still-pending global finite-difference theorem, item 7.5.

Twenty-three of 24 named items proved in the manuscript now have formal coverage. The cumulative corpus contains **439 named theorem declarations and 94 explicit definitions across 38 modules**. Three classical inputs and two conjectures remain separately tracked. All 31 upstream proof modules and the six earlier supplements remain unchanged.

New module	Theorems	Definitions
`HurwitzConvolution`	13	3
`HurwitzInverse`	6	1
`StandardWindowPeriod`	8	1
`DifferenceFiltration`	4	0
`GlobalEulerBoundary`	7	1
`DworkCriterion`	7	4
`PeriodExamples`	12	0
Total added	57	10

The counts include supporting lemmas, conditional implications and exact examples. They are not counts of independent discoveries. The conditional implications do not promote their antecedents to proved facts.

The independent route

In characteristic p, both the first and pth coefficient shifts obey a Leibniz rule for Hurwitz convolution. A section supported at multiples of m, with $m \mid p-1$, has equal first and pth shifts. Its constructed reciprocal inherits this equality. Identifying that reciprocal with the existing reduced Euler sequence gives its period on the positive-index tail.

What remains

Theorem 7.5 asks for powers as high as $p^{\min(k,mn)}$ and covers nonstandard residue classes. A period modulo p does not establish that stronger result. This proves a genuine standard-window mod-p fragment and precise conditional interfaces for the remaining argument, while keeping item 7.5 pending.

1. Coefficient products and reciprocal differentiation

A characteristic-p argument without factorial division

For sequences $f, g : \mathbb{N} \to K$, where K is a field, define

$$(f \star g)(d) = \sum_{i=0}^{d} \binom{d}{i} f(i) g(d-i), \qquad (U^a f)(d) = f(d+a).$$

These are Hurwitz coefficients. The notation does not divide by $d!$ in $\mathbb{F}_p$. In particular, the implementation is not ordinary power-series multiplication with undefined inverse factorials in positive characteristic.

The identity sequence is $\mathbf{1}(d) = \delta_{d0}$. The new source proves the actual higher product rule

$$U^a(f \star g) = \sum_{i=0}^{a} \binom{a}{i} (U^i f) \star (U^{a-i} g).$$

The argument starts with Pascal's identity for the first shift, then inducts on a. All sums are finite at each coefficient.

The prime-shift cancellation

For prime p and characteristic p, every interior binomial coefficient in row p vanishes. Hence

$$U^p(f \star g) = (U^p f) \star g + f \star (U^p g).$$

The first-shift rule has exactly the same form. Both are checked for the literal coefficient product.

Suppose $g(0) = 1$. The source constructs f by the full triangular recurrence

$$f(d) = \delta_{d0} - \sum_{i<d} \binom{d}{i} f(i) g(d-i)$$

and proves $f \star g = \mathbf{1}$. It also proves cancellation: if $a \star g = 0$, then $a = 0$, by induction on the first nonzero coefficient.

If $U^p g = Ug$, differentiate the inverse equation with both operators and subtract. The terms involving $f \star (Ug)$ cancel, leaving

$$(U^p f - Uf) \star g = 0.$$

The proved cancellation law yields

$$\boxed{U^p f = Uf.}$$

The section identity is an explicit premise of this general reciprocal lemma. The next page proves that premise for the specific section used by the Euler sequence.

Principal targets.

`Hurwitz.shift_convolution`, `Hurwitz.prime_shift_convolution`

`Hurwitz.convolution_left_eq_zero`

`HurwitzInverse.inverse_convolution`

`HurwitzInverse.inverse_prime_difference`

2. Identification with the reduced Euler sequence

Corollary 8.5; manuscript page 21

Work over $\mathbb{F}_p = \mathbb{Z}/p\mathbb{Z}$. For positive $m \mid p-1$, take the literal section

$$g_m(d) = \begin{cases} 1, & m \mid d, \\ 0, & m \nmid d. \end{cases}$$

It satisfies $g_m(0) = 1$. Since $p \equiv 1 \pmod{m}$, the conditions $m \mid d + p$ and $m \mid d + 1$ are equivalent. The source therefore proves $U^p g_m = U g_m$.

Let f_m be the reciprocal constructed on the previous page. A separate strong-induction proof establishes its actual support:

$$m \nmid d \quad \Longrightarrow \quad f_m(d) = 0.$$

This support is not included as an assumption of the construction.

The same residual sequence, not a renamed substitute

Evaluate $f_m \star g_m = \mathbf{1}$ at $d = mn$. Reindex the surviving summation indices by $i = mq$ using the proved support. The result is

$$\sum_{q=0}^{n} \binom{mn}{mq} f_m(mq) = \delta_{n0}.$$

The fifth block independently constructed the unique sequence $e_n^{(m,p)}$ satisfying this triangular system. Applying that uniqueness theorem gives

$$\boxed{f_m(mn) = e_n^{(m,p)}.}$$

Thus the reciprocal really is connected to the manuscript's Lucas-reduced inverse.

The positive-tail period

Write $h = (p-1)/m$. For $n \geq 1$, evaluate $U^p f_m = U f_m$ at the nonnegative degree $mn - 1$:

$$f_m(mn + p - 1) = f_m(mn).$$

Since $mn + p - 1 = m(n + h)$, the identified sequence satisfies

$$\boxed{e_{n+h}^{(m,p)} = e_n^{(m,p)} \quad (n \geq 1).}$$

Induction gives $e_{n+uh}^{(m,p)} = e_n^{(m,p)}$ for every $u \geq 0$. This proves a period, not necessarily the least positive period. The proof also includes $p = 2$, where $m = 1$ and $h = 1$.

`WindowPeriod.multiple_period`

3. Actual packet congruences and sharp boundaries

Consequences for the standard window; not the full Theorem 7.5

The fifth block constructed integral lifts $\widehat{C}_{mp,j}(n) \in \mathbb{Z}_p$ of the original rational coefficients when $0 \leq j < p$, and proved that their residues equal $e_n^{(m,p)}$.

Applying the actual residue map and its kernel ideal to the new period gives

$$\boxed{p \mid \widehat{C}_{mp,j}(n+uh) - \widehat{C}_{mp,j}(n) \quad \text{in } \mathbb{Z}_p}$$

for $n \geq 1$ and $u \geq 0$. Every higher positive difference is a difference of terms already divisible by p. Consequently,

$$p \mid \Delta_{uh}^{k} \widehat{C}_{mp,j}(n) \qquad (k \geq 1,\ n \geq 1).$$

A ring-homomorphism lemma identifies the image of these differences in $\mathbb{Q}_p$ with the differences of the original rational coefficient function. This is not vacuous field divisibility. The valuation version uses order infinity at zero.

Three checked boundaries

The initial row. For $(p, m) = (3, 2)$, the same reduced recurrence gives $e_0 = 1$ and $e_1 = -1 = 2$ in $\mathbb{F}_3$. Its proposed period is one, so the positive-tail result cannot in general include row zero.

The divisor hypothesis. At $(p, m) = (5, 3)$, where $3 \nmid 4$, the independently computed reduced row is

$$(e_0, e_1, e_2, e_3) = (1, 4, 4, 2).$$

Replacing h by the integer quotient $\lfloor 4/3 \rfloor = 1$ does not give a period: $e_3 \neq e_2$.

No automatic extra power. The original rational triangular coefficients satisfy

$$C_{6,0}(1) = -1, \quad C_{6,0}(2) = 923, \quad v_3\big(C_{6,0}(2) - C_{6,0}(1)\big) = v_3(924) = 1.$$

A period modulo 3 therefore cannot simply be reported as a period modulo 9. This is consistent with the global theorem's proposed first-difference bound. It is not a counterexample to Theorem 7.5.

Principal targets.

`WindowPeriod.standard_window_period_divisibility`

`GlobalEulerBoundary.standard_window_all_orders_mod_p`

`GlobalEulerBoundary.lifted_difference_coe`

`PeriodExamples.period_can_fail_at_zero`

`PeriodExamples.first_difference_precision_is_one`

4. Exact interfaces for the remaining global argument

Conditional results are not counted as completion of item 7.5

Let p be prime and m a positive divisor of $p - 1$. For a sequence e in a commutative coefficient ring, define its actual packed Hurwitz sequence

$$X(d) = \begin{cases} e(d/N), & N \mid d, \\ 0, & N \nmid d, \end{cases} \qquad N = mp.$$

Let $L = p(p-1)$ and $\delta = U^{p+L} - U^p = U^{p^2} - U^p$. The source proves the operator dictionary

$$(\delta^s X)(d) = \Delta_L^s X(d + ps).$$

At the valid nonnegative coefficient degree $d = mpn - ps$, with $s \le mn$, this becomes

$$(\delta^s X)(mpn - ps) = \Delta_h^s e(n), \qquad h = (p-1)/m.$$

The packed sequence and difference operations are definitions. Their coefficient correspondence is proved before any divisibility assumption is introduced.

A sufficient condition, explicitly conditional

Define flatness by the actual coefficientwise divisibility assertion

$$\delta^s X(d) \in p^s R \qquad (s, d \ge 0).$$

The new theorem proves that this hypothesis implies

$$\boxed{p^{\min(k,mn)} \mid \Delta_h^k e(n).}$$

First, coefficient extraction proves the triangular region $k \le mn$. A separate induction on difference order proves that this region is equivalent to the complete saturated estimate. This implication is useful over $\mathbb{Z}_p$. Interpreting it over a field would not supply the intended integral content.

Normalization is also an explicit implication

Using the existing definition $E_{Nn}^{(N,j)} = j! C_{N,j}(n)$, the source proves that multiplication by $j!$ commutes with every iterated difference. If the unnormalized difference has precision A, the normalized difference has precision $A - v_p(j!)$. Precision is defined as

$$x = 0 \quad \text{or} \quad v_p(x) \ge A,$$

so zero and negative factorial-loss thresholds are handled correctly. For $j < p$, the loss is zero.

Not established here. The general unnormalized Euler family has not been proved to possess the required flat integral lift, especially across singular residue intervals. The retrieved 18-page supporting prose proof uses weighted Amice/Mahler bounds, singular ratios and nonsingular propagation. Those obligations remain, and the full arbitrary-multiple global estimate is not promoted by these interfaces.

5. Verification record and reproducibility boundary

Evidence accompanies the source, not only the summary

aeb72f1e9981b6d35b426b16dca7759be3e7ba06.

Nine dependency heads are compared with their recorded manifest pins. The compiled Mathlib cache is reused, not independently rebuilt. The source checker rejects admitted proofs and selected trust-bypass constructs. The transitive axiom audit is a separate check.

E.8 Standard-window higher differences

Scope and result

The all-residue Theorem 7.5 is treated separately. This argument proves its full saturated higher-power **estimate throughout the standard window**, rather than only a period modulo p. For every prime p, positive $m \mid p-1$, $0 \le j < p$, and natural n, k, u, put $h = (p-1)/m$. Then

$$\boxed{\Delta_{uh}^{k} C_{mp,j}(n) = 0 \quad \text{or} \quad v_p\Big(\Delta_{uh}^{k} C_{mp,j}(n)\Big) \ge \min\{k, mn\}.}$$

The unnormalized family $j!C_{mp,j}(n)$ satisfies the same bound. Both statements concern the original rational coefficient function, identified with its actual integral p-adic lift. They include $p = 2$, $k = 0$, $n = 0$, and the additional harmless case $u = 0$.

Coverage remains 23 of 24 named items proved in the manuscript. Three classical inputs and two conjectures remain separate. The new result covers every permissible residue when $m = 1$, but not the range $p \le j < mp$ when $m > 1$.

The cumulative corpus has **526 explicit theorem declarations and 107 explicit definitions in 47 modules**. Counts include support lemmas and examples, not independent discoveries. All 38 upstream proof modules and seven earlier supplements are preserved.

1. The characteristic-zero product rule

The normalized defect is not an ordinary derivation

Let A be a commutative algebra over a characteristic-zero field K, and let U be an actual K-derivation. The source defines

$$B = \frac{U^{p^2} - U^{p}}{p}, \qquad M_q(f,g) = \sum_{a=1}^{q-1} \frac{1}{p}\binom{q}{a}(U^a f)(U^{q-a} g), \quad q = p, p^2.$$

The coefficients of each M_q are proved integral: the middle entries of a prime-power binomial row are divisible by p. In Lean they are implemented as natural quotients, with exact division proved before the product identity is used. Induction on derivative order establishes the full Leibniz formula and hence

$$\boxed{B(fg) = B(f)g + fB(g) + M_{p^2}(f,g) - M_p(f,g).}$$

The middle terms are essential. At $p = 3$, $f = t$ and $g = t^2$, the constant coefficient of $B(fg)$ is -2, whereas that of $B(f)g + fB(g)$ is zero. This inequality is itself Lean-checked.

All orders, without a circular closure assumption

Let $I \subset A$ be a subring stable under U. Define

$$\mathrm{Bounded}_r(f) \iff B^s f \in I \ (0 \le s \le r), \qquad \mathrm{Flat}(f) \iff B^s f \in I \ (s \ge 0).$$

The definitions contain no product or inverse closure requirement. Since B commutes with U, derivatives of a bounded element remain bounded. Induction on r in the displayed product rule then proves closure under multiplication. The finite middle sums use the lower-order induction hypothesis, not the desired next-order conclusion.

For an actual inverse $fg = 1$, applying the product rule and multiplying by g gives

$$B(g) = -g^2 B(f) - gM_{p^2}(f,g) + gM_p(f,g).$$

If $g \in I$, induction on r proves boundedness of g from boundedness of f. At each successor stage the preceding stage supplies boundedness of g needed on the right. Passing to all finite orders proves reciprocal closure for an integral inverse.

`DworkClosure.flat_mul`, `DworkClosure.flat_inverse`

2. The actual integral Hurwitz lattice

Connecting differential expressions to coefficient divisibility

The specialization works inside $\mathbb{Q}_p[[t]]$ and uses factorial-scaled coefficients

$$a_f(d) = d![t^d]f, \qquad I_p = \{f \in \mathbb{Q}_p[[t]] : a_f(d) \in \mathbb{Z}_p \text{ for every } d\}.$$

The source constructs I_p as a subring. Actual exponential-series multiplication gives

$$a_{fg}(d) = \sum_{r=0}^{d} \binom{d}{r} a_f(r) a_g(d-r), \qquad a_{Uf}(d) = a_f(d+1).$$

These identities prove multiplication and derivative stability of the lattice. Membership does not require ordinary power-series coefficients to lie in $\mathbb{Z}_p$.

The reciprocal is integral

For $f \in I_p$ with constant coefficient one, the usual power-series reciprocal is used. Its inverse equation yields the exact coefficient recurrence

$$a_{f^{-1}}(d) = \delta_{d0} - \sum_{r=0}^{d-1} \binom{d}{r} a_{f^{-1}}(r) a_f(d-r).$$

Strong induction proves that all of these coefficients are integral. Combining this construction with the preceding all-order theorem proves flatness of the *actual reciprocal*. No flatness or integrality of that reciprocal is assumed in the normalized-series specialization.

The earlier coefficient criterion is recovered exactly

Define the literal coefficient defect

$$(\delta a)(d) = a(d + p^2) - a(d + p).$$

The new source proves, for every s, d,

$$a_{B^s f}(d) = p^{-s}(\delta^s a_f)(d).$$

For an integral coefficient x, it proves the bridge

$$\boxed{p^{-s}x \in \mathbb{Z}_p \quad \Longleftrightarrow \quad p^s \mid x \text{ in } \mathbb{Z}_p.}$$

Thus the differential definition is equivalent to the existing coefficient-level Dwork criterion. Division occurs in $\mathbb{Q}_p$, while the assertion after division is membership in $\mathbb{Z}_p$. It is not divisibility in the field. Zero coefficients satisfy every finite precision condition.

3. A nonsingular Euler-operator argument

The standard interval without an analytic power-series-in-the-index premise

On Hurwitz coefficients, the actual Euler operator plus c is

$$(\Lambda_c a)(d) = (d + c)a(d).$$

Direct induction proves its commutator with every defect iterate:

$$\delta^s \Lambda_c a = \Lambda_c \delta^s a + sp\big(pU^{p^2} - U^p\big)\delta^{s-1} a, \qquad s \geq 1.$$

Suppose a is integral and supported at degrees divisible by p, and $p \nmid c$. Every supported pivot $d + c$ is proved to be a unit of $\mathbb{Z}_p$. The defect preserves this support. Induction in the commutator identity therefore proves

$$\mathrm{Flat}(\Lambda_c a) \Longrightarrow \mathrm{Flat}(a).$$

This is a reflection theorem on the integral supported domain. It does not assume flatness of the proposed preimage, and does not assert invertibility at a singular pivot $p \mid c$.

Apply it to the explicit normalized sections

Set $N = mp$ and, for $0 \le j < p$, define integral Hurwitz coefficients

$$g_j(d) = \begin{cases} \binom{d+j}{d}^{-1}, & N \mid d, \\ 0, & N \nmid d. \end{cases}$$

The inverse binomial is constructed using the actual unit pivots already proved by Lucas reduction. Its image in $\mathbb{Q}_p$ is proved equal to the displayed reciprocal.

For $j = 0$, g_0 is the literal N-divisibility indicator. Because $N \mid p(p-1)$, the two shifts in δg_0 agree and $\delta g_0 = 0$. It is flat at every order. The actual binomial identity gives

$$\Lambda_{j+1} g_{j+1} = (j+1) g_j.$$

As $1 \le j + 1 < p$, the nonsingular reflection theorem inductively proves flatness of every g_j in the standard window. There is no uniform-convergence assumption in this argument.

Principal targets.

`StandardWindowDwork.kernel_coe`, `StandardWindowDwork.kernel_euler_step`

`StandardWindowDwork.kernel_flat`

4. From these sections to the original Euler packets

Actual reciprocal, actual rational sequence, every order and step multiple

The factorial-ratio identity is proved coefficient by coefficient:

$$\sum_{d \ge 0} g_j(d) \frac{t^d}{d!} = j! \sum_{r \ge 0} \frac{t^{Nr}}{(Nr + j)!}.$$

The right side is precisely the normalized source kernel from the first block, not a replacement family. The earlier rational identity for its reciprocal is transported to $\mathbb{Q}_p[[t]]$. A separate encoding theorem identifies the reciprocal's coefficients with the already constructed $\mathbb{Z}_p$ lifts of the original $C_{N,j}(r)$.

All-order reciprocal closure therefore gives flatness of the actual packed Euler coefficient sequence. The earlier coefficient-extraction theorem now has a *proved antecedent* for every $j < p$, and yields

$$p^{\min(k, mn)} \mid \Delta_h^k C_{mp,j}(n) \quad \text{in } \mathbb{Z}_p, \qquad h = (p-1)/m.$$

A new finite telescoping argument proves the extension to arbitrary natural multiples of h. Its first-step identity is

$$f(n+uh) - f(n) = \sum_{a=0}^{u-1} \Delta_h f(n+ah).$$

Commutation of differences and induction on their order transfer any fixed ideal bound valid on a forward tail. The required precision $\min(k, mn)$ is nondecreasing as the starting row advances. Hence

$$\boxed{p^{\min(k,mn)} \mid \Delta_{uh}^{k} C_{mp,j}(n) \quad (0 \le j < p).}$$

The scalar-extension bridge identifies these differences with the original rational coefficient function. The rational theorem explicitly allows zero differences, avoiding the library's finite valuation convention at zero. Since $j!$ is a unit for $j < p$, both normalized and unnormalized versions have the same precision.

Scope. The proof includes all primes, all rows and orders, and all natural step multipliers. For $m = 1$, the standard window is the complete allowed residue range. For larger m, residues $p \le j < mp$ are not covered by this theorem. The earlier one-power period is not the source of the new higher-power estimate.

Principal targets.

`StandardWindowDwork.window_is_reciprocal`, `StandardWindowDwork.standard_window_flat`

`StandardWindowDwork.standard_window_global_bound`

`StandardWindowPrecision.normalized_window_precision`

`StandardWindowPrecision.unnormalized_window_precision`

`StandardWindowPrecision.modulus_p_complete_family`

5. Examples, verification and the remaining gap

The coverage count is unchanged; the unresolved theorem now has a stronger proved part

The original rational recurrence gives

$$C_{6,2}(1) = -\frac{1}{28}, \quad C_{6,2}(2) = \frac{425}{364}, \quad C_{6,2}(3) = -\frac{2039759}{2660}.$$

Consequently, the new source proves

$$\Delta_1^2 C_{6,2}(1) = -\frac{949959}{1235}, \qquad v_3\big(\Delta_1^2 C_{6,2}(1)\big) = 2.$$

This attains the bound $\min(2, 2 \cdot 1) = 2$. A claim of a third power is rejected. The separate cubic example proves that the normalized differential defect is not an ordinary derivation. Controls also reject an asserted unit pivot at $c = p$ and the prime-power binomial-divisibility formula at a composite base.

Recorded checks

The cumulative verifier rebuilds all 47 modules and audits all 633 explicit declarations: 526 theorems and 107 definitions. Warnings are errors, unexpected axiom dependencies are rejected, and 27 deliberately invalid proof controls are tested. The allowed transitive axioms remain `propext`, `Classical.choice` and `Quot.sound`. Exact results, compiler commands and source hashes are in the accompanying machine-readable reports.

What is still unproved

The all-residue Theorem 7.5 requires the additional range $p \le j < mp$. Its supporting prose proof treats singular ratios at $c = p, 2p, \dots, (m-1)p$ through weighted Amice estimates and a dual Mahler pairing, then propagates across the intervening indices. Those actual-family estimates and the full remaining propagation are not supplied by this part . A unit argument at $p \nmid c$ cannot be used at $p \mid c$.

The standard-window theorem is an infinite family. Its width gives no numerical proportion of the work needed for the all-residue theorem. The two native conjectures remain unproved.

E.9 Singular Amice Supplement

Scope and result

Let p be prime, let $m \mid p-1$, and put $N = mp$. For $1 \le a < m$, put $c = ap$ and define the original exponential section and ratio by

$$H_{N,c}(t) = \sum_{n \ge 0} \frac{t^{Nn+c}}{(Nn+c)!}, \qquad R_c(t) = \frac{tH_{N,c-1}(t)}{H_{N,c}(t)}.$$

The quotient is interpreted after removing its forced zero. This block proves, for the actual rational coefficients α_d,

$$R_{ap}(\log(1+T)) = \sum_{d \ge 0} \alpha_d T^d, \qquad \boxed{\alpha_d = 0 \text{ or } v_p(\alpha_d) \ge -\lfloor d/p \rfloor .}$$

Equivalently, every $p^{\lfloor d/p \rfloor}\alpha_d$ belongs to the actual completed ring $\mathbb{Z}_p$. The zero-safe alternative is explicit in the formal rational statement.

This is the weighted estimate of Proposition 4.7 in the supporting argument. It is **not yet the singular higher finite-difference theorem**. The full all-residue Paper IX Theorem 7.5 remains pending, and full manuscript coverage stays at **23 of 24**.

No hidden estimate. The final weighted-ratio theorem assumes primality, the modulus divisibility and the specified residue bounds. It does not assume weighted section membership, reciprocal closure, the ratio identity, a Mahler pairing or the desired higher-difference bound. Pages 2–5 describe the constructed objects and proved bridges.

1. Integral cyclic coefficients

Work first in an arbitrary commutative ring R. If $z^p = 1$, set

$$I = (p, z-1), \qquad P = (p).$$

Expanding $((z-1)+1)^p = 1$ and using divisibility of every interior binomial coefficient in prime row p gives

$$(z-1)^p \in PI.$$

Every other degree-p product of the two generators of I also belongs to PI. The formal ideal proof therefore establishes

$$\boxed{I^p \subseteq PI.}$$

For $q = p\lfloor q/p \rfloor + (q \bmod p)$, strong induction and the factorial valuation identity give

$$\boxed{I^q \subseteq P^{v_p(q!)}}.$$

In detail, write $b = \lfloor q/p \rfloor$. Then

$$I^q \subseteq P^b I^b \subseteq P^{b+v_p(b!)} = P^{v_p(q!)}.$$

No integral-domain hypothesis or division in a field is used here.

Now take the integral cyclic group ring

$$R_N = \mathbb{Z}[\mathbb{Z}/N\mathbb{Z}], \qquad x = [1], \qquad x^N = 1,$$

and assume $N \mid p(p-1)$. Thus $(x^{p-1})^p = 1$. Each genuine consecutive block

$$\prod_{i=0}^{p-1} \bigl(x - (pb+i)\bigr)$$

belongs to $(p, x^{p-1} - 1)$. This follows from the actual polynomial identity

$$\prod_{i \in \mathbb{F}_p} (X - i) = X^p - X$$

modulo p, not from a hypothesized valuation of the product.

For the falling factorial $(x)_d = \prod_{i=0}^{d-1}(x-i)$, grouping into consecutive blocks gives

$$(x)_d \in I^{\lfloor d/p \rfloor} \subseteq \bigl(p^{v_p(\lfloor d/p \rfloor !)}\bigr).$$

Every integral residue coordinate therefore satisfies

$$\boxed{p^{v_p(\lfloor d/p \rfloor !)} \mid [(r)](x)_d \quad \text{in } \mathbb{Z}.}$$

Dividing a coordinate by $d!$ is done only afterward, using $v_p(d!) = \lfloor d/p \rfloor + v_p(\lfloor d/p \rfloor !)$. This establishes the weighted denominator estimate before any field-valued divisibility could make it vacuous.

Modules. `CyclotomicFiltration`, `PrimeBlockPolynomial`, and `CyclicAmiceCoefficients`.

2. Connection to the actual section

An integral coordinate estimate becomes relevant only after connecting it to the manuscript's generating functions. For a residue $r \in \mathbb{Z}/N\mathbb{Z}$, define

$$H_r(t) = \sum_{d \geq 0} \mathbf{1}_{d \equiv r \ (N)} \frac{t^d}{d!}, \qquad F_r(T) = H_r(\log(1+T)).$$

The implementation uses the actual formal logarithm and substitution in $\mathbb{Q}[[T]]$. It proves

$$H_r' = H_{r-1}, \qquad (1+T)F_r' = F_{r-1},$$

and hence the coefficient recurrence

$$(d+1)[T^{d+1}]F_r = [T^d]F_{r-1} - d[T^d]F_r.$$

The initial values are $F_r(0) = \mathbf{1}_{r=0}$.

Independently, let $b_{d,r}$ be the residue-r coordinate of $(x)_d$ in R_N. Actual group-ring multiplication gives

$$b_{0,r} = \mathbf{1}_{r=0}, \qquad b_{d+1,r} = b_{d,r-1} - d\, b_{d,r}.$$

Induction comparing these two recurrences proves

$$\boxed{d![T^d]H_r(\log(1+T)) = b_{d,r}.}$$

Thus the cyclic coefficient is not an unrelated stand-in for a section coefficient. For the canonical label $0 \le c < N$, the formal section is also proved equal to the original `ExponentialSection.originalSection` used in the existing Euler project.

Weighted membership

The class used in the formalization is

$$\mathcal{W}_p = \left\{ F \in \mathbb{Q}_p[[T]] : p^{\lfloor d/p \rfloor}[T^d]F \in \mathbb{Z}_p \text{ for every } d \right\}.$$

The integral-coordinate estimate from page 2 now proves

$$\boxed{H_r(\log(1+T)) \in \mathcal{W}_p}$$

for every residue r, including the singular ones. Rational coefficients are mapped into $\mathbb{Q}_p$ by the actual coefficient ring homomorphism.

The same source package retains the earlier independent formal identity

$$d![T^d]\exp(x\log(1+T)) = (x)_d$$

over a commutative $\mathbb{Q}$-algebra. The section bridge above does not rely on selecting or averaging roots in a cyclotomic extension.

Principal targets.

`factorial_coeff_section`; `section_weighted_integral`;

`weighted_section`.

3. Weighted closure and the normalized denominator

Let $w(d) = \lfloor d/p \rfloor$. Since $w(i) + w(d-i) \le w(d)$, the coefficient formula for a product proves closure of $\mathcal{W}_p$ under multiplication. Additive closure is immediate. For $U \in \mathcal{W}_p$ with $U(0) = 1$, strong induction in the actual reciprocal coefficient recurrence proves

$$\boxed{U^{-1} \in \mathcal{W}_p.}$$

This inverse property is a theorem, not an additional field in a structure encoding weighted series.

Differentiation and the Euler field

The derivative coefficient is $(d+1)a_{d+1}$. If $p \nmid d+1$, the adjacent weights agree. If $p \mid d+1$, the integer factor $d+1$ compensates for the one-unit weight increase. Therefore ordinary differentiation preserves $\mathcal{W}_p$.

For the actual logarithm, its coefficient denominator is d, and the proved inequality

$$v_p(d) \le \lfloor d/p \rfloor \qquad (d > 0)$$

implies $\log(1+T) \in \mathcal{W}_p$. Consequently

$$L_T F = \log(1+T)(1+T)F'$$

also preserves $\mathcal{W}_p$.

Removing a singular forced zero

Put $c = ap < N$ and define the actual normalized kernel

$$K_c(t) = c! \sum_{n \ge 0} \frac{t^{Nn}}{(Nn+c)!}, \qquad K_c(0) = 1.$$

Let $\ell(T) = \log(1+T)/T$, defined by shifting logarithm coefficients, not by inverting T. Set

$$U(T) = \ell(T)^c K_c(\log(1+T)).$$

The formal proof establishes $U(0) = 1$ and the exact factorization

$$H_{N,c}(\log(1+T)) = \frac{T^c}{c!} U(T).$$

It follows coefficientwise that

$$[T^d]U = c![T^{d+c}]H_{N,c}(\log(1+T)).$$

Because $p^a \mid (ap)!$ and $\lfloor (d+ap)/p \rfloor = a + \lfloor d/p \rfloor$, the already proved section estimate gives $U \in \mathcal{W}_p$. Thus $U^{-1} \in \mathcal{W}_p$ as well. The factorial divisibility is derived from the pinned Legendre valuation theorem.

Boundary. The original positive-address section has zero constant coefficient. It is not the series to which unit inverse closure is applied.

4. The singular ratio estimate

For a positive address c, the rational ratio is independently constructed from the original kernels:

$$R_c(t) = c\,K_{c-1}(t)K_c(t)^{-1}.$$

The scalar factor c is necessary. The source proves the cleared identity

$$\boxed{R_c(t)H_{N,c}(t) = tH_{N,c-1}(t).}$$

This connects the constructed object to the original unnormalized ratio A_{c-1}/A_c. It does not assign the desired transformed formula as its definition.

After actual logarithmic substitution and the chain rule,

$$R_c(\log(1+T))H_{N,c}(\log(1+T)) = L_T H_{N,c}(\log(1+T)).$$

Insert the proved factorization $H_{N,c}(\log(1+T)) = T^c U/c!$. Leibniz differentiation and cancellation of that nonzero section give

$$\boxed{R_c(\log(1+T)) = c(1+T)\ell(T) + (L_T U)U^{-1}.}$$

All differentiation, substitution, nonzeroness and cancellation obligations are proved in the source.

For $c = ap$, the second summand belongs to $\mathcal{W}_p$ by the closure results on page 4. The first does too: shifting the logarithm coefficient loses at most one unit of the floor weight, so $p\ell(T) \in \mathcal{W}_p$, and the integer a supplies the remaining factor. Therefore

$$\boxed{R_{ap}(\log(1+T)) \in \mathcal{W}_p.}$$

The final rational coefficient theorem states the bound with an explicit zero alternative. No finite-valued default valuation at zero is used as the meaning of unlimited precision.

Checks that prevent a normalization mistake

The source proves that the actual ratio has constant coefficient c, not one. In the concrete case $N = 6, c = 3$, the universal theorem gives weighted membership and the constant coefficient is proved to be 3.

It also derives $[T^3]H_{3,0}(\log(1+T)) = 1/6$ from the actual differential recurrence and checks its valuation $v_3(1/6) = -1$. Thus weighted membership does not mean ordinary coefficient integrality. This value attains the allowed floor weight at degree three.

Principal target. `SingularRatioAmice.paper_singular_amice_estimate`. The theorem's assumptions contain only the declared arithmetic parameter conditions.

5. Verification and the remaining theorem

The verifier retains the previous 27 invalid-proof controls and adds two: incorrectly promoting a weighted coefficient to an integral one, and incorrectly normalizing the singular ratio constant to one. Missing imports, panics and timeouts do not qualify as successful negative controls. The preserved source checker rejects proof placeholders, added axioms and selected kernel-bypass constructs.

Independent finite regressions

The new exact-rational regression program is a separate implementation, not Lean extraction. Its checked scope is:

Finite check	Count
Integral cyclic-coordinate numerator tests	17,775
Corresponding section-weight tests	17,775
Direct logarithmic composition comparisons	24
Singular ratio families	13
Singular ratio coefficient comparisons	597
Weighted product, inverse and derivative cases	120

For $p = 3, N = 6, c = 3$, this independent computation obtains the degree-six ratio coefficient $1/10080$, with valuation -2, attaining the allowed weight. This particular coefficient calculation is recorded as a finite regression, not as a new Lean theorem. A violating modulus $p = 3, N = 4$ yields a section coefficient of valuation -4 at degree nine, showing that the modulus divisibility hypothesis cannot simply be discarded.

What has not been proved by this block

To obtain the singular higher-difference theorem, the weighted coefficient estimate must still be connected to the dual Mahler polynomial filtration and its integral pairing. The argument must then establish the required ratio flatness, propagate between singular indices, and assemble the original all-residue Euler family. None of these obligations is replaced by the finite regression tests.

Neither native conjecture is resolved by these arguments. Compiler evidence and source records are supplied separately.

E.10 All Residue Completion Supplement

Scope and final statement

Let p be a prime, let $m > 0$ divide $p-1$, put $N = mp$ and $h = (p-1)/m$, and let $0 \le j < N$. The original rational packet is defined by

$$\sum_{q=0}^{n} \binom{Nn+j}{Nq} C_{N,j}(q) = \delta_{n0}, \qquad E_j(n) = j!\, C_{N,j}(n).$$

For every $n, k, u \in \mathbb{N}$, the new formal result establishes

$$\boxed{E_j(n) \in \mathbb{Z}_p, \qquad \Delta_{uh}^k E_j(n) \in p^{\min(k,mn)}\mathbb{Z}_p.}$$

Here $\Delta_h f(n) = f(n+h) - f(n)$. The corresponding rational valuation statement is zero-safe:

$$\Delta_{uh}^k E_j(n) = 0 \quad \text{or} \quad v_p\big(\Delta_{uh}^k E_j(n)\big) \ge \min(k, mn).$$

For the normalized coefficients, the exact correction is retained:

$$\boxed{\Delta_{uh}^k C_{N,j}(n) = 0 \quad \text{or} \quad v_p\big(\Delta_{uh}^k C_{N,j}(n)\big) \ge \min(k, mn) - v_p(j!).}$$

The manuscript's odd-prime, positive-u theorem is a specialization. The formal statement also includes zero row, zero order, zero multiplier, and the $p = 2, m = 1$ subcase. This does not assert a different or broader external dyadic conjecture.

Principal declaration. `KomorebiPaperIX.Theorem75.global_finite_difference` states the integrality and both precision bounds together, for the original coefficient functions. Its hypotheses are primality, $m > 0$, $m \mid p-1$ and $j < mp$, not an assumed flatness or weightedness certificate.

1. Stability of the weighted differential ring

The construction uses the actual weighted subring

$$\mathcal{W}_p = \left\{ F(T) = \sum_{d \ge 0} a_d T^d : \; p^{\lfloor d/p \rfloor} a_d \in \mathbb{Z}_p \text{ for every } d \right\}.$$

The coefficient condition agrees with the singular-Amice construction. The formal source checks the complete formal-series statement below.

Put

$$\Theta = (1+T)\frac{d}{dT}, \qquad B_\Theta = \frac{\Theta^{p^2} - \Theta^p}{p}.$$

The coefficient formula

$$[T^d]\Theta F = (d+1)a_{d+1} + d a_d$$

proves $\Theta \mathcal{W}_p \subseteq \mathcal{W}_p$. If the floor weight increases between d and $d+1$, then $p \mid d+1$, which compensates for that increase.

The normalized defect is not assumed to be a derivation. Its proved product rule contains the two middle Leibniz sums:

$$B_\Theta(FG) = (B_\Theta F)G + F(B_\Theta G) + \mathcal{B}_p(F,G).$$

The coefficients of $\mathcal{B}_p$ are the actual integral quotients $\binom{p^2}{a}/p$ and $\binom{p}{a}/p$. Derivative stability and this correction formula show that the elements $F \in \mathcal{W}_p$ satisfying $B_\Theta F \in \mathcal{W}_p$ are closed under the finite ring operations.

The scalar input is proved for every natural b, including nonunits:

$$\boxed{p^2 \mid b^{p^2} - b^p \quad \text{in } \mathbb{Z}.}$$

Because $\Theta(1+T)^b = b(1+T)^b$, the binomial expansion of $T^p = ((1+T)-1)^p$ then proves stability of the divided generator T^p/p. For $d = pq + r$, $0 \le r < p$, every weighted monomial has the exact factorization

$$a_d T^d = (p^q a_d)\left(\frac{T^p}{p}\right)^q T^r.$$

The scalar $p^q a_d$ is integral by the actual weight condition. Thus all weighted monomials, and all finite weighted polynomials, satisfy the defect condition.

Finally, $[T^d]B_\Theta F$ depends only on coefficients through $d + p^2$. Replacing F by this finite prefix proves the result for the entire formal series, without an analytic convergence assumption:

$$\boxed{B_\Theta \mathcal{W}_p \subseteq \mathcal{W}_p, \qquad B_\Theta^s \mathcal{W}_p \subseteq \mathcal{W}_p \ (s \ge 0).}$$

Modules. `WeightedAmiceRing`, `FrobeniusSquare`, `ThetaWeighted`.

2. Actual substitution and singular higher differences

Let

$$\mathcal{E}(F)(t) = F(e^t - 1), \qquad D = \frac{d}{dt}, \qquad B_D = \frac{D^{p^2} - D^p}{p}.$$

All substitutions use Mathlib's actual formal exponential, logarithm and substitution maps. The chain rule gives

$$D\mathcal{E}(F) = \mathcal{E}(\Theta F), \qquad B_D^s \mathcal{E}(F) = \mathcal{E}(B_\Theta^s F).$$

The implementation also proves the inverse-substitution identity

$$\mathcal{E}\big(f(\log(1+T))\big) = f(t).$$

The relevant integral subring is the *Hurwitz* subring

$$\mathcal{H}(\mathbb{Z}_p) = \{f \in \mathbb{Q}_p[[t]] : \ n![t^n]f \in \mathbb{Z}_p \text{ for every } n\}.$$

It is not coefficientwise integrality of ordinary power-series coefficients. The precise connection is

$$n![t^n]\mathcal{E}(F) = [T^0]\Theta^n F.$$

Since every iterate of Θ preserves $\mathcal{W}_p$, the right side is integral. Therefore $\mathcal{E}(\mathcal{W}_p) \subseteq \mathcal{H}(\mathbb{Z}_p)$. Applying the same statement to every $B^s_\Theta F$ proves

$$\boxed{f(\log(1+T)) \in \mathcal{W}_p \quad \Longrightarrow \quad B^s_D f \in \mathcal{H}(\mathbb{Z}_p) \text{ for every } s.}$$

This is the proved transfer that was missing in the earlier attempt. No weighted Mahler pairing is assumed. The formal differential route supplies an alternative bridge.

Application to the actual singular ratios

The singular-ratio construction independently gives

$$H_{N,c}(t) = \sum_{n\geq 0} \frac{t^{Nn+c}}{(Nn+c)!}, \quad A_c(t) = t^{-c}H_{N,c}(t), \quad R_c = \frac{A_{c-1}}{A_c}.$$

The notation $t^{-c}H_{N,c}$ means removing its proved initial zero coefficients. For each $c = ap$, $1 \leq a < m$, that source proves $R_{ap}(\log(1+T)) \in \mathcal{W}_p$. The new transfer consequently proves flatness of the *same* rational ratio after scalar extension to $\mathbb{Q}_p$.

The actual ratio is also proved to be an expansion in t^N, so its coefficients vanish outside multiples of N. Constructed $\mathbb{Z}_p$ lifts and the established coefficient criterion now give, for its literal Hurwitz coefficients $r_a(n)$,

$$\boxed{\Delta^k_{uh} r_a(n) \in p^{\min(k,mn)}\mathbb{Z}_p.}$$

The separate rational precision theorem is obtained through the coefficient-lift equality. Divisibility in the field $\mathbb{Q}_p$ is never substituted for this assertion.

Modules. `WeightedDworkTransfer`, `SeriesDifferenceBridge`, `RatioSeriesSupport`.

3. Nonsingular propagation without an assumed limit

For consecutive original sections, the already defined ratios satisfy

$$R_c H_{N,c} = tH_{N,c-1}, \qquad H'_{N,c} = H_{N,c-1}.$$

Differentiating the first relation, using the relation for R_{c-1}, and cancelling a section whose leading coefficient is proved nonzero gives the actual Riccati equation

$$\boxed{tR_c' = R_c(1 + R_{c-1} - R_c), \qquad 2 \le c < N.}$$

It is not an equation imposed on a replacement ratio. Write

$$q = R_{c-1} - (c-1), \qquad y = R_c - c.$$

Both have zero constant coefficient. With $\Lambda_c = tD + c$, the equation becomes

$$\boxed{\Lambda_c y = cq + yq - y^2.}$$

When $p \nmid c$, define the actual inverse coefficientwise:

$$[t^d]\Lambda_c^{-1} f = \frac{[t^d]f}{d+c}.$$

On p-supported degrees, $d + c$ is a genuine p-adic unit. The proof establishes Hurwitz integrality of this solution, its support, both inverse identities, and preservation of full flatness using the earlier all-order Euler commutator theorem. The singular pivots $c = ap$ are never declared to be units.

Now define explicit iterations

$$y_0 = 0, \qquad y_{r+1} = \Lambda_c^{-1}(cq + y_r q - y_r^2).$$

If q is flat and p-supported, every iterate has those properties. The crucial link to the actual ratio is an exact finite-prefix theorem:

$$\boxed{[t^d]y_r = [t^d]y \qquad (d \le r).}$$

Indeed,

$$(cq + zq - z^2) - (cq + yq - y^2) = (z - y)(q - z - y).$$

The second factor has zero constant term. Multiplication therefore raises the established agreement prefix by one. Coefficientwise division by $d + c$ preserves that prefix.

For fixed s, d, the coefficient $d![t^d]B_D^s y$ depends only on the coefficients of y through $d + p^2 s$. Choosing the matching finite iterate proves its integrality. This establishes flatness of the actual y, and hence of R_c, without postulating flatness of the solution or invoking an unproved analytic fixed-point theorem.

Modules. `EulerSeriesInverse`, `RiccatiFlatPropagation`, `RatioRiccati`.

4. All-residue assembly and original coefficients

The standard-window source and inverse results supply R_1 and $F_{N,0}$. Induction over $1 \le c < N$ now has two proved cases. At $p \mid c$, the singular weighted estimate and the new substitution theorem give flatness. At $p \nmid c$, the preceding Riccati propagation applies. Thus every actual ratio R_c is flat.

Let $K_j(t)$ be the normalized section kernel with constant coefficient one. The constructed unnormalized Euler series is

$$F_{N,j}(t) = j!\, K_j(t)^{-1}.$$

The source/inverse identities and the factorial successor identity prove

$$F_{N,j+1} = F_{N,j} R_{j+1}, \qquad F_{N,j} = F_{N,0} \prod_{c=1}^{j} R_c.$$

The product formula is not an assembly hypothesis. Proved flatness of all factors and the original product-closure theorem establish flatness of the full family.

Coefficient extraction identifies, literally,

$$(Nn)! [t^{Nn}] F_{N,j} = j!\, C_{N,j}(n).$$

The support outside multiples of N is proved separately. The constructed integral lift therefore represents the original rational coefficient function. The existing saturation criterion and the proved step-multiple argument give the ideal bound at every order, row and multiplier. Multiplication by $j!$ commutes with finite differences, giving precisely the displayed normalization loss.

Exact examples outside the standard window

For $(p, m, j) = (3, 2, 3)$, the source derives

$$C_{6,3}(1) = -\frac{1}{84}, \quad C_{6,3}(2) = \frac{703}{5460}, \quad C_{6,3}(3) = -\frac{223199}{7980}.$$

Consequently,

$$\Delta_1^2\big(3! C_{6,3}\big)(1) = -\frac{1464768}{8645}, \qquad v_3\left(-\frac{1464768}{8645}\right) = 2.$$

This attains $\min(2, 2 \cdot 1) = 2$. At the regular address $j = 4$ beyond the singular boundary, the source likewise proves

$$\Delta_1^2\big(4! C_{6,4}\big)(1) = -\frac{102745512}{2377375},$$

and applies the universal exponent-two bound to this actual coefficient function.

The earlier no-loss counterexample is retained: $v_3(C_{6,3}(2) - C_{6,3}(1)) = 0$. Proving the corrected theorem does not make that false normalized claim true.

Modules. `AllRatiosDwork`, `AllResidueEuler`, `Theorem75`, `AllResidueExamples`.

5. Verification record and claim boundary

Each local module is rebuilt in a fresh output directory, with warnings treated as errors. A live `#printaxioms` audit checks every registered declaration, permitting only `propext`, `Classical.choice` and `Quot.sound`, or subsets.

E.11 Nishibuchi conjecture completion

1. The complete external statement

For $N > 0$ and $0 \le j < N$, use the original unnormalized convention

$$\sum_{d\ge 0} \mathcal{E}_d^{(N,j)} \frac{t^d}{d!} = \left(\sum_{n\ge 0} \frac{t^{Nn}}{(Nn+j)!} \right)^{-1}.$$

The existing packet convention satisfies $\mathcal{E}_{Nn}^{(N,j)} = j! C_{N,j}(n)$. The formalization defines the degree-indexed coefficients through the actual factorial-scaled series coefficients, proves their packet identification, and checks the cleared generating identity with the original exponential section.

Theorem E.1. *Let p be prime, $m > 0$, and assume $m \mid p-1$ or $m = 2$. Put $N = mp$ and $q = \operatorname{lcm}(2, p-1)$. Every $\mathcal{E}_{Nn}^{(N,j)}$ is p-adically integral. For every $r \ge 1$,*

$$\boxed{\mathcal{E}_{Nn+qp^r}^{(N,j)} \equiv \mathcal{E}_{Nn}^{(N,j)} \pmod{p^r} \qquad (0 \le j < N,\ n \ge r).}$$

In particular, the positive sufficient threshold $n_0 = r$ works uniformly in all allowed parameters.

This is the parameter range and displacement of Nishibuchi's Conjecture 3.9 in arXiv:2605.10677v2. The explicit threshold also establishes the suggested bound $n_0 \le r$. The original paper already proves the $p = 2, m = 2, j = 0$ period as a special case, with all starting rows. This extension does not claim that special case as a new discovery.

Principal declaration

`KomorebiPaperIX.NishibuchiCompletion.conjecture_3_9`

The theorem type includes only the stated arithmetic hypotheses. There is no assumed congruence, weighted estimate, or flatness certificate. Precision is the zero-safe predicate $x = 0$ or $v_p(x) \ge r$. Its connection to genuine ideal divisibility in $\mathbb{Z}_p$ is used in the proof.

Claim boundary. This establishes a sufficient threshold and a period, not the earliest starting index, the least period, or a pointwise optimal valuation formula. The correspondence with the externally written statement is a mathematical review of definitions and quantifiers, not an automated semantic-equivalence theorem. The two native conjectures in Paper IX remain unchanged and unproved.

2. The missing dyadic branch

For odd primes, the extra option $m = 2$ already divides $p-1$. Therefore the only allowed family outside the preceding all-residue theorem is $p = 2, m = 2$, with $N = 4$.

The new proof establishes a higher-difference estimate for every one of its four addresses:

$$\boxed{v_2\Big(\Delta_u^k C_{4,j}(n)\Big) \ge \min(k, n) \qquad (0 \le j < 4).}$$

All natural u, k, n are allowed, including zero step, zero order and zero differences. The same bound holds for $j!C_{4,j}(n)$. Both a genuine $\mathbb{Z}_2$ divisibility theorem and a valuation theorem for the original rational sequence are included.

An explicit source instead of an assumed regularity condition

Let $g_j(n) = \binom{4n+j}{4n}^{-1}$. Its four formulas are

$$\begin{aligned} g_0(n) &= 1, \\ g_1(n) &= (4n+1)^{-1}, \\ g_2(n) &= ((4n+1)(2n+1))^{-1}, \\ g_3(n) &= 3((4n+1)(2n+1)(4n+3))^{-1}. \end{aligned}$$

Every denominator is odd. The code constructs the actual unit inverses in $\mathbb{Z}_2$ and proves these identities against the original binomial coefficients, including $n = 0$.

Define a Kummer sequence over a commutative ring by

$$\mathcal{P}_a(f) \quad \Longleftrightarrow \quad a^k \mid \Delta_1^k f(n) \text{ for all } k, n.$$

The exact discrete product rule

$$\Delta_1^s(fg)(n) = \sum_{i=0}^{s} \binom{s}{i} \Delta_1^i f(n)\, \Delta_1^{s-i} g(n+i)$$

is proved by induction. It proves closure under products. Applied to $fg = 1$, the same formula isolates $\Delta_1^s g(n) f(n+s)$. Induction and multiplication by $g(n+s)$ prove closure under actual pointwise inverses.

An affine sequence whose slope is divisible by a satisfies $\mathcal{P}_a$. Consequently the four displayed source sequences satisfy $\mathcal{P}_2$. No numerical interpolation or finite set of samples is used in that deduction.

Source modules: `KummerSequences`, `DyadicFourKernel`.

3. The dyadic differential operator and reciprocity

The operator required here is

$$\boxed{B_4 = \frac{D^8 - D^4}{2}, \qquad D = \frac{d}{dt}.}$$

It is not the preceding $p = 2$ specialization $(D^4 - D^2)/2$. It is also not an ordinary derivation. The new algebra module proves the actual product formula, including the middle derivative sums whose coefficients are $\binom{8}{i}/2$ and $\binom{4}{i}/2$.

Write $\mathcal{H}_{\mathrm{int}}$ for the subring of $\mathbb{Q}_2[[t]]$ whose factorial-scaled coefficients belong to $\mathbb{Z}_2$. Flatness means $B_4^s F \in \mathcal{H}_{\mathrm{int}}$ for every s. The proof of multiplicative and reciprocal closure is induction on s, using the full product correction. It separately proves that the actual reciprocal has integral Hurwitz coefficients when $F(0) = 1$.

Pack g_j into degrees divisible by four and form its actual EGF. The formal coefficient identity is

$$G_j(t) = \sum_{n\ge 0} g_j(n)\frac{t^{4n}}{(4n)!} = j!\sum_{n\ge 0}\frac{t^{4n}}{(4n+j)!}.$$

Its inverse is therefore the original normalized packet EGF. The source Kummer property gives flatness of G_j. The proved reciprocal closure gives flatness of G_j^{-1}.

For a packed coefficient sequence e, the exact extraction formula is

$$\left(U^8 - U^4\right)^k \operatorname{pack}_4(e)(4n-4k) = \Delta_1^k e(n), \qquad k \le n.$$

Here U is the coefficient shift. The nonnegative extraction index is why the first estimate covers $k \le n$. The existing saturation lemma extends it to all k with exponent $\min(k, n)$, and the step-multiple lemma extends step one to every natural u.

Identity with the original rational coefficients

The integral lift is constructed from the decoded coefficients of the actual reciprocal. The code proves

$$\operatorname{coe}(e_j(n)) = C_{4,j}(n) \quad \text{in } \mathbb{Q}_2,$$

and proves that the coefficient map commutes with every difference stencil. Multiplying by $j!$ yields the unnormalized family. The valuation result is not divisibility in a field.

Source modules: `CubicDworkAlgebra`, `CubicDworkClosure`; `DyadicFourDwork` and `DyadicFourCongruences`.

4. From differences to the exact external period

Let f take values in a commutative ring and suppose

$$p^{\min(k,r)} \mid \Delta_h^k f(n) \qquad \text{for every } k.$$

The proved finite Newton expansion is

$$f(n + p^{r-1}h) - f(n) = \sum_{k=1}^{p^{r-1}} \binom{p^{r-1}}{k} \Delta_h^k f(n).$$

For $k \ge r$, the difference already supplies p^r. For $1 \le k < r$, the code proves the integer divisibility

$$p^r \mid \binom{p^{r-1}}{k} p^k.$$

It follows from $k\binom{p^{r-1}}{k} = p^{r-1}\binom{p^{r-1}-1}{k-1}$ and $v_p(k) < k$. Thus every summand is divisible by p^r, including the endpoint $r = 1$.

Divisor branch

For $m \mid p-1$, the preceding all-residue theorem provides the needed differences as soon as $r \le mn$. With $q = \operatorname{lcm}(2, p-1)$, the required packet step q/m is proved to be an integer multiple of $(p-1)/m$. The degree conversion is checked exactly:

$$mp\left(n + p^{r-1}\frac{q}{m}\right) = mpn + qp^r.$$

This retains the stronger sufficient condition $r \le mn$ on the divisor branch. The uniform choice $n \ge r$ implies it for every positive m.

Exceptional branch

For $p = 2, m = 2$, $q = 2$ and the packet displacement is 2^{r-1}. The new dyadic bound supplies the hypothesis when $n \ge r$, and

$$4\big(n + 2^{r-1}\big) = 4n + 2^{r+1}.$$

The $p = 2, m = 1$ branch is also checked using $q = 2$, not an incorrectly substituted $q = p - 1 = 1$.

An exact arithmetic check, not an optimality claim

The independent rational recurrence gives $C_{4,1}(1) = -1/5$ and $C_{4,1}(2) = 121/45$. Their difference is $26/9$, of 2-adic valuation one. This agrees with the new bound at $n = k = u = 1$. The source also contains universal instantiations of the degree-indexed theorem at all four dyadic addresses and at an odd singular address.

Source modules: `PeriodFromDifferences`, `NishibuchiCompletion`, `ConjectureExamples`.

5. Verification, provenance and boundary

Reproduction

```
bash Run-Portable.sh /path/to/Komorebi_Portable_Lean_4.34.0-rc2
```

The external Conjecture 3.9 is distinct from Paper IX's native Conjectures 13.2 and 13.3. Those two remain unproved. The present result does not assert least periods, earliest thresholds, or an optimal exponent for every individual parameter tuple. It makes no historical-priority claim relative to other unpublished work.

F Worked arithmetic and lifting atlas

These examples connect the coefficient calculus with the correction machinery. They instantiate the statements in the main text rather than add new universal claims. Each displayed rational value, residue, and finite reconstruction is checked by the accompanying exact script.

F.1 Compute the reciprocal before estimating it

For width N and address j, the normalized source and its reciprocal are

$$G_{N,j}(t) = j! \sum_{n\ge 0} \frac{t^{Nn}}{(Nn+j)!}, \qquad G_{N,j}(t)^{-1} = \sum_{n\ge 0} C_{N,j}(n) \frac{t^{Nn}}{(Nn)!}.$$

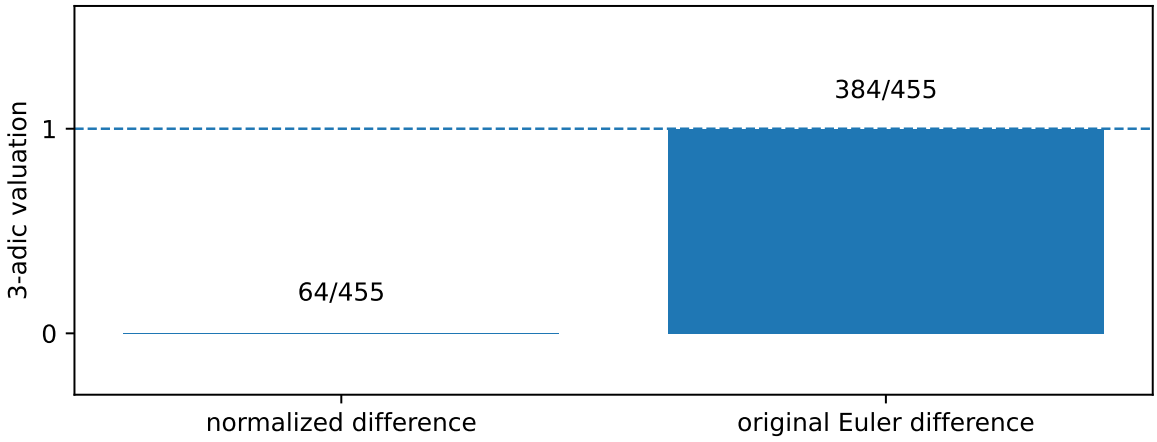
Multiplying the two series and clearing the factorials gives an exact triangular recurrence:

$$C_{N,j}(0) = 1, \qquad C_{N,j}(n) = -\frac{\sum_{r=0}^{n-1} \binom{Nn+j}{Nr} C_{N,j}(r)}{\binom{Nn+j}{Nn}}.$$

address j	C(0)	C(1)	C(2)
0	1	-1	69
1	1	-1/5	121/45
2	1	-1/15	13/45
3	1	-1/35	59/1155

The table is for $N = 4$. The first two address-zero rows illustrate the computation without any valuation estimate:

$$C_{4,0}(1) = -1, \qquad C_{4,0}(2) = -\left(1 + \binom{8}{4}(-1)\right) = 69.$$



At address one, the same recurrence yields $C_{4,1}(1) = -1/5$ and $C_{4,1}(2) = 121/45$. These are exact rational coefficients, not rounded approximations. The second implementation in the supplied script inverts the ordinary power series first, then multiplies by $(Nn)!$. Agreement between the two constructions checks the factorial placement.

F.2 The normalization loss is a real boundary

The original Euler coefficient is $E_{Nn}^{(N,j)} = j!C_{N,j}(n)$. Multiplication by $j!$ changes the available p-adic precision. That change cannot be discarded outside the unit-factorial window.

Take $p = 3$, $N = 6$, $j = 3$, and compare rows one and two. Exact inversion gives

$$C_{6,3}(1) = -\frac{1}{84}, \quad C_{6,3}(2) = \frac{703}{5460}, \quad C_{6,3}(2) - C_{6,3}(1) = \frac{64}{455}.$$

Neither 64 nor 455 is divisible by three, so the normalized difference has valuation zero. The original coefficient difference is $3! \cdot 64/455 = 384/455$, of valuation one.

This is the counterexample behind the corrected factorial-loss statement. A bound for the original Euler normalization must lose $v_p(j!)$ when translated to $C_{N,j}$. For $0 \leq j < p$, that loss is zero. The distinction concerns which sequence the theorem measures, not a numerical weakness of the calculation.

F.3 Odd primes require the sign twist

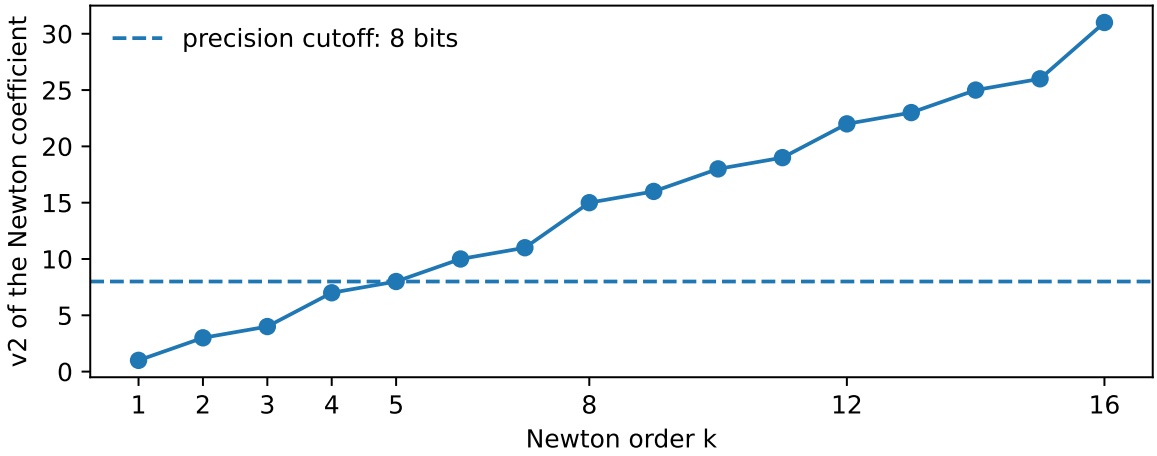
The prime-power transfer controls a sign-twisted reciprocal sequence at odd primes. It must not be read as an ordinary-difference theorem for the untwisted coefficients.

At $N = p = 3$ and $j = 0$, put $A(n) = (-1)^n C_{3,0}(n)$. The first three rows are

row n	C at width 3, address 0	(-1)^n C(n)
0	1	1
1	-1	1
2	19	19

The ordinary first difference at row zero is $-1 - 1 = -2$. It is a 3-adic unit, so an asserted lower bound of one for that difference would be false. The twisted first difference is zero, whose mathematical valuation is $+\infty$. At the next row, the twisted difference is $19 - 1 = 18$, of valuation two.

Equivalently, the untwisted sequence is acted on by $T_H = S^H - (-1)^H$, where S advances one row. At odd step one this is $S + 1$, not $S - 1$. The zero in the example is handled by a zero-safe divisibility statement rather than a finite valuation equality. The explicit sign and the zero convention are both part of the theorem's interface.



F.4 Newton coordinates turn precision into a finite computation

Let $b_k = \Delta_1^k C_{4,0}(0)$. The first coefficients obtained from the difference triangle are

$$(b_0, b_1, b_2, b_3, b_4) = (1, -2, 72, -33872, 60511872).$$

The exact Newton identity recovers each nonnegative integer row:

$$C_{4,0}(n) = \sum_{k=0}^{n} b_k \binom{n}{k}.$$

For this address the proved law is $v_2(b_k) = 2k - s_2(k)$ for $k \geq 1$. Every $k \geq 5$ therefore has $v_2(b_k) \geq 8$. Since $\binom{n}{k}$ is integral, those terms vanish modulo 256. Thus, for every $n \geq 0$,

$$C_{4,0}(n) \equiv 1 + 254\binom{n}{1} + 72\binom{n}{2} + 176\binom{n}{3} + 128\binom{n}{4} \pmod{256}.$$

The uniform truncation follows from the coefficient theorem. The script separately checks the exact Newton reconstruction and this reduction for rows 0 through 32. Those finite checks validate the worked arithmetic without replacing the theorem.

F.5 A compatible root is built one digit at a time

Take $F(x) = x^2 - 7$ over the 3-adic integers and start with $x_1 = 1$ modulo three. If $F(x_L) = 3^L r_L$, the next representative has the form $x_{L+1} = x_L + 3^L t_L$. Its correcting digit satisfies

$$r_L + 2x_L t_L \equiv 0 \pmod 3.$$

L	3^L	current x	next digit	next x
1	3	1	1	4
2	9	4	1	13
3	27	13	0	13
4	81	13	2	175
5	243	175	0	175

For example, $F(1)/3 = -2$ and $2x_1 = 2$, so the next digit is one and $x_2 = 4$. Then $F(4)/9 = 1$, again giving digit one and $x_3 = 13$. At the next stage the residual is divisible by three, so digit zero is correct. A zero digit is not a stalled construction.

Every center remains congruent to one modulo three. Hence $2x_L$ stays a unit, and the correction equation has a unique digit at every stage. The representatives are compatible and their increments are divisible by 3^L. Completeness gives a limit, and continuity of the polynomial gives a root of F. The finite table exhibits the construction. The unit derivative is what supports indefinite continuation.

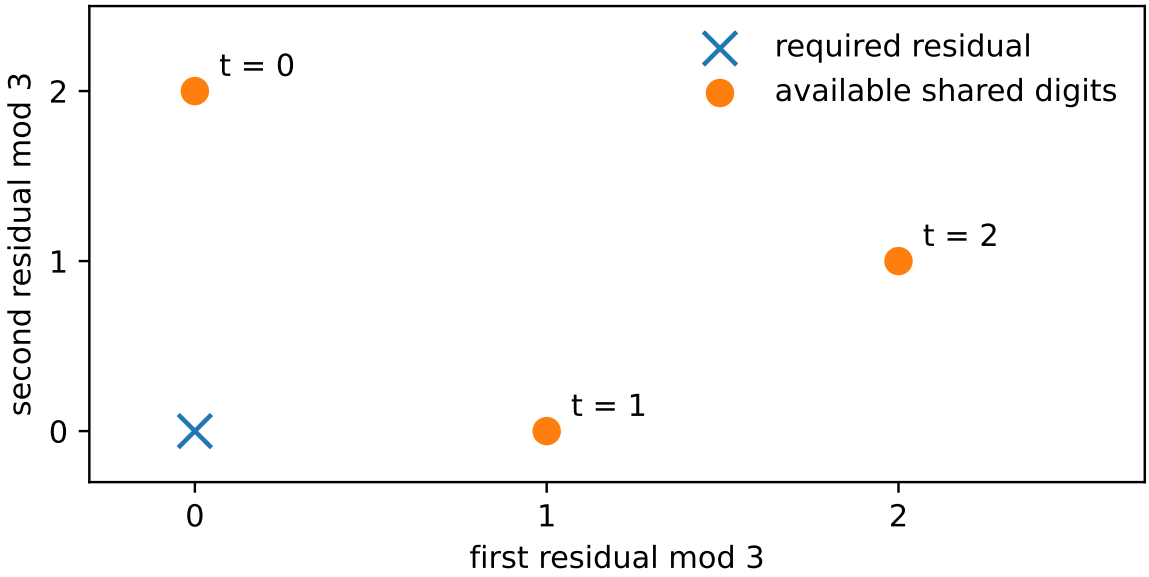
F.6 A singular residual can stop a lift

Now take $F(x) = x^2 - 3$ at the residue $x = 0$ modulo three. The residual is $r = F(0)/3 = -1$ and the Jacobian is zero modulo three. The next-digit equation would require

$$-1 + 0 \cdot t \equiv 0 \pmod 3,$$

which has no solution.

digit t	candidate y	y^2 - 3	residue mod 9
0	0	-3	6
1	3	6	6
2	6	33	6



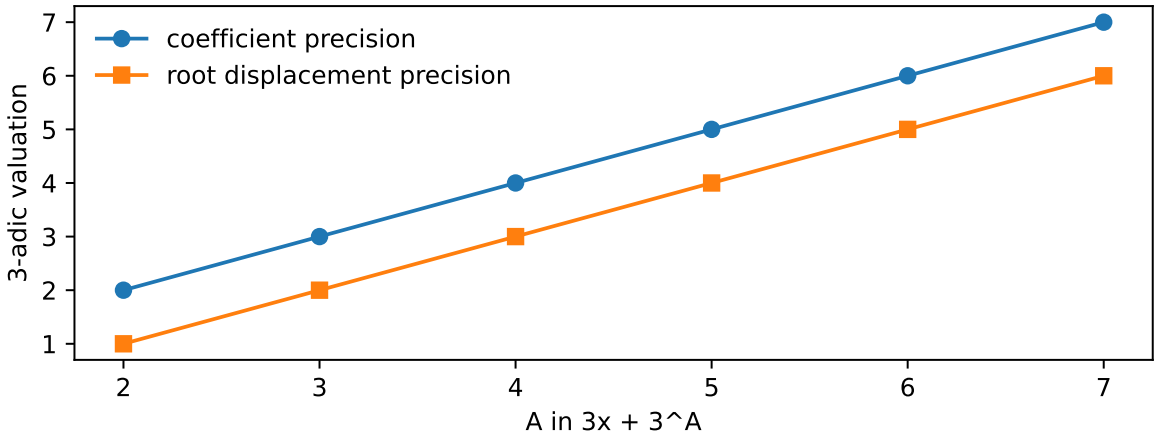
The three representatives of the old root class modulo nine all leave residual six modulo nine. Thus the root class exists at precision three but does not lift to precision nine. This is an exact obstruction, not failure of an iterative search.

A singular Jacobian alone does not imply failure. For $F(x) = x^2$ at the same center, the residual is zero and all three candidate digits lift to roots modulo nine. The obstruction is the residual class in the cokernel of the actual Jacobian. It is this class, rather than the rank by itself, that decides whether a next lift exists.

F.7 Separate corrections need not be one shared correction

Consider the two-component system $F(x) = (x, x-3)$ at $x = 0$, with $q = 3$ and $L = 1$. Both components vanish modulo three. After writing a candidate as $y = 3t$, its residual vector modulo three is

$$\bar{r} + J\bar{t} = (0,2) + (t,t) = (t, t-1).$$



The first coordinate can be corrected by $t = 0$. The second can be corrected by $t = 1$. No digit corrects both. The available residuals are $(0,2)$, $(1,0)$, and $(2,1)$, none of which is $(0,0)$.

The combined Jacobian maps t to the diagonal vector (t,t). Its image is smaller than the product of its coordinate images. Checking the two projected obstructions independently therefore loses the compatibility condition. The common-correction theorem retains the full residual vector and the shared digit space, which is exactly the information needed to detect this failure.

F.8 A derivative weight can cost one digit of root precision

Compare the linear equations $F(x) = 3x = 0$ and $G_A(x) = 3x + 3^A = 0$, where $A \geq 2$. Their coefficient difference has 3-adic valuation A, but their roots differ by

$$x_A - 0 = -3^{A-1}, \qquad v_3(x_A) = A - 1.$$

The derivative has valuation one. Solving the correction equation divides by three, so one digit of coefficient precision is lost in root displacement. The calculation is exact for every displayed A and also follows immediately from the two linear equations.

This example explains why weighted lifting and deformation estimates track a Jacobian loss rather than silently treating every invertible derivative over $\mathbb{Q}_p$ as a unit over $\mathbb{Z}_p$. A valuation-zero derivative would not incur this particular loss. Nonlinear systems additionally require their stated neighborhood, residual, and right-inverse hypotheses.

The eight examples use exact rational and integer arithmetic. The computation scripts and tested ranges accompany the sources. This atlas adds no Lean endpoint and changes no formal claim in the companion.

Reading scope

This guide explains the indexing, valuation gains, exact periods, and remaining boundaries through exact arithmetic and theorem-derived figures. The main text supplies the proofs. The formal companion supplies the formal source and evidence map.

1 The object: rows, degrees, and normalization

The visual guide accompanies *Euler Congruences: Completion, Factorial Strengthening, and Sharp Dyadic Geometry*. It makes the indexing, precision gains, and boundaries of the results visible. The main text contains the proofs. The separate Lean guide records which statements are already formalized and which belong to the new mathematical extension.

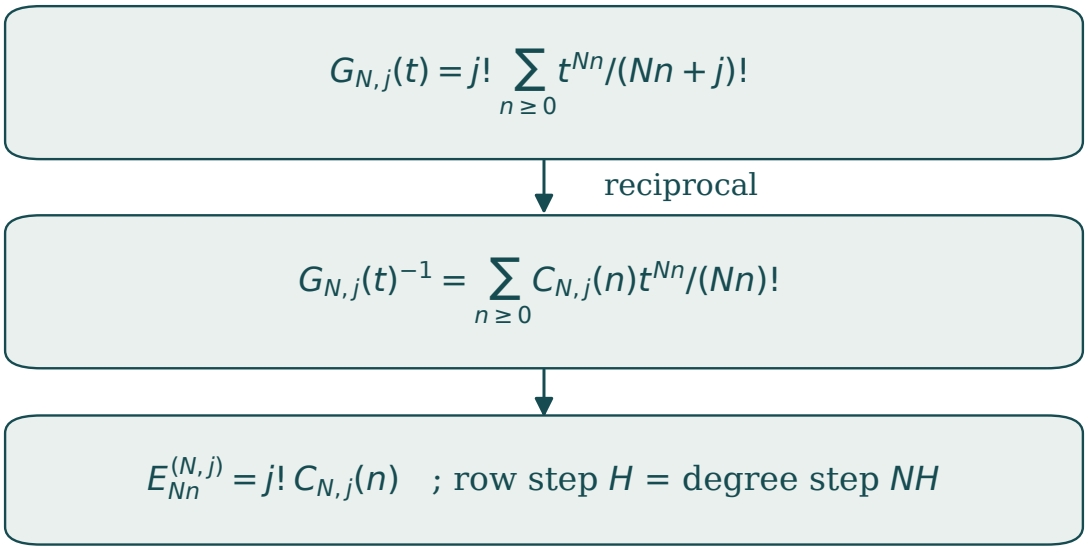


Figure 1. The actual reciprocal series is the source of every coefficient in this guide. The factorial normalization changes valuations as well as the constant term.

There are two coefficient conventions, and they must stay distinct:

$$C_{N,j}(0) = 1, \qquad E_0^{(N,j)} = j!, \qquad v_2(E_{Nn}^{(N,j)}) = v_2(C_{N,j}(n)) + v_2(j!).$$

The last equality uses $v_2(0) = +\infty$. Congruences of dyadic rational numbers mean membership in the corresponding ideal of $\mathbb{Z}_2$. A displayed rational denominator is invertible modulo 2^r when it is odd.

Symbol	Meaning	At rank four
n	packed row index	Euler degree $4n$
H	positive row step	Euler degree step $4H$
k	number of differences	order k, independent of n
j	address within a section	$0, 1, 2, 3$

For example, $C_{4,1}(1) = -1/5$ and $C_{4,1}(2) = 121/45$. Their difference is $26/9$, of valuation one. The row difference joins Euler degrees 4 and 8.

2 What the original conjecture asked

Nishibuchi's Conjecture 3.9 concerns a prime p, a positive integer m with $m \mid p-1$ or $m = 2$, and every address $0 \le j < mp$. Put

$$N = mp, \qquad q = \operatorname{lcm}(2, p-1).$$

It asserts p-adic integrality of the actual generalized Euler coefficients and eventual periodicity at every precision:

$$\text{for every } r \ge 1, \quad E^{(mp,j)}_{mpn+qp^r} \equiv E^{(mp,j)}_{mpn} \pmod{p^r} \quad \text{for all sufficiently large } n.$$

The completed theorem gives the explicit sufficient threshold $n \ge r$ in every permitted branch. Its formal capstone is the theorem named `NishibuchiCompletion.conjecture_3_9`. No conjectural flatness premise is supplied to that theorem.

Prime branch	Allowed m	q	Row step for the original shift
$p = 2$	1	2	2^r
$p = 2$	2	2	2^{r-1}
p odd	$m \mid p-1$	$p-1$	$\dfrac{p-1}{m}p^{r-1}$

For odd primes, $m = 2$ is already in the divisor branch. The conversion is exact:

$$N\left(\frac{q}{m}p^{r-1}\right) = qp^r.$$

At $p = 2, m = 2$, the original conjectured Euler-degree shift 2^{r+1} is the row step 2^{r-1} for the rank-four sequence.

The source already contains special cases. In particular, Nishibuchi's Proposition 3.10 treats the rank-four address-zero dyadic period from row zero and an eventual cubic case. The completion covers the full quantified conjecture. The new dyadic work then removes starting-row restrictions from higher differences and determines substantially more precise laws.

The conjecture is cited in the source list at the back. The statement uses its coefficient normalization and actual Euler degrees.

3 Removing the starting-row threshold

At rank four the earlier completed estimate was $v_2(\Delta_H^k C_j(n)) \geq \min(k, n)$. The strengthened theorem reaches every starting row, including $n = 0$, and every order, including $k > n$.

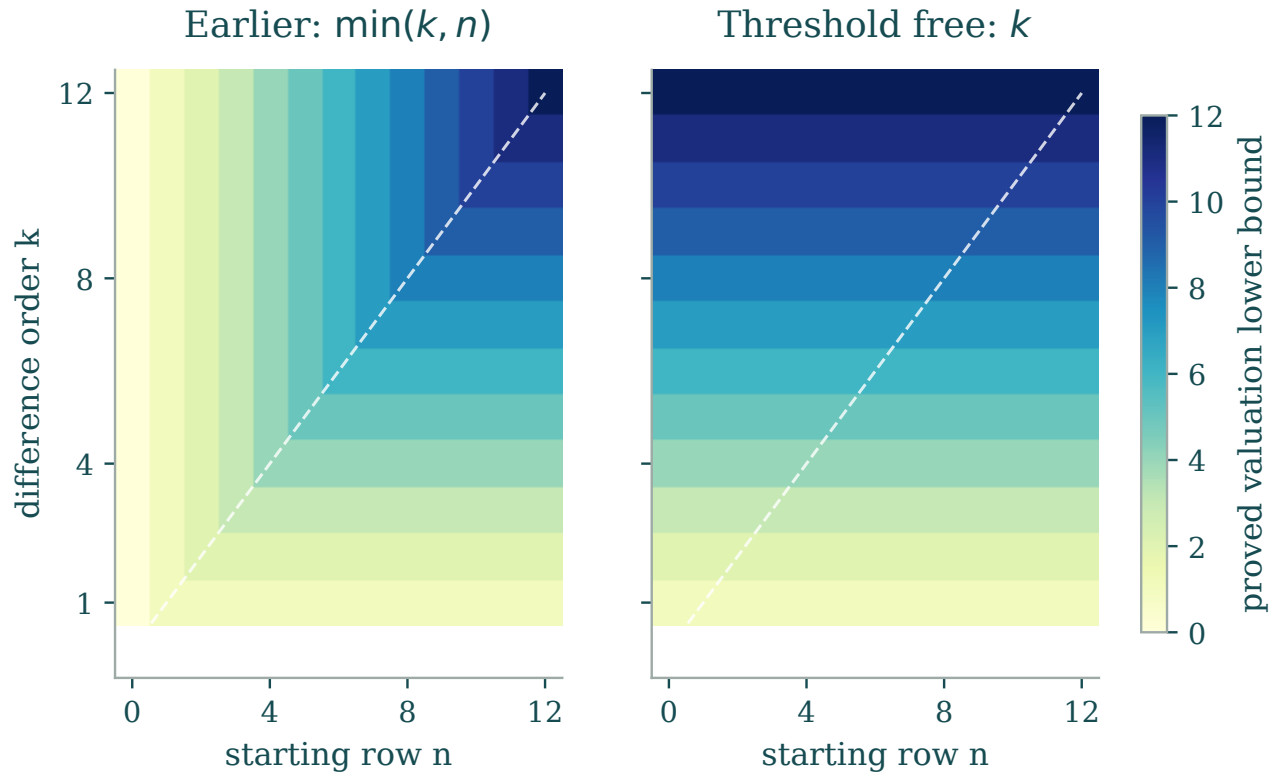

Figure 2. Unit-step lower bounds on a finite display window. Each colored cell is obtained from a proved formula, rather than from sampled coefficients. The dashed line indicates $k = n$.

For *every* dyadic section size $N = 2^a$, $a \geq 0$, every permitted address, and all positive steps,

$$v_2\big(\Delta_{H_1} \cdots \Delta_{H_k} C_{N,j}(n)\big) \geq k + \sum_{\nu=1}^{k} v_2(H_\nu), \qquad n \geq 0.$$

The corresponding statement for $E_{Nn}^{(N,j)}$ adds $v_2(j!)$.

The proof acts on the full factorial-scaled power series before it extracts a packed row. This avoids the old extraction constraint $k \leq n$. Reciprocal induction controls the unique term with the highest inverse order in the commuting product expansion. All other terms are covered by the preceding induction stages.

The figure displays the gain at unit step. An even step contributes additional precision, and the theorem permits different steps in the same difference.

4 Each step contributes its own precision

Write $Sf(n) = f(n+1)$ and $\Delta_H = S^H - 1$. Mixed differences commute. Their exact finite expression is

$$\Delta_{H_1} \cdots \Delta_{H_k} f(n) = \sum_{A \subseteq \{1,\dots,k\}} (-1)^{k-|A|} f\left(n + \sum_{i \in A} H_i\right).$$

Repeated subset offsets are combined with their signed multiplicities.

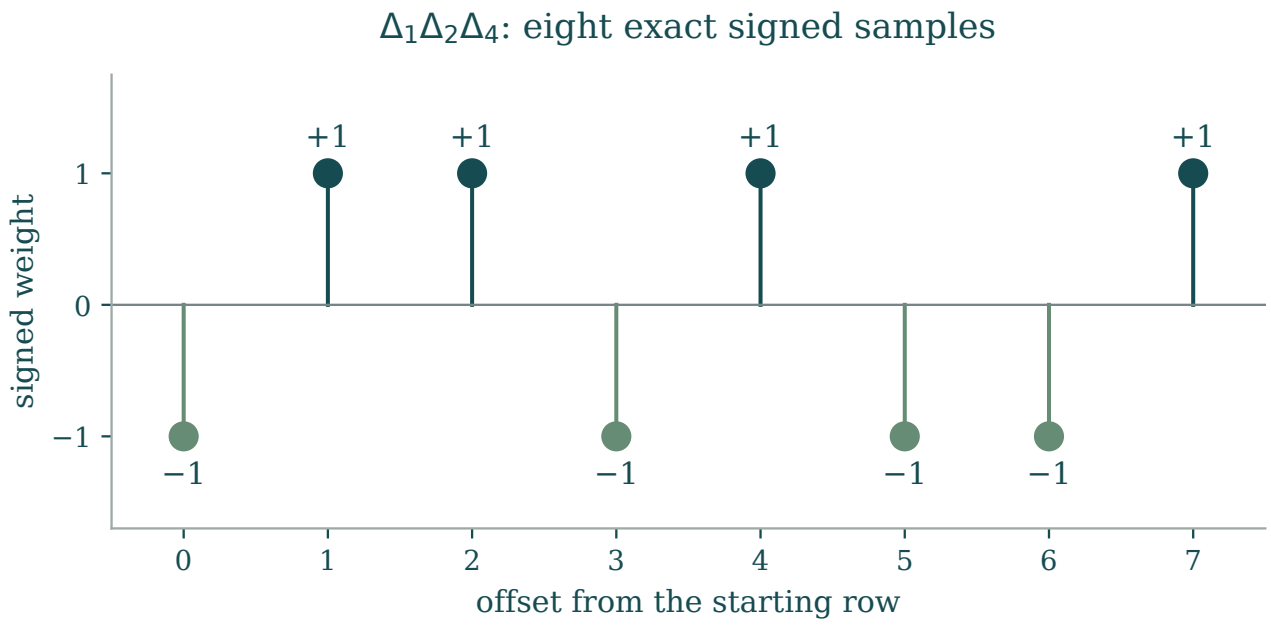

Figure 3. For steps $(1, 2, 4)$ all eight offsets are distinct. This is an exact signed stencil, rather than an approximate derivative.

For this stencil, the general dyadic bound is

$$3 + v_2(1) + v_2(2) + v_2(4) = 6.$$

At rank four the factorial theorem improves it to seven for addresses zero and one. Exact rational evaluation gives $v_2(\Delta_1\Delta_2\Delta_4 C_0(0)) = 7$. The order is odd, so the mixed-step equality criterion also proves this valuation at *every* starting row.

There is a prime-power extension. For $N = p^a$, $a \geq 1$, the sign-corrected operator is

$$T_H = S^H - (-1)^H, \qquad v_p\Big(T_{H_1} \cdots T_{H_k} E^{(N,j)}(n)\Big) \geq v_p(j!) + \sum_{i=1}^{k} \big(1 + v_p(H_i)\big).$$

Here $E^{(N,j)}(n) = E^{(N,j)}_{Nn}$. For an odd prime, an ordinary first difference need not have positive valuation: at address zero its first two normalized values are 1 and -1, with difference -2. The sign correction is therefore essential to this prime-power theorem.

5 The final rank-four congruence

For $n \ge 0$, $k \ge 1$, and $H \ge 1$, the actual Euler coefficients satisfy

$$\sum_{i=0}^{k} (-1)^{k-i} \binom{k}{i} E^{(4,j)}_{4(n+iH)} \equiv 0 \pmod{2^{\,v_2(k!)+k v_2(H)+A_j(k)}},$$

where

$$\begin{aligned} A_0(k) = A_1(k) &= k, \\ A_2(k) &= \max\{k+4,\ 2k+\lfloor k/2 \rfloor + 1\}, \\ A_3(k) &= k+2. \end{aligned}$$

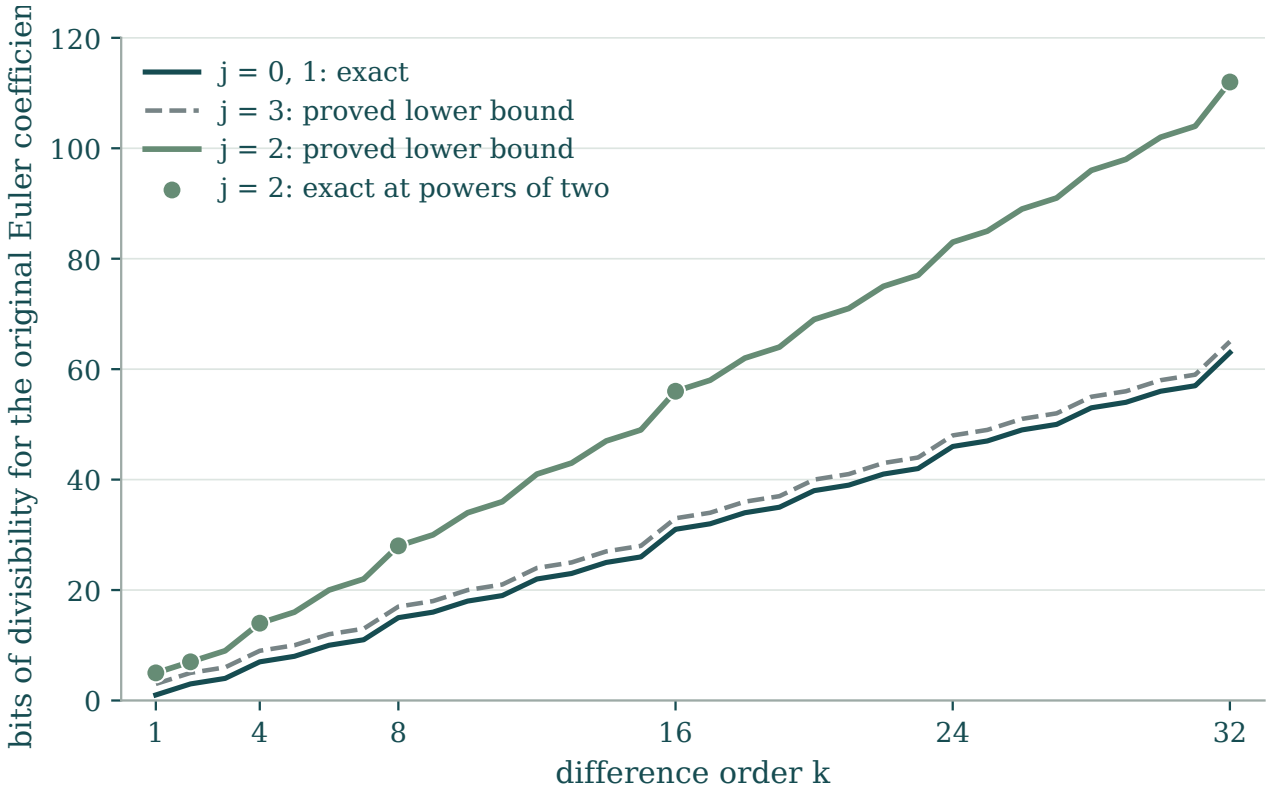

Figure 4. The exponent of the final Euler congruence at unit step. The address zero and one curve is exact at every order. Marked address-two orders are universally exact. The other displayed address-two and address-three values are proved lower bounds.

At a common step with $v_2(H) = s$, add ks to every displayed exponent. Thus a doubling of the step gains one additional bit *per difference*, rather than one bit for the whole expression.

This statement combines two different proved bounds at address two. A lower bound is not automatically an exact valuation: divisibility may be stronger at unmarked orders or at particular starting rows.

6 Why address two has a different slope

The normalized address-two sequence obeys both

$$v_2(\Delta_{H_1}\cdots\Delta_{H_k}C_2(n)) \geq k + v_2(k!) + 3 + \sum_i v_2(H_i),$$
$$v_2(\Delta_{H_1}\cdots\Delta_{H_k}C_2(n)) \geq 2k + v_2(k!) + \lfloor k/2\rfloor + \sum_i v_2(H_i).$$

Their maximum supplies the useful envelope.

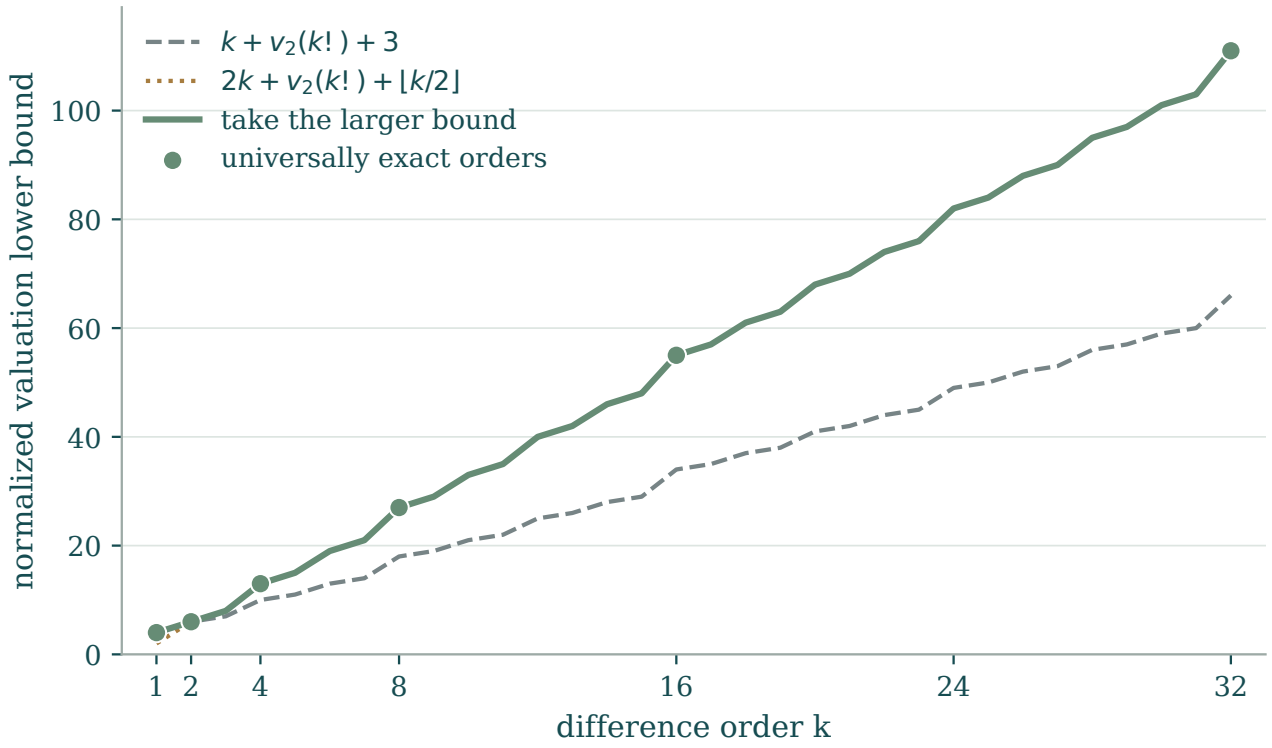

Figure 5. Normalized address-two precision. The paired filtration controls the large-order slope. At order one the constant-surplus bound is stronger.

For every base row and every positive step list, equality is proved when k is a power of two:

$$v_2(\Delta_{H_1}\cdots\Delta_{H_k}C_2(n)) = V_2(k) + \sum_i v_2(H_i),$$

with $V_2(1) = 4$, $V_2(2) = 6$, and $V_2(k) = 2k + v_2(k!) + k/2$ for $k = 2^r \geq 4$. The infinite marked family establishes sharpness at unbounded orders.

For original Euler coefficients add one, since $v_2(2!) = 1$. The extra $\lfloor k/2\rfloor$ comes from a paired divided-power filtration in the Bernoulli transformation. It does not arise by fitting the plotted points.

7 When mixed steps attain the baseline

For addresses $j = 0, 1$, put

$$V = k + v_2(k!) + \sum_i v_2(H_i), \qquad q = \#\{i : H_i \text{ is even}\}.$$

The valuation equals V exactly when k is odd or q is even.

Order parity	Number of even steps	Conclusion
k odd	either parity	exact valuation V
k even	q even	exact valuation V
k even	q odd	valuation at least $V + 1$

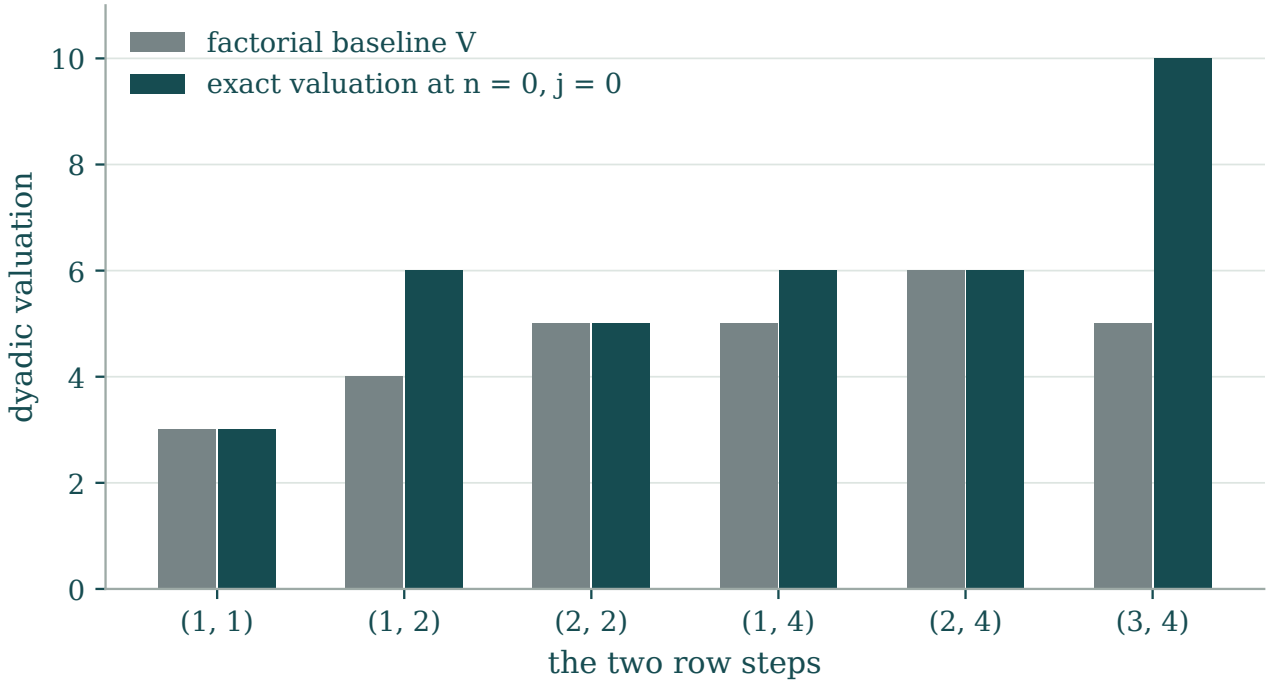

Figure 6. Exact rational examples at order two and base zero. Strict cases show why the factorial baseline cannot always be called an equality for mixed steps. The universal parity criterion is proved separately.

For instance,

$$\Delta_1\Delta_2 C_0(0) = -33728, \qquad v_2(-33728) = 6, \qquad V = 4.$$

Cancellation removes the leading term, and here it removes two bits beyond the baseline. The parity theorem proves strictness in this case. It does not give a complete formula for the further depth.

With a common step, q is either zero or k. Consequently the exceptional parity never occurs, and the homogeneous address-zero/one formula is always exact.

8 First differences determine an exact metric

All four rank-four sequences satisfy the sharp first-difference law

$$v_2(C_j(n+H) - C_j(n)) = v_2(H) + b_j, \qquad b = (1,1,4,2).$$

For the actual Euler coefficients this becomes

$$v_2(E^{(4,j)}_{4(n+H)} - E^{(4,j)}_{4n}) = v_2(H) + B_j, \qquad B = (1,1,5,3).$$

Both laws hold at every starting row and every positive integer step.

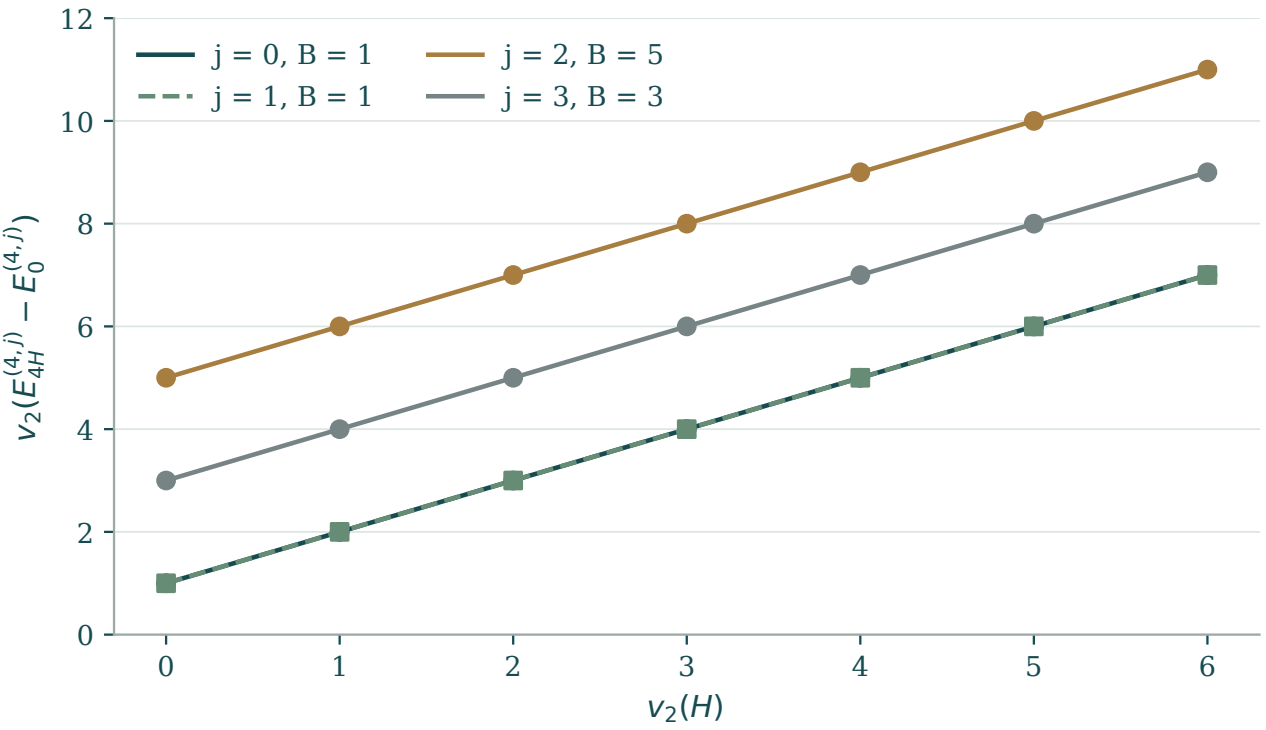

Figure 7. The proved Euler metric laws, with exact modular sample points at base zero and steps $H = 2^s$. Addresses zero and one have the same scale. Their circle and square marks overlap.

In dyadic distance, $|x|_2 = 2^{-v_2(x)}$. After continuous interpolation to $\mathbb{Z}_2$, the law reads

$$|E^{(4,j)}(x) - E^{(4,j)}(y)|_2 = 2^{-B_j}|x-y|_2.$$

It says exactly how much the map shrinks distances. It also prevents any hidden collision at finer precision: distinct inputs remain distinct after the known scale is removed.

The scale of address two is 2^{-5} in the original normalization and 2^{-4} in the normalized sequence. Omitting its factor 2! would change the period claimed for the original coefficients.

9 Least periods, rather than sufficient periods

At precision 2^r the least positive *row* period is

$$P_j(r) = 2^{\max(0,r-B_j)}, \qquad B = (1,1,5,3).$$

The exact valuation law proves both periodicity and minimality. A step H is a period precisely when $v_2(H) + B_j \geq r$.

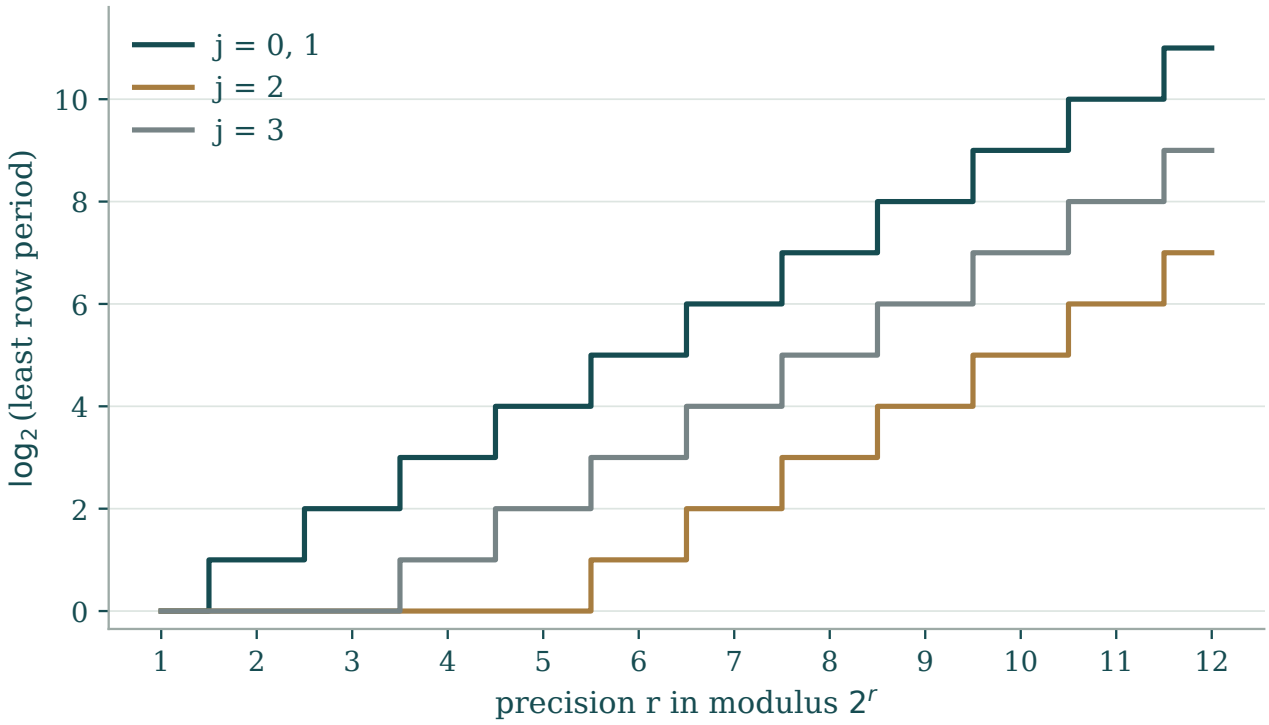

Figure 8. Binary logarithms of the least row periods. A height of zero means period one. These are theorem-derived values, valid at every precision.

Modulo $256 = 2^8$, the least periods are

$$(P_0(8), P_1(8), P_2(8), P_3(8)) = (128, 128, 8, 32).$$

In actual Euler degree, multiply by four:

$$(512, 512, 32, 128).$$

For address two, precision at most 2^5 already has row period one. Its Euler coefficients all lie in $2 + 32\mathbb{Z}_2$. Further precision resolves additional dyadic digits within that residue class.

The original rank-four conjectural shift has row step 2^{r-1}. It remains a valid period for every address, but addresses two and three usually admit shorter periods. The sharp theorem identifies the shortest one.

10 A full period visits every allowed residue

For each address the exact interpolation image is

$$E^{(4,j)}(\mathbb{Z}_2) = j! + 2^{B_j}\mathbb{Z}_2.$$

When $r > B_j$, a least period lists every residue in this coset modulo 2^r exactly once. The following figure checks this assertion by exact arithmetic at precision 256.

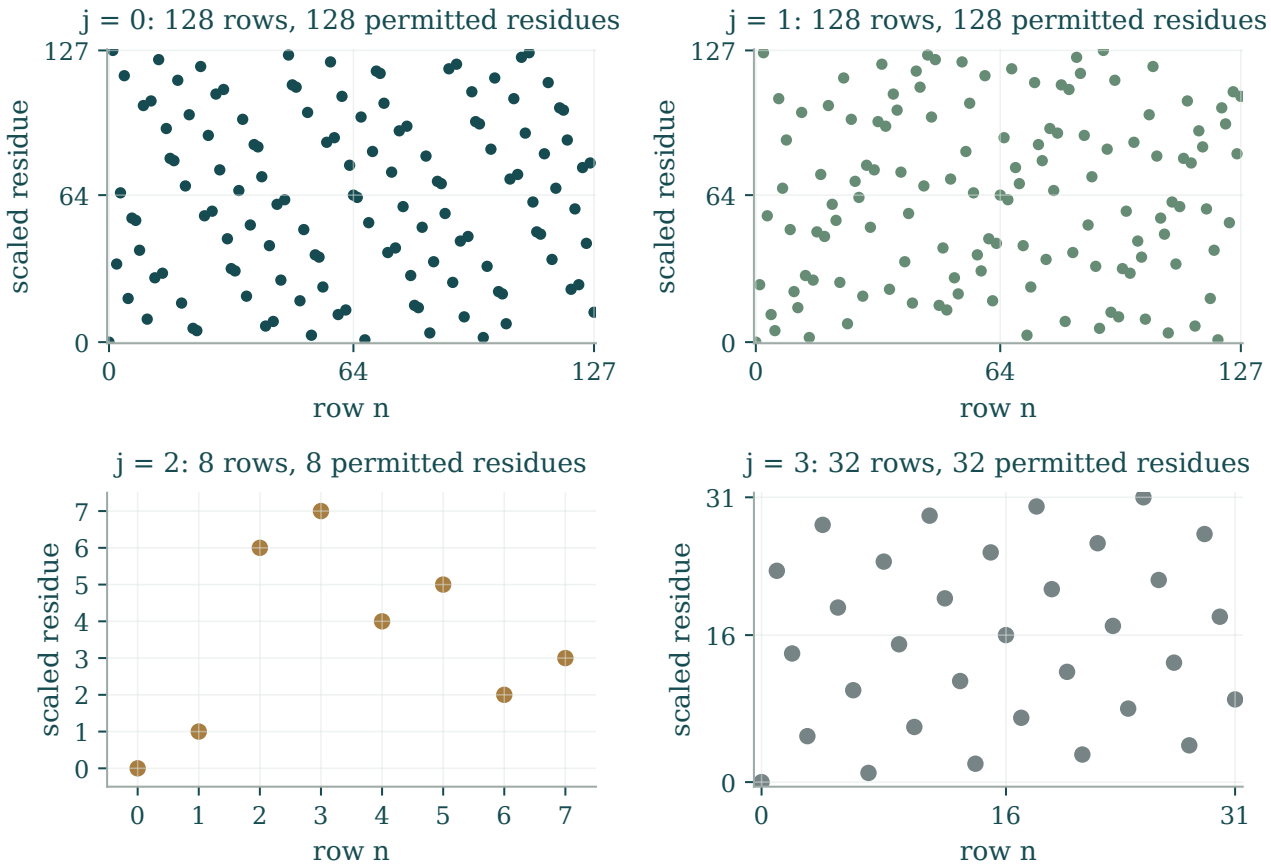

Figure 9. Exact residue permutations modulo 256. The vertical coordinate is $y_n = (E_{4n}^{(4,j)} - j!)/2^{B_j}$ modulo $P_j(8)$. Each panel contains one full least period. Every vertical residue occurs once.

No decimal approximation is used to form these residues. The generating series is inverted modulo 2^{256} using odd denominators, then the exact result is reduced modulo 256. An independent rational inversion checks the initial coefficients.

The shapes are permutations, not monotone real functions. Their organizing property is dyadic distance: agreement in input low bits forces the same agreement in the scaled output low bits.

11 Seeing the scaled isometry

The map

$$x \longmapsto \frac{E^{(4,j)}(x) - j!}{2^{B_j}}$$

is a bijective isometry of $\mathbb{Z}_2$. Its finite reductions preserve the number of common low binary digits.

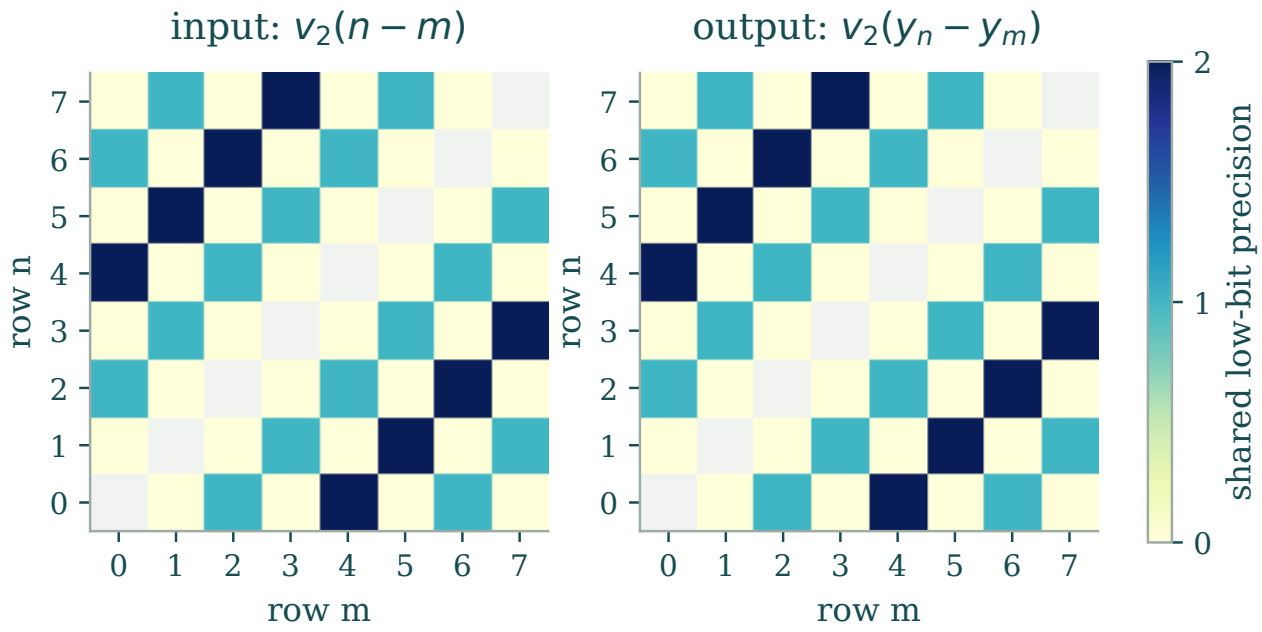

Figure 10. Address two modulo 256 gives an eight-element quotient. The two exact matrices coincide: every pair of distinct rows has the same dyadic valuation before and after the scale is removed. The diagonal represents $v_2(0) = +\infty$ and is left blank.

If $n - m$ is odd, the rows disagree in their first binary digit and the matrix entry is zero. If it is divisible by two but not four, they share exactly one low digit. An entry two means agreement through two low digits.

This structure explains the residue permutation in the preceding section. At each new precision, every input residue has exactly two lifts. An isometry distinguishes those lifts at the corresponding output precision. Starting from the single residue at the scale threshold, induction gives surjectivity and a unique inverse residue at every finite level.

The finite matrix is an illustration of that proof. Its eight rows alone would not establish a statement about the whole of $\mathbb{Z}_2$.

12 How far the simple metric law extends

Sharp first-difference laws hold for every address at ranks 2, 4, and 8. The arrays below give their normalized scales $b_{N,j}$ and original Euler scales $B_{N,j} = b_{N,j} + v_2(j!)$.

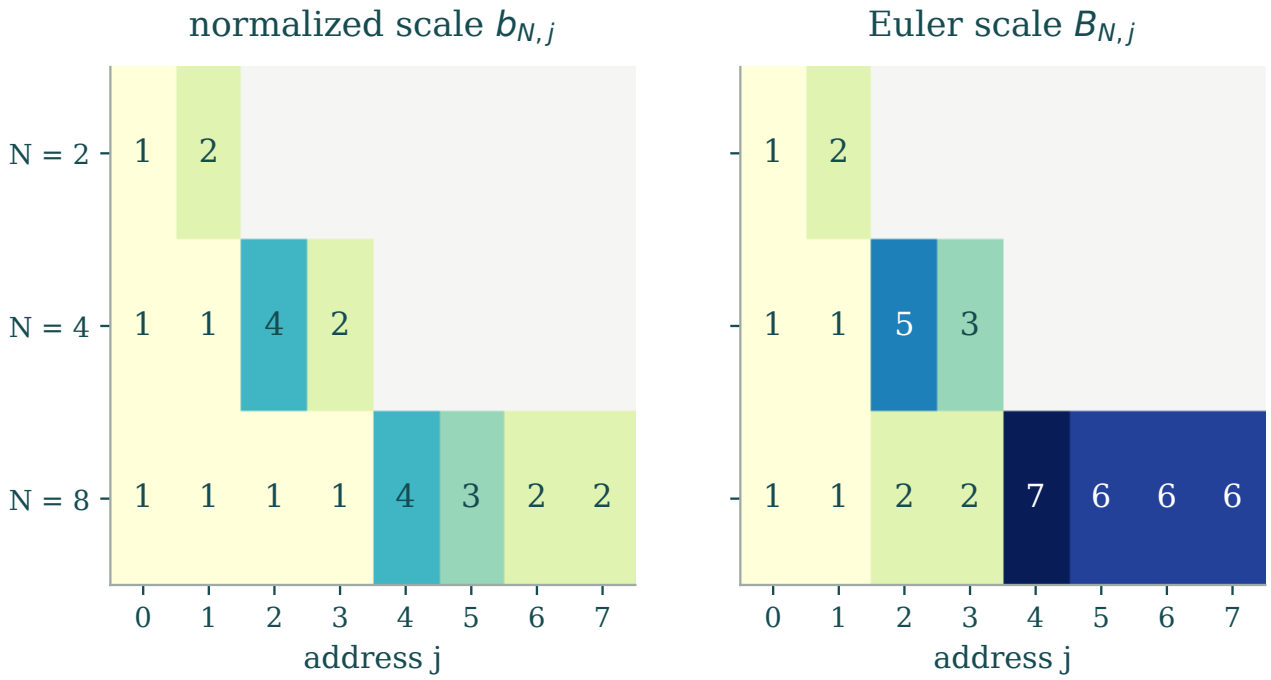

Figure 11. Proved scale arrays for the three small ranks. Blank cells are outside the address range. The Euler normalization contributes the factorial valuation, which is already substantial at the larger addresses of rank eight.

There is also an infinite family: at every $N = 2^a \geq 4$, all lower-half addresses $j < N/2$ have normalized scale one. Their Euler scale is $1 + v_2(j!)$.

The same constant-scale proposal fails at some upper-half addresses:

(N, j)	$v_2(C(1) - C(0))$	Step-two prediction	Actual step-two valuation
$(16, 9)$	5	6	7
$(32, 18)$	6	7	6
$(32, 19)$	5	6	7

These are exact rational counterexamples to the additional metric proposal. They do not contradict the universal higher-difference *lower* bound, which continues to hold at every address of every dyadic rank.

13 From factorial gain to analytic radius

At every center $x_0 \in \mathbb{Z}_2$, the interpolations admit ordinary Taylor series $C_j(x_0+z) = \sum_{d\ge 0} a_{j,d}(x_0) z^d$. For positive degrees,

$$\begin{aligned} v_2(a_{j,d}(x_0)) &= d && (j=0,1),\\ v_2(a_{2,d}(x_0)) &\ge \max\{2d + \lfloor d/2 \rfloor,\ d+3\},\\ v_2(a_{3,d}(x_0)) &\ge d. \end{aligned}$$

At address two equality with $5d/2$ holds along every power-of-two degree $d \ge 4$.

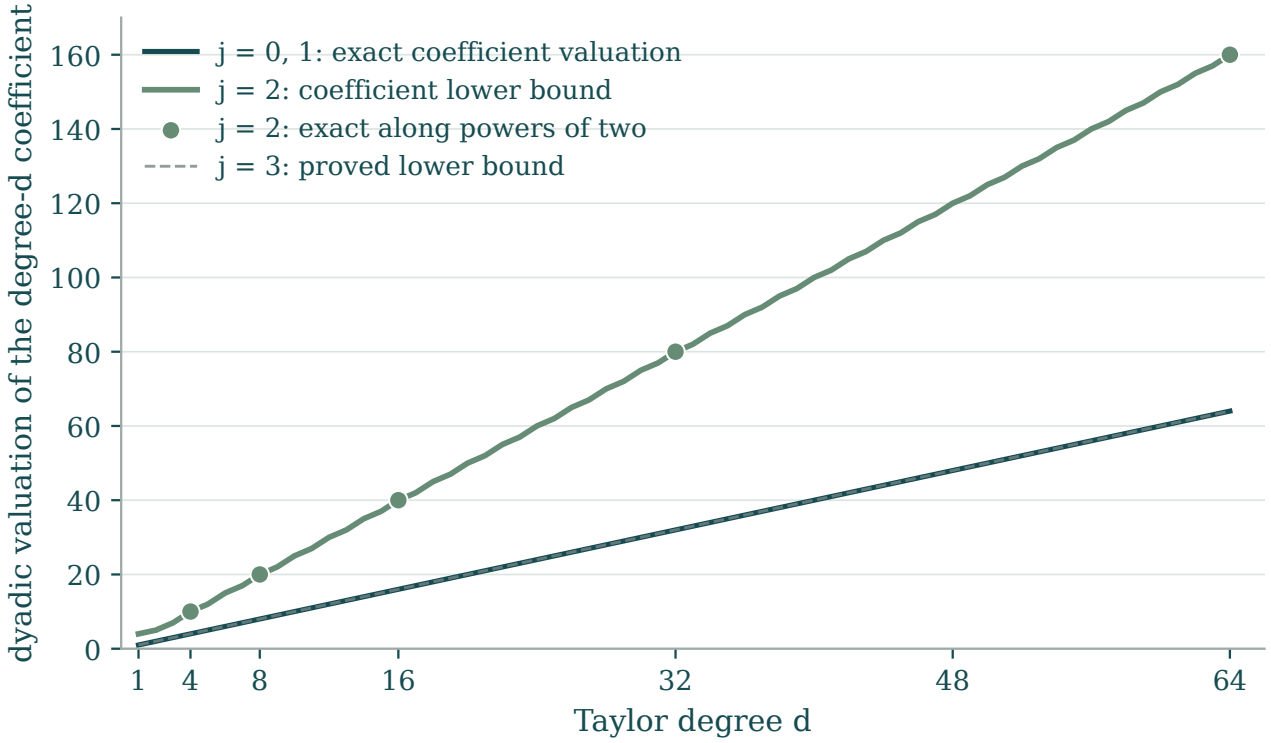

Figure 12. The Taylor coefficient precision slopes. The degree-zero coefficient is excluded. Marked address-two degrees belong to an unbounded proved equality family, rather than a finite observed pattern.

The radius is $2^{\liminf_d v_2(a_d)/d}$ in the normalized dyadic absolute value. Hence

$$R_0 = R_1 = 2, \qquad R_2 = 2^{5/2}, \qquad R_3 \ge 2.$$

The exact radius of address three is not asserted. For address two, the lower bound gives convergence inside the claimed radius and the unbounded equality family prevents a larger one.

The proof converts the factorial Newton estimates into ordinary Taylor coefficients with the Stirling relations. Generic continuity or first-order Lipschitz bounds alone do not supply this analytic conclusion.

14 Which evidence does which job

The package has three complementary levels of evidence. They answer different questions, and the final claims retain those distinctions.

Evidence	What it establishes	Verification scope
Lean theorem	The precise formal statement follows from its recorded dependencies and the accepted foundational axioms.	The completed Nishibuchi conjecture, earlier Chapter IX theory, and the inherited rank-four ordinary-step, sharp-period, and isometry results. See the Lean guide for build provenance.
Algebraic proof and audit	A universal mathematical result, subject to the written proof and its stated inputs.	The new general prime-power transfer, mixed-step and factorial gains, exact higher-order families, broader dyadic metric laws, and radius results.
Exact computation	The implemented assertion holds in its recorded finite domain, or an exact counterexample refutes an extension.	Coefficient regressions, period illustrations, and sharpness or cancellation checks.

The generic theorem uses the integral Hurwitz-series product and reciprocal induction. The factorial theorem uses divided powers and explicit transforms of the ordinary Euler and Bernoulli series. The ordinary Euler arithmetic input is the classical Frobenius congruence, with normalization checked against Gessel's primary exposition. Address two has a self-contained central-factorial Bernoulli argument. Addresses one and three use the proved tangent and cotangent transfers.

The exact regressions include more than 1.8 million bounded difference checks through row 512. Smaller runs test the stronger address-two filtration and mixed parity law. Their records specify precision, coefficient definitions, inputs and tested ranges.

The figures in this guide have a separate reproducibility record: `sources/generate_figures.py`, `figures/exact_figure_data.json`, and `figures/figure_manifest.json`. Its exact assertions validate the illustration data. Theorem-derived curves are explicitly recorded as such.

The new general transfer, mixed-step, factorial, and analytic extension has not been newly formalized in Lean. The rank-four ordinary-step and sharp-period results have inherited Lean coverage, as mapped in the companion. Mathematical audits in this package are internal reviews, not claims of external peer review.

15 Reading the conclusion at the right strength

The original quantified Nishibuchi conjecture is completed. The stronger dyadic result applies without a starting-row threshold, and the rank-four theory now has factorial precision, exact common-step laws for addresses zero and one, an infinite exact address-two family, optimal periods, and exact analytic radii for three addresses.

For a common step, the final congruence to use is

$$\Delta_H^k E^{(4,j)}(n) \equiv 0 \pmod{2^{v_2(k!)+kv_2(H)+A_j(k)}}, \quad n \geq 0,\ k, H \geq 1,$$

with

$$(A_0, A_1, A_2, A_3) = \big(k, k, \max\{k+4, 2k+\lfloor k/2 \rfloor + 1\}, k+2\big).$$

For different steps, replace $kv_2(H)$ by $\sum_i v_2(H_i)$ in the lower bound. The address-zero/one equality rule then depends on order parity and the number of even steps.

Statement	Final status
Nishibuchi Conjecture 3.9, all allowed branches	completed as the formal capstone
All-row dyadic mixed-difference bound	proved and audited
Rank-four factorial and paired bounds	proved and audited
All common-step exact valuations, $j = 0, 1$	proved at all rows and orders
Address-two exact valuations at power-of-two orders	proved for all positive step lists
Complete exact address-two formula at other orders	open
Complete exact higher-order address-three formula	open
Exact address-three analytic radius	open
Simple constant metric at every upper-half address	false, with exact witnesses retained
Separate Euler-tail universal simplicity problem	open as a distinct research program

The remaining questions do not weaken the completed conjecture. They specify the next boundary of the stronger theory. The main text gives the proofs and precise dependency statements, while the Lean guide supplies the formal coverage map and a reproducible route to its recorded checks.

16 Compute the reciprocal before estimating it

For width N and address j, the normalized source and its reciprocal are

$$G_{N,j}(t) = j! \sum_{n \ge 0} \frac{t^{Nn}}{(Nn+j)!}, \qquad G_{N,j}(t)^{-1} = \sum_{n \ge 0} C_{N,j}(n) \frac{t^{Nn}}{(Nn)!}.$$

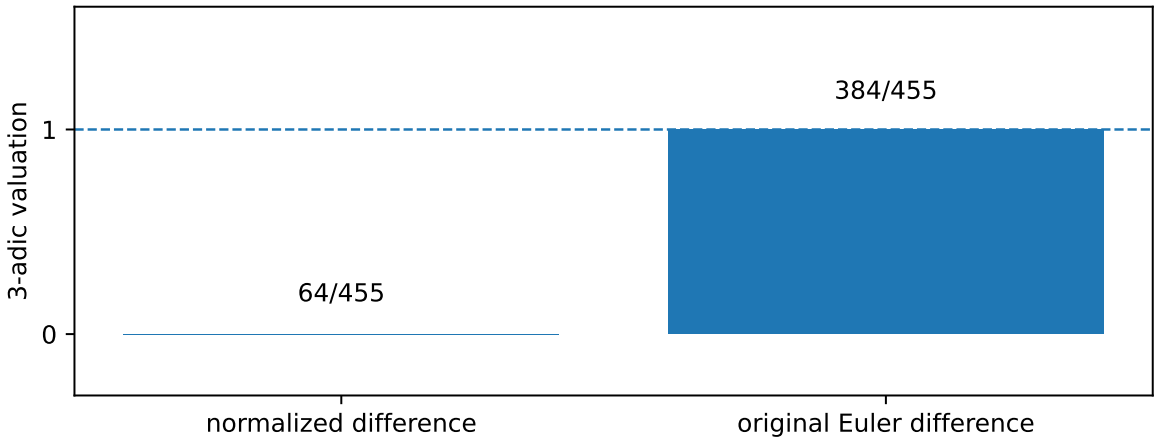
Multiplying the two series and clearing the factorials gives an exact triangular recurrence:

$$C_{N,j}(0) = 1, \qquad C_{N,j}(n) = -\frac{\sum_{r=0}^{n-1} \binom{Nn+j}{Nr} C_{N,j}(r)}{\binom{Nn+j}{Nn}}.$$

address j	C(0)	C(1)	C(2)
0	1	-1	69
1	1	-1/5	121/45
2	1	-1/15	13/45
3	1	-1/35	59/1155

The table is for $N = 4$. The first two address-zero rows illustrate the computation without any valuation estimate:

$$C_{4,0}(1) = -1, \qquad C_{4,0}(2) = -\left(1 + \binom{8}{4}(-1)\right) = 69.$$



At address one, the same recurrence yields $C_{4,1}(1) = -1/5$ and $C_{4,1}(2) = 121/45$. These are exact rational coefficients, not rounded approximations. The second implementation in the supplied script inverts the ordinary power series first, then multiplies by $(Nn)!$. Agreement between the two constructions checks the factorial placement.

17 The normalization loss is a real boundary

The original Euler coefficient is $E_{Nn}^{(N,j)} = j!C_{N,j}(n)$. Multiplication by $j!$ changes the available p-adic precision. That change cannot be discarded outside the unit-factorial window.

Take $p = 3$, $N = 6$, $j = 3$, and compare rows one and two. Exact inversion gives

$$C_{6,3}(1) = -\frac{1}{84}, \quad C_{6,3}(2) = \frac{703}{5460}, \quad C_{6,3}(2) - C_{6,3}(1) = \frac{64}{455}.$$

Neither 64 nor 455 is divisible by three, so the normalized difference has valuation zero. The original coefficient difference is $3! \cdot 64/455 = 384/455$, of valuation one.

This is the counterexample behind the corrected factorial-loss statement. A bound for the original Euler normalization must lose $v_p(j!)$ when translated to $C_{N,j}$. For $0 \leq j < p$, that loss is zero. The distinction concerns which sequence the theorem measures, not a numerical weakness of the calculation.

18 Odd primes require the sign twist

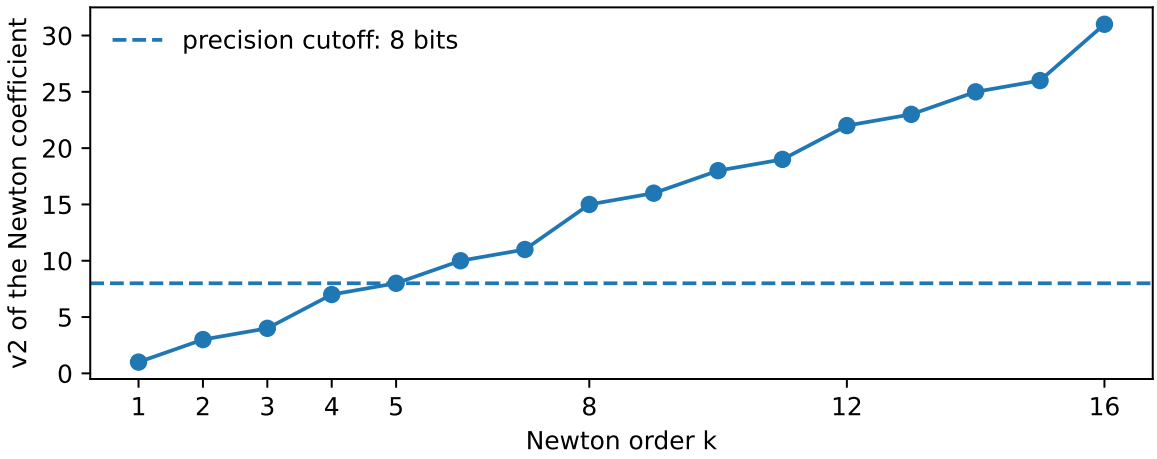
The prime-power transfer controls a sign-twisted reciprocal sequence at odd primes. It must not be read as an ordinary-difference theorem for the untwisted coefficients.

At $N = p = 3$ and $j = 0$, put $A(n) = (-1)^n C_{3,0}(n)$. The first three rows are

row n	C at width 3, address 0	(-1)^n C(n)
0	1	1
1	-1	1
2	19	19

The ordinary first difference at row zero is $-1 - 1 = -2$. It is a 3-adic unit, so an asserted lower bound of one for that difference would be false. The twisted first difference is zero, whose mathematical valuation is $+\infty$. At the next row, the twisted difference is $19 - 1 = 18$, of valuation two.

Equivalently, the untwisted sequence is acted on by $T_H = S^H - (-1)^H$, where S advances one row. At odd step one this is $S + 1$, not $S - 1$. The zero in the example is handled by a zero-safe divisibility statement rather than a finite valuation equality. The explicit sign and the zero convention are both part of the theorem's interface.



19 Newton coordinates turn precision into a finite computation

Let $b_k = \Delta_1^k C_{4,0}(0)$. The first coefficients obtained from the difference triangle are

$$(b_0, b_1, b_2, b_3, b_4) = (1, -2, 72, -33872, 60511872).$$

The exact Newton identity recovers each nonnegative integer row:

$$C_{4,0}(n) = \sum_{k=0}^{n} b_k \binom{n}{k}.$$

For this address the proved law is $v_2(b_k) = 2k - s_2(k)$ for $k \geq 1$. Every $k \geq 5$ therefore has $v_2(b_k) \geq 8$. Since $\binom{n}{k}$ is integral, those terms vanish modulo 256. Thus, for every $n \geq 0$,

$$C_{4,0}(n) \equiv 1 + 254\binom{n}{1} + 72\binom{n}{2} + 176\binom{n}{3} + 128\binom{n}{4} \pmod{256}.$$

The uniform truncation follows from the coefficient theorem. The script separately checks the exact Newton reconstruction and this reduction for rows 0 through 32. Those finite checks validate the worked arithmetic without replacing the theorem.

20 A compatible root is built one digit at a time

Take $F(x) = x^2 - 7$ over the 3-adic integers and start with $x_1 = 1$ modulo three. If $F(x_L) = 3^L r_L$, the next representative has the form $x_{L+1} = x_L + 3^L t_L$. Its correcting digit satisfies

$$r_L + 2x_L t_L \equiv 0 \pmod 3.$$

L	3^L	current x	next digit	next x
1	3	1	1	4
2	9	4	1	13
3	27	13	0	13
4	81	13	2	175
5	243	175	0	175

For example, $F(1)/3 = -2$ and $2x_1 = 2$, so the next digit is one and $x_2 = 4$. Then $F(4)/9 = 1$, again giving digit one and $x_3 = 13$. At the next stage the residual is divisible by three, so digit zero is correct. A zero digit is not a stalled construction.

Every center remains congruent to one modulo three. Hence $2x_L$ stays a unit, and the correction equation has a unique digit at every stage. The representatives are compatible and their increments are divisible by 3^L. Completeness gives a limit, and continuity of the polynomial gives a root of F. The finite table exhibits the construction. The unit derivative is what supports indefinite continuation.

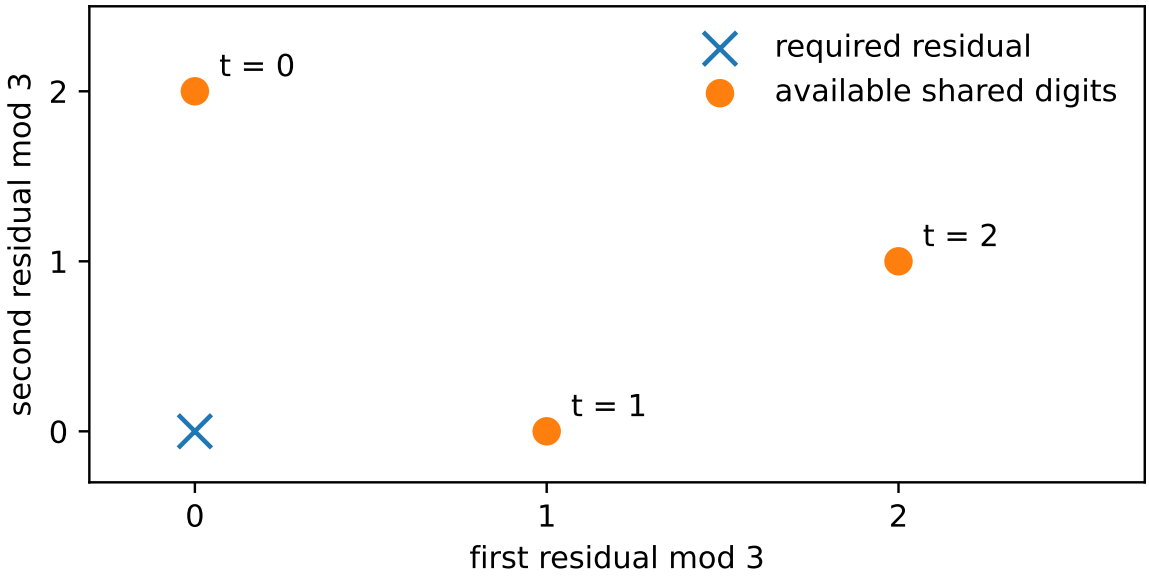
21 A singular residual can stop a lift

Now take $F(x) = x^2 - 3$ at the residue $x = 0$ modulo three. The residual is $r = F(0)/3 = -1$ and the Jacobian is zero modulo three. The next-digit equation would require

$$-1 + 0 \cdot t \equiv 0 \pmod 3,$$

which has no solution.

digit t	candidate y	y^2 - 3	residue mod 9
0	0	-3	6
1	3	6	6
2	6	33	6



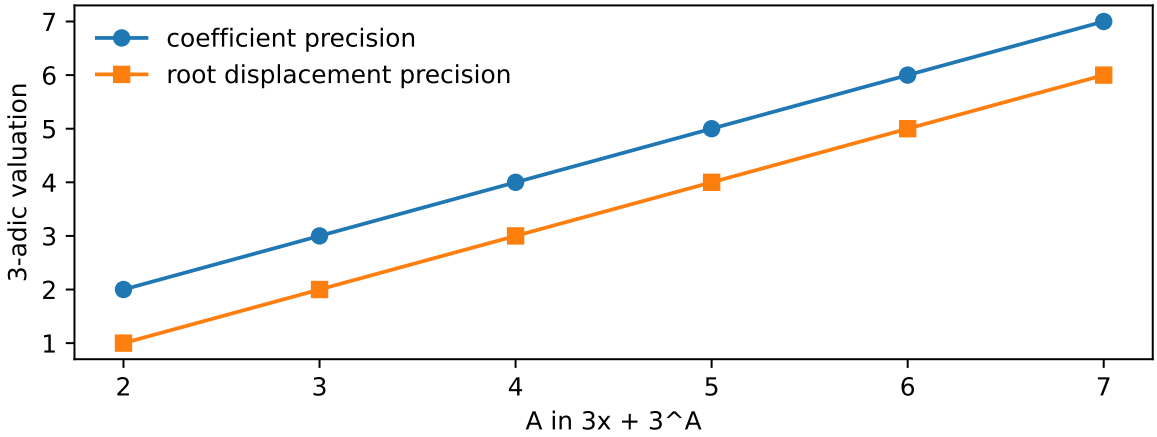
The three representatives of the old root class modulo nine all leave residual six modulo nine. Thus the root class exists at precision three but does not lift to precision nine. This is an exact obstruction, not failure of an iterative search.

A singular Jacobian alone does not imply failure. For $F(x) = x^2$ at the same center, the residual is zero and all three candidate digits lift to roots modulo nine. The obstruction is the residual class in the cokernel of the actual Jacobian. It is this class, rather than the rank by itself, that decides whether a next lift exists.

22 Separate corrections need not be one shared correction

Consider the two-component system $F(x) = (x, x-3)$ at $x = 0$, with $q = 3$ and $L = 1$. Both components vanish modulo three. After writing a candidate as $y = 3t$, its residual vector modulo three is

$$\bar{r} + J\bar{t} = (0,2) + (t,t) = (t, t-1).$$



The first coordinate can be corrected by $t = 0$. The second can be corrected by $t = 1$. No digit corrects both. The available residuals are $(0,2)$, $(1,0)$, and $(2,1)$, none of which is $(0,0)$.

The combined Jacobian maps t to the diagonal vector (t,t). Its image is smaller than the product of its coordinate images. Checking the two projected obstructions independently therefore loses the compatibility condition. The common-correction theorem retains the full residual vector and the shared digit space, which is exactly the information needed to detect this failure.

23 A derivative weight can cost one digit of root precision

Compare the linear equations $F(x) = 3x = 0$ and $G_A(x) = 3x + 3^A = 0$, where $A \geq 2$. Their coefficient difference has 3-adic valuation A, but their roots differ by

$$x_A - 0 = -3^{A-1}, \qquad v_3(x_A) = A - 1.$$

The derivative has valuation one. Solving the correction equation divides by three, so one digit of coefficient precision is lost in root displacement. The calculation is exact for every displayed A and also follows immediately from the two linear equations.

This example explains why weighted lifting and deformation estimates track a Jacobian loss rather than silently treating every invertible derivative over $\mathbb{Q}_p$ as a unit over $\mathbb{Z}_p$. A valuation-zero derivative would not incur this particular loss. Nonlinear systems additionally require their stated neighborhood, residual, and right-inverse hypotheses.

The eight examples use exact rational and integer arithmetic. Their recorded finite ranges and computation scripts are supplied with the sources. The atlas adds no Lean endpoint and changes no formal claim in the companion.

CHAPTER X

Universal Residual Seeds

Deformation forests, transport categories, and conditional system completion

The congruence study is followed by a framework for residual seeds and compatible arithmetic descriptions.

Residual seeds, deformation forests and transport categories organize conditional system completion. Supplied arithmetic and carrier data remain explicit inputs.

IN THIS CHAPTER

Mathematical text 1170

Visual studies 1227

Formal companion 2350

Sources and references 2690

Scope

The target family and recovered carrier are independent existential outputs. Identifying them and proving nonzero occupancy require additional premises. Source families, carrier presentations and local comparisons remain supplied.

The next chapter studies local packet geometry and the remaining obligations of arithmetic realization.

Reading scope

Residual forests describe deformation above a fixed residual root. The later constructions compare compatible families and recover summands inside supplied carriers. Universal companion existence, carrier existence, and nonzero occupancy require additional inputs. Section D assembles the conditional result and states those inputs explicitly.

Abstract

A residual representation is a zeroth-order coordinate. All positive-depth perturbations above it may fill its formal deformation neighborhood, but they cannot move into a different residual class. This chapter develops the corresponding universal object: a residual forest whose roots are residual representations, whose finite levels are lifts modulo powers of a uniformizer, and whose infinite branches are complete characteristic-zero objects. We prove the residual partition, no-crossing, inverse-limit reconstruction, finite-branch compactness, exact smooth and singular branch counts, packet decomposition of tangent and obstruction cohomology, a directed minimum-seed theorem, rational seed-zeta formulas, and finite companion-forest completion. The coefficient prime two is represented by a weighted forest in which characteristic-zero packets may merge modulo two and become visible only at later depth. We then define a prime-independent system seed through a common Frobenius spine, prove a compatible-carrier summand theorem under finite Frobenius separation, and reduce finite occupancy in a fixed semisimple carrier to the nonnegative integer trace of an exact joint projector. The chapter does not prove that every admissible residual companion exists or that every finite Hecke packet is occupied. Those two existence statements remain the exact horizontal boundary beyond vertical deformation theory.

A route through the chapter

The central distinction is between a residual root, a coherent branch and an occupied packet in a carrier. Sections 2–7 develop the finite and formal machinery. Sections 8–11 assemble its arithmetic uses under stated hypotheses. The residue-counting arguments appear in Appendix C. Appendix D states the conditional occupied-system completion theorem. The visual studies provide worked examples of the same constructions.

Read for	Follow this route
The mathematical core	Residual partition, reconstruction, smooth and singular counts, cohomology packets and directed seed rank.
The arithmetic assembly	Common coefficient data, finite Frobenius separation, explicit carrier summands and inverse-limit-closed profiles.
The formal contract	The formal companion explains the terminal theorem and its three direct dependency modules, with a statement register and a guide to each hypothesis.
The finite examples	Plates X.1–X.30 show residue tables, projector tests, countermodels and norm-character examples.

Two outputs require two sets of inputs. The terminal theorem proves that a transported target family exists and that the declared summand can be recovered inside a supplied compatible carrier. It does not identify those two objects. An application that needs such an identification must supply its comparison. Likewise, zero multiplicities are permitted by the formal assembly, so a nonzero conclusion retains a separate nonzero premise.

Mathematical and formal scope. The final source is over the rational absolute Galois group. Carrier data, constituent comparisons and a completed source family are explicit inputs. The formal companion distinguishes the amended conditional statements from stronger existence questions and identifies their recorded verification. Earlier source contracts remain available in the accompanying research records.

1 The universal seed at residual depth

The earlier chapters treat a seed as a primitive object together with an operator grammar, a packet system, a topology, and an exact reconstruction law. In arithmetic deformation problems, the primitive coordinate has two layers:

$$\boxed{\text{residual root} \quad + \quad \text{positive-depth deformation coordinates.}}$$

The distinction is structural. A correction divisible by the uniformizer changes higher digits but leaves the residual digit fixed. Therefore the correct universal arithmetic seed cannot be one residual representation unless the admissible residual space has only one point. It must contain every residual root and the complete formal neighborhood above each root.

Let $\mathcal{O}$ be a complete discrete valuation ring with uniformizer ϖ, maximal ideal (ϖ), residue field

$$k = \mathcal{O}/(\varpi), \qquad |k| = q,$$

and fraction field K. When a characteristic-zero conclusion is intended, assume additionally that $\operatorname{char} K = 0$. The general counting statements do not require that restriction. Let $\mathcal{M}$ be a moduli functor on complete local Noetherian $\mathcal{O}$-algebras with residue field k, equipped with a well-defined reduction map

$$\operatorname{red}_A : \mathcal{M}(A) \longrightarrow \mathcal{M}(k).$$

For a Galois representation this means either that a framed integral model has been fixed or that the residual semisimplified class is used.

Definition 1.1 (Residual seed system)**.** For $\bar{x} \in \mathcal{M}(k)$, define the residual fiber

$$\mathcal{M}_{\bar{x}}(A) = \{x \in \mathcal{M}(A) : \operatorname{red}_A(x) = \bar{x}\}.$$

The point $\bar{x}$ is the residual root. The family of all nonempty fibers is the residual special fiber, and the formal deformation problems above them form the residual forest.

For a Galois problem the principal example is

$$\bar{\rho} : G_{F,S} \longrightarrow \mathrm{GL}_n(k),$$

with a deformation functor $\mathrm{Def}_{\bar{\rho}}$ cut out by a determinant and selected local conditions.

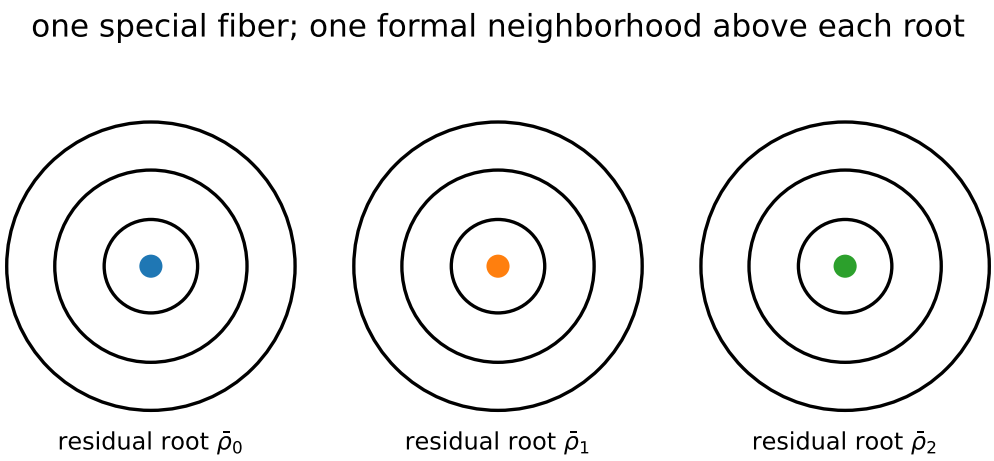


Figure 1. The universal residual seed is not one point. It is the special fiber together with one complete formal neighborhood above each admissible root.

1.1 What the chapter is designed to separate

Three statements are often compressed into one sentence even though they have different logical content.

1. **Vertical completeness:** every compatible perturbation stream above a fixed root reconstructs a point of its complete deformation space.
2. **Horizontal companion existence:** every required residual root, including roots at other coefficient primes, actually exists.
3. **Occupancy:** the resulting arithmetic packet occurs in a nonzero global carrier of the required type.

The first belongs to deformation and inverse-limit theory. The second is a residual companion problem. The third is an arithmetic or automorphic nonvanishing problem. Neither of the last two follows from arbitrarily deep perturbation above one already occupied root.

2 Residual partition and no crossing

Theorem 2.1 (Residual partition)**.** *For every coefficient algebra A,*

$$\boxed{\mathcal{M}(A) = \bigsqcup_{\bar{x} \in \mathcal{M}(k)} \mathcal{M}_{\bar{x}}(A).}$$

Proof. Every A-valued object has one reduced object $\mathrm{red}_A(x) \in \mathcal{M}(k)$, so the union is exhaustive. Two distinct fibers cannot intersect because an object cannot have two different reductions. Hence the union is disjoint. □

Theorem 2.2 (No crossing under positive-depth perturbation)**.** *Suppose $x, y \in \mathcal{M}(\mathcal{O})$ are related by a deformation operation that is congruent to the identity modulo ϖ. Then*

$$\mathrm{red}(x) = \mathrm{red}(y).$$

Every finite composition remains in one residual fiber. If an infinite perturbation stream converges in the ϖ-adic topology, its limit remains in the same fiber. The existence of that limit is an explicit hypothesis, not a consequence of positive depth alone.

Proof. A correction in $\varpi\mathcal{O}$ vanishes after reduction modulo ϖ. Thus one operation preserves the residual root, and induction proves the finite statement. For a convergent stream, convergence at the first finite precision makes its reduction eventually equal to that of its limit. Every term already has the initial reduction, so the limit has that reduction too. Completeness applies to Cauchy streams. It does not make every root-preserving stream Cauchy. For example, $0, 3, 0, 3, \ldots$ has constant reduction modulo 3 but no limit modulo 9. □

Corollary 2.3 (Zeroth-order obstruction)**.** *If two admissible objects have different residual roots, no sequence of genuinely positive-depth perturbations beginning at one can reach the other. A horizontal transport between their roots is a zeroth-order operation, not a deeper lift.*

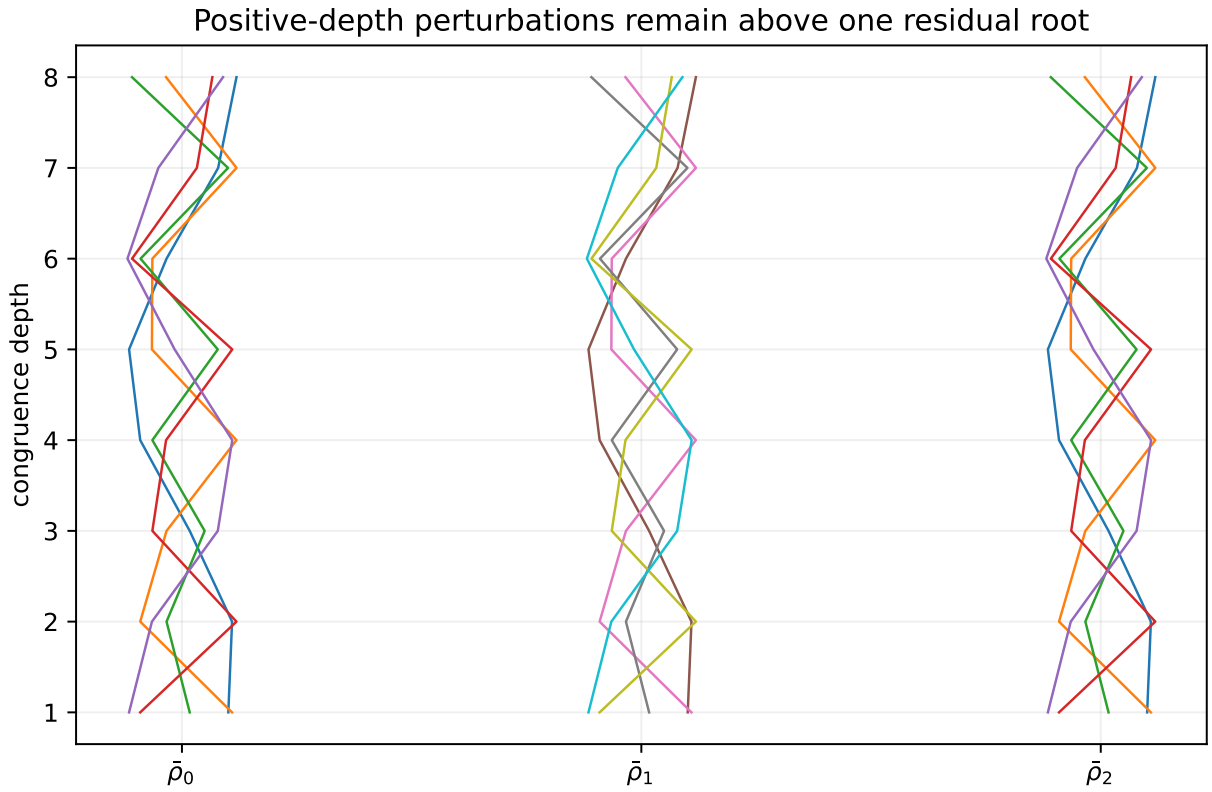

Figure 2. Each perturbation stream remains above its initial residual root. Refinement adds digits vertically. It does not move a branch horizontally.

Numerical Certificate 2.4 (Exact residual partition)**.** The finite implementation partitions the integers $0, \dots, 8$ into the three classes modulo 3:

$$\{0,3,6\}, \qquad \{1,4,7\}, \qquad \{2,5,8\}.$$

Every tested correction of the form $x \mapsto x + ph$ preserves the residual class exactly.

3 Lift forests and inverse-limit reconstruction

Fix $\bar{x} \in \mathcal{M}(k)$. For $m \geq 1$, set

$$X_m(\bar{x}) = \mathcal{M}_{\bar{x}}(\mathcal{O}/\varpi^m).$$

Reduction gives transition maps

$$r_{m+1,m} : X_{m+1}(\bar{x}) \longrightarrow X_m(\bar{x}).$$

A compatible branch is a sequence $(x_m)_{m\geq 1}$ satisfying

$$r_{m+1,m}(x_{m+1}) = x_m.$$

Classical Input 3.1 (Represented complete deformation problems)**.** When a deformation functor is represented by a complete local ring $R_{\bar{x}}$, its $\mathcal{O}$-valued points are continuous local maps $R_{\bar{x}} \to \mathcal{O}$. Completeness identifies such maps with compatible maps to every quotient $\mathcal{O}/\varpi^m$.

Theorem 3.2 (Formal inverse-limit reconstruction)**.** *Assume $\mathcal{M}_{\bar{x}}$ is represented by a complete local $\mathcal{O}$-algebra $R_{\bar{x}}$. Then reduction induces a natural bijection*

$$\boxed{\mathcal{M}_{\bar{x}}(\mathcal{O}) \cong \varprojlim_m \mathcal{M}_{\bar{x}}(\mathcal{O}/\varpi^m).}$$

Proof. A continuous local homomorphism $R_{\bar{x}} \to \mathcal{O}$ reduces to a compatible family of homomorphisms into $\mathcal{O}/\varpi^m$. Conversely, compatible finite-level maps determine a map

$$R_{\bar{x}} \longrightarrow \varprojlim_m \mathcal{O}/\varpi^m \cong \mathcal{O}.$$

The two constructions are inverse because equality in a separated complete ring is detected modulo every power of its maximal ideal. □

Theorem 3.3 (Finite-branch compactness)**.** *Suppose every $X_m(\bar{x})$ is finite and nonempty and every node has finitely many children. Then the lift tree above $\bar{x}$ contains an infinite compatible branch.*

Proof. The tree is infinite because it has a nonempty level at every depth, and it is finitely branching by hypothesis. König's lemma gives an infinite path. The edge relation is reduction, so that path is a compatible branch. □

Surjectivity of every transition map is sufficient but not necessary. Finite branching and nonempty arbitrarily deep levels are the compactness mechanism.

Proposition 3.4 (Smooth formal branch count)**.** *If*

$$R_{\bar{x}} \cong \mathcal{O}[[t_1, \dots, t_d]] \quad \textit{as complete local } \mathcal{O}\textit{-algebras},$$

then

$$\boxed{\#X_m(\bar{x}) = q^{d(m-1)}.}$$

Fix a uniformizer and a section $s : k \to \mathcal{O}$ of reduction, with $s(0) = 0$. Every $\mathcal{O}$-valued branch is encoded by d positive-depth digit streams

$$t_i = s(a_{i,1})\varpi + s(a_{i,2})\varpi^2 + \cdots, \qquad a_{i,j} \in k,$$

Proof. A local map sends each parameter into the image of (ϖ) in $\mathcal{O}/\varpi^m$. Conversely, every tuple in that image is nilpotent and defines a coefficient-preserving evaluation homomorphism. This homomorphism is local. To prove uniqueness without assuming continuity of an arbitrary competing homomorphism, observe in one variable that a homomorphism killing X^N only sees the finite polynomial truncation modulo X^N. Induction over the finite number of variables gives uniqueness in all dimensions. The actual local maps are therefore in bijection with the full parameter tuple set. Its cardinality is $q^{d(m-1)}$, including the zero-dimensional chart.

For integral maps, reduce an arbitrary tuple in $(\varpi)\mathcal{O}$ at every precision, evaluate there, and use the represented-map reconstruction theorem. The finite evaluations are compatible, the reconstructed algebra map is local, and every competing local map has the same finite reductions. Separatedness gives uniqueness. Local maps are continuous in the maximal-ideal adic topologies. This establishes the integral parameter classification rather than assuming it from the finite count.

For the digit claim, subtract the chosen representative of the residue and divide the remainder by the uniformizer. Iterating gives unique digits. Conversely, the partial sums of any digit stream form a compatible Cauchy family and reconstruct uniquely by completeness and separatedness. More precisely, for each parameter there is a unique stream $(a_{i,j})_{j\geq 1}$ such that

$$\varpi^{n+1} \mid t_i - \sum_{j=1}^{n} s(a_{i,j})\varpi^j \qquad (n \geq 0).$$

The section is a set-theoretic section of reduction, not an asserted embedding of residue fields into the coefficient ring. Finally, a supplied local $\mathcal{O}$-algebra isomorphism from $R_{\bar{x}}$ transports both the map classification and the count. □

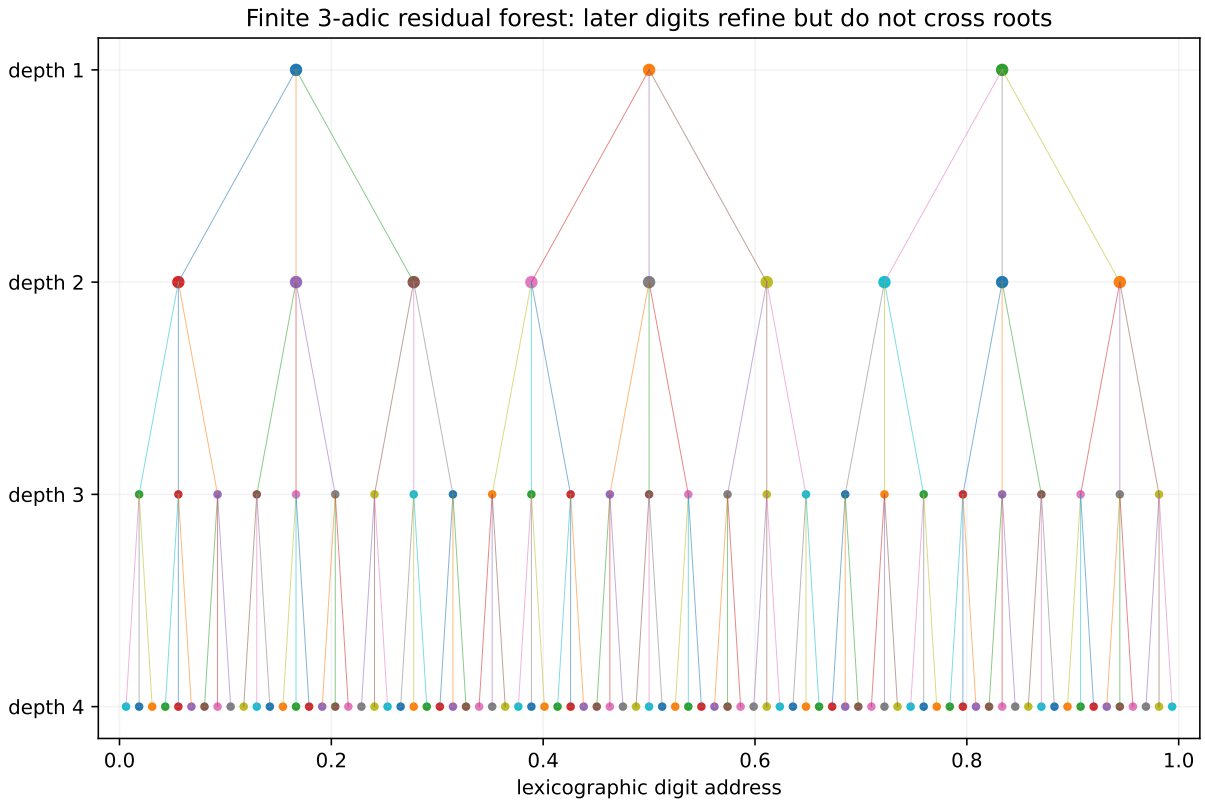

Figure 3. The first four levels of a full 3-adic digit forest. A path is a compatible finite-depth perturbation stream.

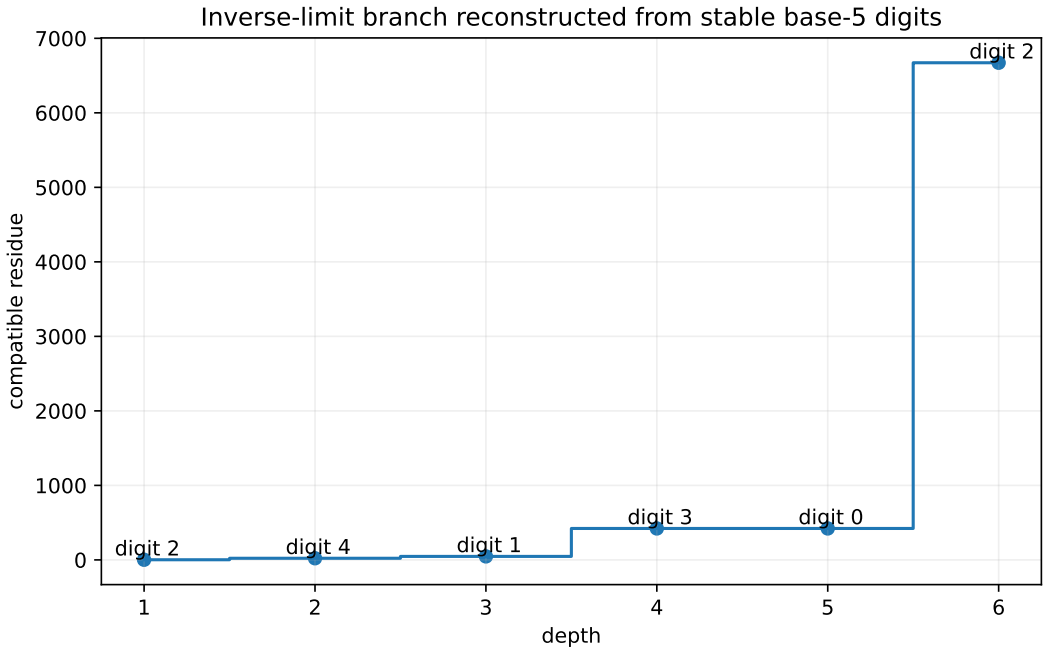

Figure 4. A compatible base-five residue tower reconstructs the digit stream $(2, 4, 1, 3, 0, 2)$.

4 Tangent and obstruction packets

For a residual representation $\bar{\rho}$, first-order deformations and lifting obstructions are classically controlled by cohomology of the adjoint module. The projector calculus does not replace that theory. It resolves the controlling complex into invariant packets when suitable projectors exist.

Classical Input 4.1 (Tangent and obstruction spaces)**.** For a framed representation problem, first-order lifts are described by $Z^1(G, \operatorname{ad}\bar{\rho})$. For an unframed Schur problem, tangent directions are described by $H^1(G, \operatorname{ad}\bar{\rho})$. Relations in a presentation of a deformation ring map into $H^2(G, \operatorname{ad}\bar{\rho})$, which contains the obstruction classes.

Let

$$C^0 \xrightarrow{d_0} C^1 \xrightarrow{d_1} C^2 \to \cdots$$

be a cochain complex over a field. Suppose a finite family of projectors $P_j^r : C^r \to C^r$ satisfies

$$\sum_j P_j^r = I, \qquad P_i^r P_j^r = \delta_{ij} P_j^r, \qquad d_r P_j^r = P_j^{r+1} d_r.$$

Theorem 4.2 (Cohomology packet decomposition)**.** *Under these hypotheses, each packet is a subcomplex and*

$$\boxed{H^r(C^\bullet) \cong \bigoplus_j H^r(P_j C^\bullet).}$$

In particular,

$$H^1 = \bigoplus_j H^1_j, \qquad H^2 = \bigoplus_j H^2_j,$$

so tangent and obstruction spaces reconstruct exactly from their packet components.

Proof. For each packet, use the actual image submodules $C_j^r = \operatorname{im} P_j^r$. Commutation with the differential makes these a subcomplex. Write

$$Z^r = \ker d_r, \qquad B^r = \operatorname{im} d_{r-1} \subseteq Z^r, \qquad H^r = Z^r / B^r,$$

and define Z_j^r, B_j^r, H_j^r using the restricted differentials of $C_j^\bullet$. The inclusion $i_j : C_j^\bullet \to C^\bullet$ and the image-valued projection $p_j : C^\bullet \to C_j^\bullet$ are cochain maps, so they induce maps on these genuine quotients.

For $i \neq j$, orthogonality gives $H(p_i)H(i_j) = 0$. Idempotence gives $H(p_j)H(i_j) = I$, and completeness gives $\sum_j H(i_j)H(p_j) = I$. Thus the maps

$$[z] \longmapsto ([P_j^r z])_j, \qquad ([z_j])_j \longmapsto \left[\sum_j i_j z_j\right]$$

are inverse linear maps. The finite product equals the direct sum, proving the assertion. In the formalization, both sides are also identified with Mathlib's standard homology objects of the genuine graded complexes. □

Scope of the splitting. The algebraic proof works over any commutative ring and does not divide by 2, so it applies in characteristic two when the stated integral chain projectors exist. It does not construct

those projectors. The identification of a particular Galois tangent or obstruction problem with this cohomology remains the preceding classical input. The splitting detects vanishing:

$$H^r(C^\bullet) = 0 \quad \Longleftrightarrow \quad H^r(C_j^\bullet) = 0 \text{ for every } j.$$

It does not force either side to vanish or decouple nonlinear deformation equations. Moreover, commutation with the differential is essential: complementary idempotents on the underlying vector spaces need not preserve cocycles or coboundaries.

Naturality. If a cochain map $F : C^\bullet \to D^\bullet$ intertwines the supplied projectors, it restricts to maps $F_j : C_j^\bullet \to D_j^\bullet$. The direct-sum decomposition commutes with $H^r(F)$ and the family $H^r(F_j)$. This is checked using representatives in the actual quotients, independently of any dimension computation.

Remark 4.3 (Odd and dyadic nonlinear equations). At odd residue characteristic, a differential graded Lie model may be written in Maurer–Cartan form

$$d\eta + \frac{1}{2}[\eta, \eta] = 0,$$

and a cyclic grading converts this into exact packet convolutions. At residue characteristic two, division by 2 is not integral. A quadratic or divided-square refinement must be retained. This is one reason the dyadic residual forest is weighted rather than obtained by formal substitution into the odd-prime formulas.

Numerical Certificate 4.4 (Finite packet complex)**.** The exact modular test uses two invariant subcomplexes over $\mathbf{F}_5$. Their cohomology dimensions are

$$(0, 0, 0), \qquad (1, 2, 1),$$

and the reconstructed total is

$$\dim(H^0, H^1, H^2) = (1, 2, 1).$$

The packet-sum residual is zero.

An explicit realization of the finite pattern. A separate finite-complex implementation uses

$$\mathbf{F}_5^2 \xrightarrow{d_0} \mathbf{F}_5^4 \xrightarrow{d_1} \mathbf{F}_5^2, \quad d_0(a, b) = (a, 0, 0, 0), \quad d_1(a, b, c, d) = (b, 0).$$

The first packet is the exact complex with dimensions $(1, 2, 1)$, and the second packet has zero differentials and dimensions $(1, 2, 1)$. The actual middle cohomology is linearly isomorphic to $\mathbf{F}_5^2$, which is checked in Lean. Independent exhaustive coset tests check all three cohomology degrees after changes of basis. This realizes the displayed dimension pattern. Its formal check is distinct from the original companion implementation.

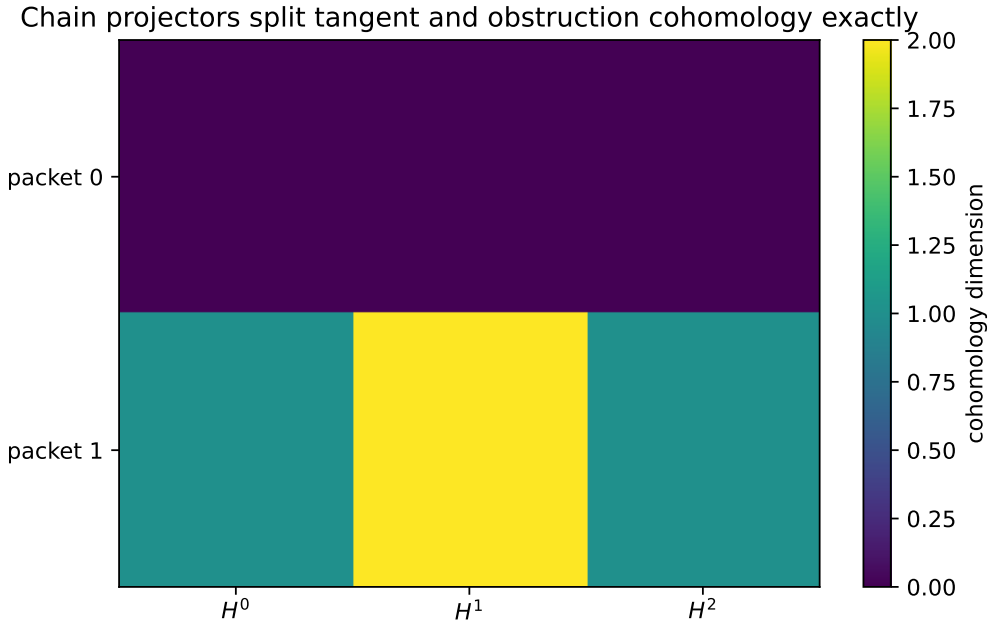

Figure 5. A finite chain-projector model. Tangent and obstruction dimensions are carried by one packet and reconstruct exactly.

5 The weighted dyadic residual forest

At an odd prime, distinct sign characters remain distinct in the residue field. At the coefficient prime two,

$$1 \equiv -1 \pmod 2.$$

Thus distinct characteristic-zero packets can share one residual root and separate only after more precision is retained.

Definition 5.1 (Visibility weight)**.** For two integral packet coordinates $a, b \in \mathcal{O}$, define their separation depth

$$w(a,b) = \min\{m \geq 1 : a \not\equiv b \pmod{\varpi^m}\},$$

when such an m exists. A dyadic packet decomposition is weighted by these first visibility depths and by the valuations of any denominators required by its rational projectors.

Example 5.2 (The two sign branches)**.** The characters $\chi_+(g) = 1$ and $\chi_-(g) = -1$ have the same reduction modulo 2, but

$$1 \not\equiv -1 \pmod 4.$$

Their first separation depth is therefore 2. One mod-two root contains two branches that become distinct at the next level.

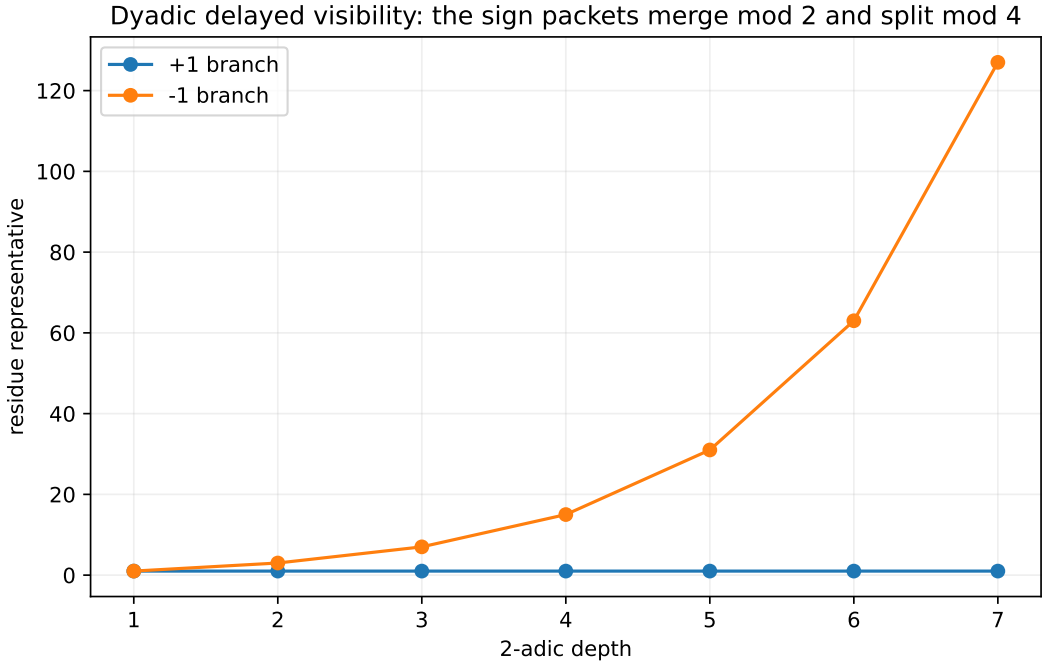

Figure 6. The sign packets merge at residual depth and separate at depth two. This is a genuine change in integral coordinates, not a numerical plotting effect.

A simple weighted formal model already captures delayed visibility. Let $w_i \geq 1$ and constrain

$$t_i \in (\varpi^{w_i}\mathcal{O} + \varpi^m\mathcal{O})/\varpi^m\mathcal{O}.$$

Then coordinate i is invisible until $m > w_i$.

Proposition 5.3 (Weighted smooth-chart count). *For weights $\boldsymbol{w} = (w_1, \ldots, w_d)$,*

$$\boxed{N_{\boldsymbol{w}}(m) = q^{\sum_{i=1}^{d} \max(m-w_i,0)}.}$$

Proof. The image of $\varpi^{w_i}\mathcal{O}$ in $\mathcal{O}/\varpi^m$ has one element when $m \leq w_i$, and q^{m-w_i} elements when $m > w_i$. Multiplying the independent coordinate counts gives the formula. □

This model does not assert that every dyadic Galois deformation ring is a weighted formal ball. It gives the exact local counting law once such weighted coordinates or a Smith-normal-form chart have been proved.

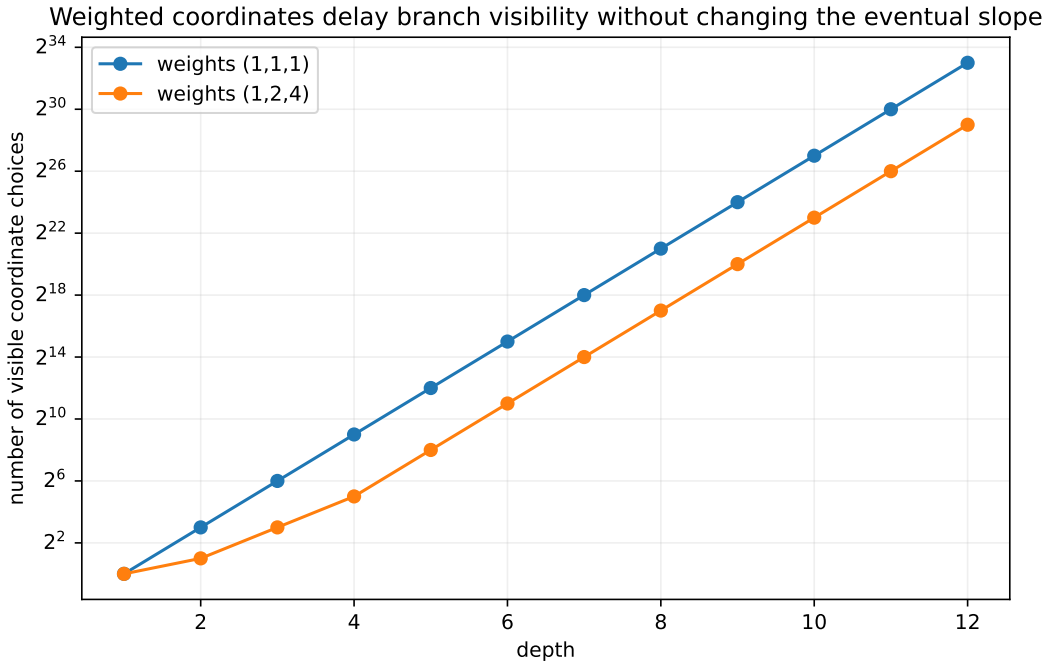

Figure 7. Weights delay finite-depth visibility. Once all coordinates are active, the asymptotic slope equals the ordinary formal dimension.

6 Seed zeta functions and branching dimensions

Finite-depth counts record more than the existence of a branch. They distinguish smooth, weighted, and singular local geometry.

Definition 6.1 (Seed zeta function)**.** For a residual root $\bar{x}$ with finite levels, define

$$\boxed{Z_{\bar{x}}(T) = \sum_{m \geq 1} \#X_m(\bar{x}) T^m.}$$

When a weighted chart is specified, write $Z_{\boldsymbol{w}}(T)$.

Theorem 6.2 (Smooth seed zeta function)**.** *For a smooth formal component of dimension d,*

$$\boxed{Z_d(T) = \frac{T}{1 - q^d T}.}$$

Proof. By the proved formal-model map-to-parameter equivalence, $\#X_m = q^{d(m-1)}$ counts all the actual local coefficient-algebra maps. Summing the geometric series gives the identity. The checked statement is an equality of infinite formal power series, with zero constant coefficient. □

Theorem 6.3 (Weighted seed zeta function)**.** *Let $1 \leq w_1 \leq \cdots \leq w_d$, put $W = \sum_i w_i$, and let*

$$a_m = q^{\sum_i \max(m - w_i, 0)}.$$

Then

$$\boxed{Z_{\boldsymbol{w}}(T) = \sum_{m=1}^{w_d} a_m T^m + q^{-W} \frac{(q^d T)^{w_d+1}}{1 - q^d T}.}$$

In particular, every weighted smooth chart has a rational seed zeta function.

Proof. The finite sum records the depths before all coordinates are active. For $m \geq w_d + 1$,

$$a_m = q^{dm-W},$$

so the remaining terms form one geometric series. □

Theorem 6.4 (Singular power seed)**.** *For integers $e \geq 1$ and $m \geq 1$, in $\mathcal{O}/\varpi^m$ the equation*

$$x^e = 0$$

has exactly

$$\boxed{q^{m-\lceil m/e \rceil}}$$

solutions. Its seed zeta function is

$$\boxed{Z_e(T) = \frac{\sum_{r=1}^{e} q^{r-1} T^r}{1 - q^{e-1} T^e}.}$$

Proof. The congruence is equivalent to

$$e\, v_\varpi(x) \geq m,$$

so x must lie in $\varpi^{\lceil m/e \rceil}\mathcal{O}/\varpi^m$, which has the stated cardinality. Write $m = ek + r$, $1 \leq r \leq e$. The exponent becomes $(e-1)k + r - 1$. Summing over $k \geq 0$ and $1 \leq r \leq e$ gives the rational expression. □

Definition 6.5 (Branching dimension)**.** When the limit exists, define the finite-level counting exponent

$$\dim_{\mathrm{seed}}(\bar{x}) = \lim_{m \to \infty} \frac{\log_q \#X_m(\bar{x})}{m}.$$

A limsup may be used in general.

Corollary 6.6 (Fractional singular dimension)**.** *For $x^e = 0$,*

$$\boxed{\dim_{\mathrm{seed}} = 1 - \frac{1}{e}.}$$

In particular, $x^2 = 0$ has branching dimension $1/2$.

Counting exponent versus compatible branches. *The preceding exponent counts all finite-level solutions, including nodes which cannot lift indefinitely. It is not the cardinality or dimension of the space of infinite branches. In fact every compatible tower of solutions to $x^e = 0$, for $e \geq 1$, is the zero tower. For each m, a solution at depth em lies in $\varpi^m\mathcal{O}/\varpi^{em}$. Its reduction at depth m is therefore zero. Compatibility proves the assertion at every depth. The formal companion identifies proofs of both this observation and the real logarithmic limit.*

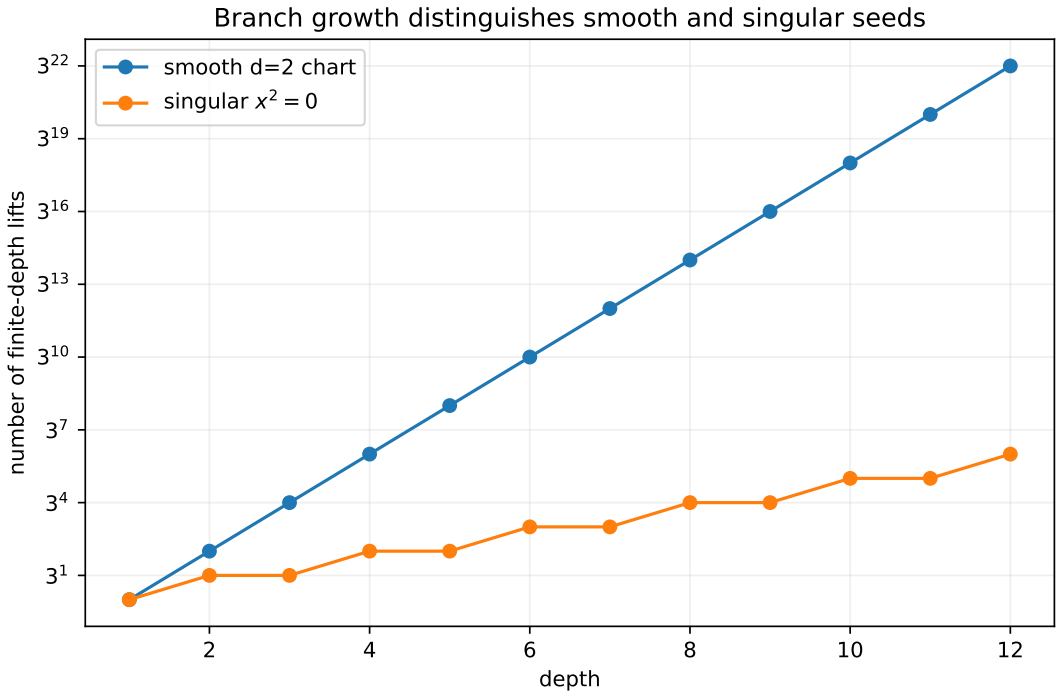

Figure 8. A smooth two-dimensional formal chart and the singular equation $x^2 = 0$ have visibly different exponential growth.

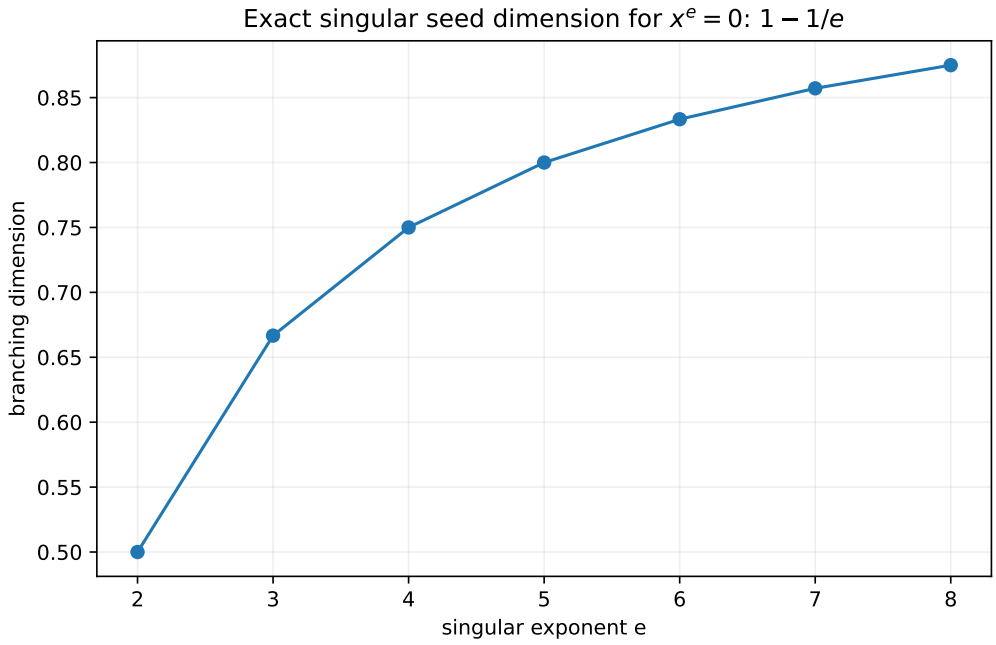

Figure 9. The finite-depth branching dimension of $x^e = 0$ is $1 - 1/e$, giving a family of fractional local growth exponents.

7 Residual transport categories

Vertical lifting never changes a residual root. Horizontal coverage requires operations whose residual effect is not congruent to the identity. Examples that may define such transports include twisting, duality, restriction, induction, tensor product, symmetric powers, exterior powers, and functorial transfer. The word "may" is essential: each operation must preserve the deformation conditions and the realization statement being transported.

Definition 7.1 (Admissible residual transport)**.** An admissible transport from $\bar{\rho}$ to $\bar{\rho}'$ consists of

$$\mathcal{T} : \bar{\rho} \longmapsto \bar{\rho}'$$

together with natural maps

$$\mathcal{T}_A : \mathrm{Def}_{\bar{\rho}}(A) \longrightarrow \mathrm{Def}_{\bar{\rho}'}(A)$$

for every coefficient algebra A, compatible with base change and reduction. When the transport is reversible, it is an isomorphism in the residual transport groupoid. One-way operations give a directed category.

For a finite collection of roots, record a directed edge $u \to v$ whenever occupancy or the relevant property is known to propagate from u to v.

Definition 7.2 (Directed seed rank)**.** For a directed transport graph G, define

$$\mathrm{srank}_G = \min\{|S| : \mathrm{Cl}_G(S) = V(G)\},$$

where $\mathrm{Cl}_G(S)$ is the set of vertices reachable from S.

Theorem 7.3 (Directed minimum-seed theorem)**.** *Let G be a finite directed graph. Collapse every strongly connected component to one vertex, obtaining the condensation DAG. Then*

$$\boxed{\mathrm{srank}_G = \#\{\textit{source strongly connected components of } G\}.}$$

One representative from each source component is a minimum seed set.

Proof. Every vertex of a finite DAG is reachable from a source, so one seed in each source component reaches the entire condensation graph. Within a strongly connected component, one vertex reaches every other. Hence the source representatives are sufficient.

Conversely, a source component has no incoming edge from another component. It cannot be reached from a seed outside itself, so every generating seed set must meet it. Therefore the number of source components is also a lower bound. □

For reversible transports the condensation has one vertex per connected component, recovering the undirected minimum-seed theorem.

Formal scope and propagation. Reachability is the reflexive-transitive closure of the supplied directed edge relation, and a strongly connected component is the actual quotient by mutual reachability. The minimum seed count is defined independently as the least cardinality of a set that reaches all vertices. Every covering set must meet every source component. Conversely, meeting every source component suffices in a finite graph. Thus any choice of one representative from each source is optimal. Empty

graphs have rank zero, and self-loops are permitted. Adding admissible edges cannot increase the minimum seed count.

If a property P propagates along every supplied edge and holds at all selected seeds, it holds at every reached vertex. These are explicit hypotheses. The minimum-seed theorem does not construct valid arithmetic edges or supply initial occupancy.

Why the finite hypothesis cannot be dropped. Take vertices $\{*\} \sqcup \{v_n : n \in \mathbf{N}\}$, with $*$ isolated and edges $v_{n+1} \to v_n$. Every strongly connected component is a singleton, and $\{*\}$ is the unique source component. No finite seed set covers all vertices: it can reach only indices no larger than the largest chosen index. Both the unique-source statement and the failure of every finite cover are checked in Lean. Hence one source component in an infinite condensation does not imply that one seed reaches all objects.

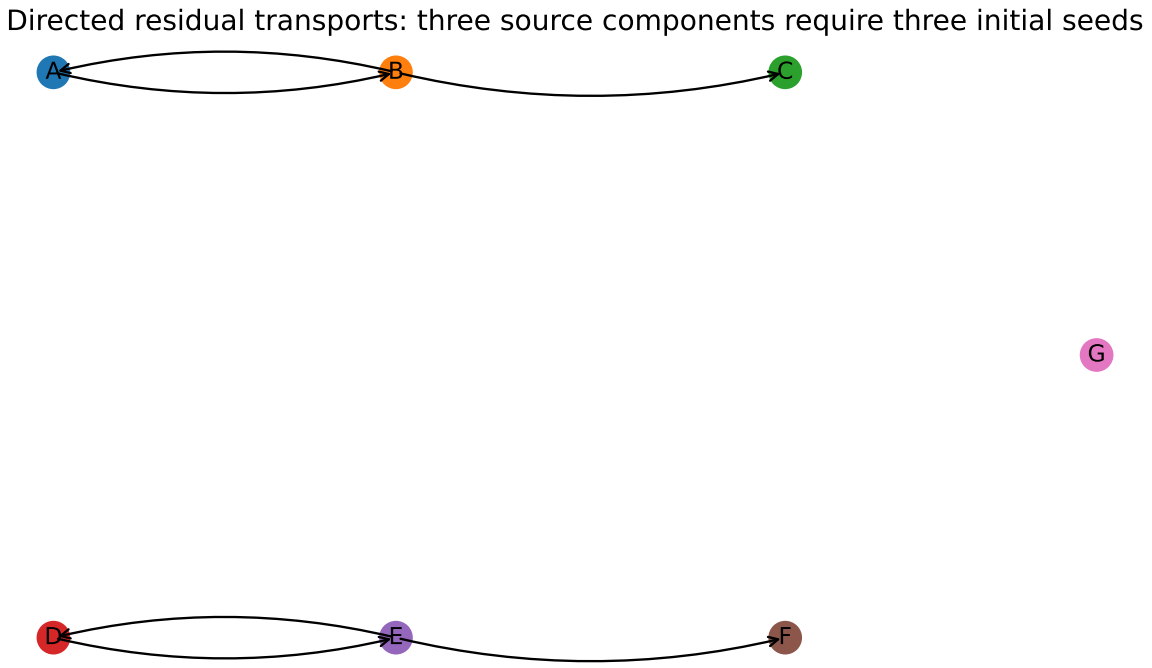

Figure 10. A finite directed transport model. The components $\{A, B\}$, $\{D, E\}$, and $\{G\}$ are sources. C and F are reached downstream.

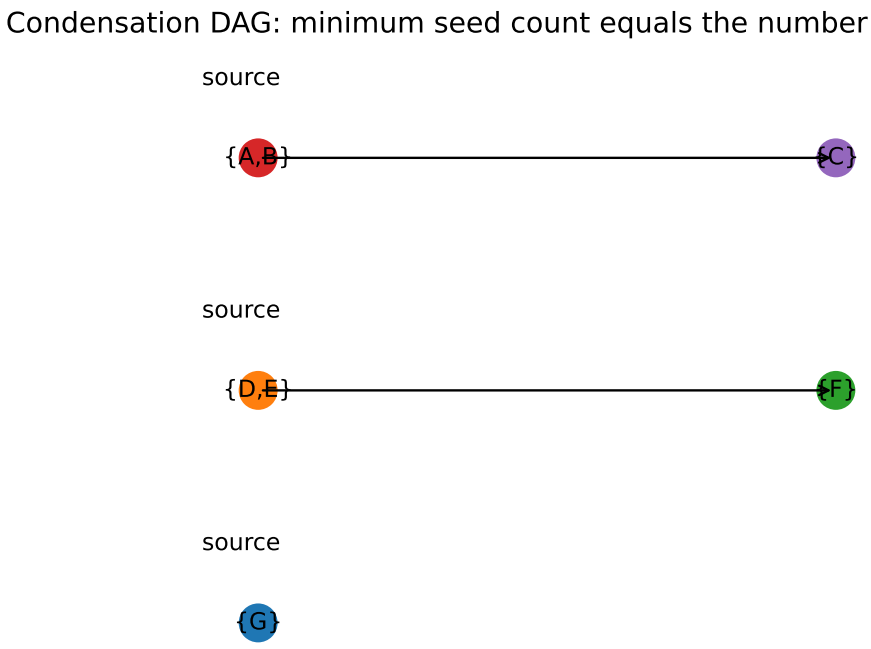

Figure 11. The condensation DAG makes the minimum seed count visible without searching every subset of roots.

Numerical Certificate 7.4 (Directed seed count)**.** The test graph has five strongly connected components and three source components. The theorem gives seed rank three. Exhaustive search over every subset of vertices independently returns three, and the selected representatives reach all seven roots.

An explicit realization of the directed graph. An independently specified graph has vertices A, B, C, D, E, F, G and the eight edges

$$A \to B,\ B \to A,\ B \to C,\ C \to F,\ D \to E,\ E \to D,\ E \to F,\ G \to F.$$

The source components are $\{A, B\}$, $\{D, E\}$, and $\{G\}$. The other components are $\{C\}$ and $\{F\}$. A bounded path search to length three is proved closed under every original edge, which certifies equality with unbounded reachability. The resulting label certificate is identified with the actual quotient by mutual reachability. Lean checks seed rank three and exactly the four minimum sets

$$\{A, D, G\}, \quad \{A, E, G\}, \quad \{B, D, G\}, \quad \{B, E, G\}.$$

Independent exact tests enumerate every directed graph on zero through four vertices, including loops, and every seed subset. These finite tests audit the implementation. The universal theorem is a separate formal proof.

8 Prime-independent system seeds

A compatible system should not be treated as an unrelated collection of λ-adic roots. Its members share algebraic Frobenius polynomials, Hodge–Tate data, determinant information, and local Weil–Deligne packets.

Definition 8.1 (Common arithmetic spine)**.** Let M be a number field. A common spine $\mathfrak{C}$ consists of:

- characteristic polynomials $P_v(X) \in M[X]$ at almost all places;
- coefficient-prime independent weight and determinant data;
- prescribed local Weil–Deligne or inertial packet labels at the ramified places.

For each finite place λ of M, let

$$X_{\lambda,m}(\mathfrak{C})$$

be the finite set of admissible objects modulo ϖ_λ^m realizing the reduction of this spine.

The system seed is the fibered object

$$\boxed{\mathscr{S}_{\mathrm{sys}} = \mathscr{S}_2^{\mathrm{wt}} \times_{\mathfrak{C}} {\prod_{\lambda\nmid 2}}' \mathscr{S}_\lambda.}$$

The fiber product notation states a compatibility requirement. It does not prove that every fiber is nonempty.

Theorem 8.2 (Adelic finite-depth completion)**.** *Assume:*

1. *an algebraic common spine $\mathfrak{C}$ over a number field M is fixed;*
2. *for every finite place λ of M and every $m \geq 1$, the companion level $X_{\lambda,m}(\mathfrak{C})$ is finite and nonempty;*
3. *the reduction forests are finitely branching;*
4. *the selected local conditions are closed under inverse limits.*

Then for every λ there is an infinite compatible branch

$$\rho_\lambda \in \varprojlim_m X_{\lambda,m}(\mathfrak{C}),$$

and the collection $\{\rho_\lambda\}_\lambda$ realizes the prescribed strictly compatible spine.

Proof. Finite-branch compactness gives an infinite branch in every coefficient-prime forest. Inverse-limit closure gives an admissible λ-adic object. By definition each finite level has the prescribed reductions of the common Frobenius and local packets. Equality at every finite precision implies equality in the complete coefficient ring. Thus all members realize the same spine. □

Corollary 8.3 (Residual companion obstruction)**.** *If*

$$X_{\lambda,1}(\mathfrak{C}) = \varnothing$$

for one coefficient prime λ, no compatible completion with spine $\mathfrak{C}$ exists. Deeper perturbations at other primes cannot create the missing residual companion.

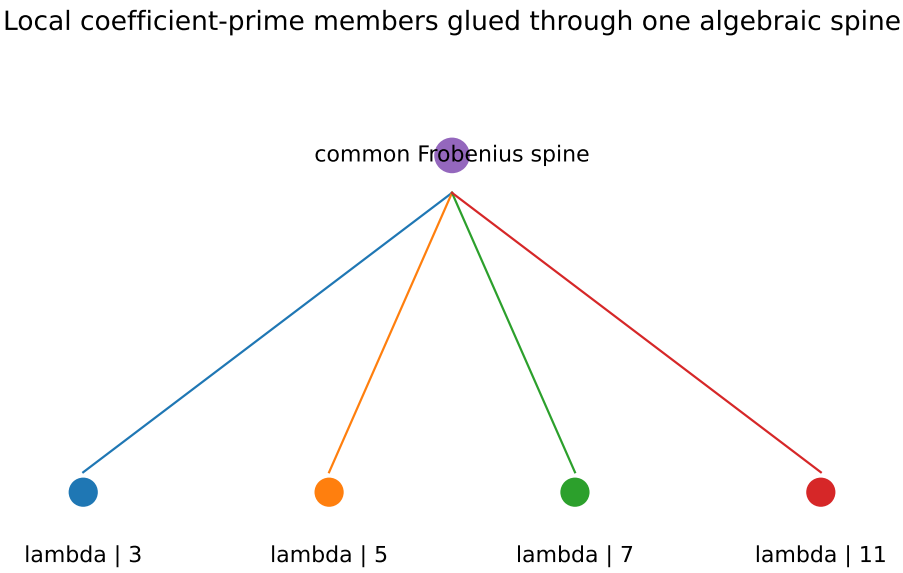

Figure 12. The local members are coordinates of one system only after their finite data descend to a common algebraic spine.

Example 8.4 (A scalar companion failure)**.** For

$$f(x) = x^2 + 1,$$

there are two simple branches at $p = 5$ and $p = 13$, no residual roots at $p = 3$ or $p = 7$, and one root modulo 2 that has no child modulo 4. A complete 5-adic branch therefore does not imply an adelic solution.

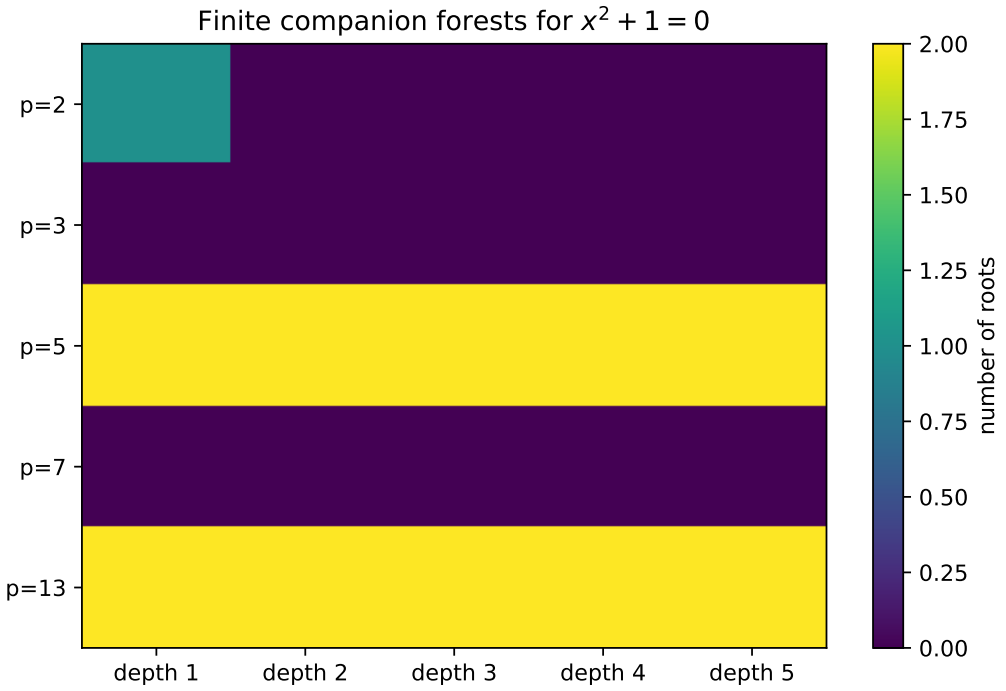

Figure 13. Finite companion levels for $x^2 + 1 = 0$. The obstruction at $2, 3, 7$ is visible before any deep lifting argument begins.

Conditional scope and complete assembly. The theorem above is conditional on the chosen spine and the stated local inverse-limit closure. In the fixed-rank integral representation setting, "closed under inverse limits" means that every compatible family of admissible finite representation classes, after coherent matrix framing and reconstruction, satisfies the full selected local realization relations. It is not merely closedness of an unrelated label space. Weight and packet relations retain their supplied arithmetic meaning. They are parameters of the universal theorem. For a general moduli functor, effectivity requires its own reconstruction hypothesis or the corresponding full meaning of admissible inverse-limit closure.

The complete Lean assembly now includes the common polynomials, good-place sets with finite complements, coefficient-specific prescribed determinants, and every selected weight and packet relation. Determinants are recovered from their actual finite-class determinants. A single common field-valued character on the whole Galois group is not assumed. The returned representations are continuous, and their reductions form the actual compatible branches. Their common polynomial identities hold at every declared good place, hence almost everywhere for each coefficient prime.

This checks Claim 8.2 as the universal conditional source theorem. The previous partial status also demanded proofs that particular intended arithmetic packets satisfy its premises. That stronger application target is not a conclusion of the theorem. Concrete Hodge–Tate and Weil–Deligne attachments, torsion interpretations, closure instances, and companion nonemptiness remain obligations of arithmetic applications. Inertial-type labels are not upgraded to full Weil–Deligne data.

Checked representation-level completion and its arithmetic boundary. The representation-level completion construction works with actual matrix representations of a fixed group. For a complete separated ring R and ideal I, compatible maps $\rho_m : G \to \mathrm{GL}_d(R/I^m)$ reconstruct a unique integral

representation for that fixed compatible family. Multiplication and inverses are verified after every reduction. If all finite representations are continuous for the discrete quotient topology, the integral representation is continuous for the ideal-adic topology. This does not assert uniqueness among all possible branches of the allowed forest.

The forest has as its level the actual subtype of representations satisfying the declared finite conditions. Those conditions must be preserved by reduction. Finiteness and nonemptiness at every level give an infinite branch and hence an actual continuous representation. Finiteness of the coefficient quotient alone is not a substitute for finiteness of the allowed representation set for an arbitrary source group. Surjectivity of the reductions is not required.

All coefficients of the characteristic polynomial commute with reduction. Consequently, prescribed integral characteristic polynomials at every precision hold exactly in the reconstructed representation. For a common coefficient field E, local integral polynomials lie in $\mathcal{O}_\lambda[X]$ and are compared with $P_v \in E[X]$ only after mapping both into the local coefficient field. No field embedding $E \to \mathcal{O}_\lambda$ is assumed. The allowed-place predicate is explicit and may depend on λ. Trivial action on a supplied subgroup is likewise detected at every precision. Identifying that subgroup with arithmetic inertia is a separate input.

The eleventh block assembles continuous coefficient-field representations, exact common polynomials and the prescribed local predicate from positive finite depths. Depth-zero finiteness and nonemptiness are derived. Claims 8.2 and 11.1 already assume inverse-limit closure of the selected local conditions. An unconditional closure theorem is not a missing hypothesis of their conditional proofs. Their conditional matrix core is checked. The remaining full arithmetic interpretation must identify the admissible finite objects and the actual local invariants with these data. The coherent-framing obligation is resolved by the completion from conjugacy classes below. An arbitrary local predicate is not being renamed Hodge–Tate or Weil–Deligne compatibility.

Completion from conjugacy classes. Over an I-adically complete separated commutative coefficient ring R, for a fixed finite rank, the formalization now takes finite-level objects to be actual matrix representations modulo conjugation by an invertible matrix. Assume the coefficient quotients R/I^k are finite. Conjugation commutes with coefficient reduction, and each conjugacy class has finitely many frames over a finite coefficient ring. Thus finite allowed class levels give finite full preimages of allowed matrix representations. Downward admissibility and positive-depth nonemptiness yield an exactly compatible matrix branch and an actual integral representation. More strongly, every prescribed compatible class branch has such representatives, using finite nonempty fibers over that branch. No surjectivity of reductions or lifting of prescribed change-of-basis matrices is assumed. This does not assert uniqueness up to integral conjugacy.

For finitely generated I with finite R/I, finiteness of R/I^k is derived. One continuous representative per allowed class suffices, because continuity is proved invariant under conjugation. Characteristic polynomials, determinants and trivial action on a supplied subgroup are likewise actual invariants. The unframed common-spine theorem constructs continuous coefficient-field representations with the prescribed whole polynomials and the explicitly supplied inverse-limit-closed local predicate.

An actual $\mathbb{Z}_3$ example applies the class-level completion theorem for the cyclic group of order two and polynomial $X^2 - 1$, producing a nonidentity generator. Another checked example has compatible classes represented by $\mathrm{diag}(1, -1)$ modulo 3 and $\mathrm{diag}(-1, 1)$ modulo 9: these chosen matrices disagree under reduction, and an actual swap of basis repairs them. Arbitrary independent representatives therefore do not replace the framing argument.

The framing obligation is finished. Identifying the manuscript's arithmetic admissible objects, actual local invariants and finite-level packet reductions with this interface remains separate. An uninterpreted local predicate is not a construction of Hodge–Tate or Weil–Deligne compatibility. The source's local closure hypothesis remains explicit. The conditional completion construction completes the universal conditional implication. These particular arithmetic applications remain unproved.

Actual local comparisons from fixed-depth certificates. Let R be an I-adically complete separated commutative ring with finite coefficient quotients and an injective map into a field K. Fix a finite matrix rank. For finitely many local group maps $\phi_s : H_s \to G$ and integral template representations τ_s, fix detecting depths d_s. At precision m retain matrices $P_{s,m}$ as part of the admissible object and require

$$\rho_m(\phi_s(h))P_{s,m} = P_{s,m}\tau_{s,m}(h).$$

For $m \geq d_s$ require their determinants to remain nonzero after reduction to R/I^{d_s}. Earlier levels omit that test. Finite occupied augmented levels give a compatible branch of both representations and comparisons. The integral limits satisfy the actual equations and have nonzero determinants, so the comparisons are units over K. A converse supplies all finite nodes from any integral realization with these detectors. Finite-level invertibility and compatible prior choices of comparisons are not assumed.

The unframed positive-depth version also retains continuity and whole common polynomials. Its actual local isomorphisms are derived from the certificates. There is no uninterpreted local-stability predicate for this particular problem. The fixed depths and augmented-level occupancy remain explicit inputs.

The formalization specializes to the actual maps $G_{\mathbb{Q}_p} \to G_{\mathbb{Q}}$ induced by the field embeddings and choices of algebraic closures. A nontrivial continuous quadratic character of $G_{\mathbb{Q}}$, constructed from its action on $i^2 = -1$, gives the integral 2-adic actions

$$\tau(\sigma) = \operatorname{diag}(1,-1), \quad \rho(\sigma) = \begin{pmatrix} 1 & -1 \\ 0 & -1 \end{pmatrix}, \quad P = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$$

at a nonidentity quadratic element. The determinant 2 is detected modulo 4. The representations are conjugate over $\mathbb{Q}_2$ but not integrally conjugate. A separate $\mathbb{Z}_3$ example invokes simultaneous completion and reconstructs a comparison which is an integral nonunit and a field unit.

The bound is substantive: for the unipotent actions $\rho_a(g) = \begin{pmatrix} 1 & ag \\ 0 & 1 \end{pmatrix}$, every integral intertwiner with ρ_1 has determinant aP_{22}^2. Taking $a = \pi^n$ for a nonzero $\pi \in I$ rules out every fixed detecting depth, even though all the field-valued approximants are isomorphic and their integral limit is trivial. This does not refute Claim 8.2, which already assumes inverse-limit closure of its chosen local conditions.

Exact prescribed local Galois action is stronger than an inertial-type label. The common arithmetic packet interpretation, its coefficient comparisons and the actual Hodge–Tate/Weil–Deligne attachment remain separate. The new theorem does not supply a uniform bound for all intended arithmetic packets. Those arithmetic applications remain unfinished. The universal conditional implication is checked in the conditional completion construction.

Derived comparison bounds. For a finite group Γ whose order is a unit in a commutative local coefficient ring R, any prescribed equivariant residual isomorphism lifts to an integral isomorphism. Lift its matrix to A and define

$$P = |\Gamma|^{-1} \sum_{g \in \Gamma} \rho(g) A \tau(g^{-1}).$$

Reindexing proves equivariance, and reduction recovers the prescribed matrix. Its determinant is a unit. Complete local coefficients with finite quotients, occupied compatible finite conditions and this residual type therefore give actual integral completion with detector depth one. A fixed continuous map $G \to \Gamma$ permits pullback to infinite source groups. The finite-level representations must factor through the same map, and the residual type is imposed on their Γ-actions. No uniform determinant bound or augmented certificate occupancy is assumed in this sector.

For a second sector let R be a DVR with uniformizer π, fraction field K and matrix rank n. If a fixed template τ has full K-linear action span, finite generation and denominator clearing give a fixed c such that

$$\pi^c M_n(R) \subseteq \operatorname{span}_R\{\tau(g) : g \in G\}.$$

Normalize a field comparison to an integral P with a unit entry. The displayed span constructs an integral B with $BP = \pi^c I$, so

$$\det P \mid \pi^{cn}, \qquad \det P \not\equiv 0 \pmod{\pi^{cn+1}}.$$

One c works for all integral representations in the fixed field-isomorphism class. Jacobson density derives full span from actual irreducibility and a scalar commutant. The formalization states these hypotheses directly and does not assume the DVR fraction field is algebraically closed.

If at every precision there is an integral representation of this rational type satisfying the finite conditions, the derived bound supplies the simultaneous certificates of the fixed-depth comparison-certificate construction and preserves the type after completion. The integral approximants are not required to be coherent, but their existence is a substantive premise. Arbitrary torsion nodes are not asserted to lift.

Over $\mathbb{Z}_3$, the actual average corrects $A = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ to $P = \left(\begin{smallmatrix} 1 & -1/2 \\ 0 & 1 \end{smallmatrix}\right)$ for the involutions $\rho(g) = \left(\begin{smallmatrix} 1 & 1 \\ 0 & -1 \end{smallmatrix}\right)$ and $\tau(g) = \operatorname{diag}(1, -1)$. It preserves the residual comparison and has determinant one. Pullback through the quadratic character of the actual $G_{\mathbb{Q}}$ gives continuous arithmetic examples. In contrast, the identity and $\operatorname{diag}(1, \operatorname{sign})$ over $\mathbb{Z}/4$ agree modulo two but are not integrally conjugate. Their group order is not a unit. These restricted results do not supply general arithmetic packet attachment, all finite-level existence statements, or cross-coefficient compatibility.

9 Compatible carriers and finite Frobenius separation

One useful completion mechanism is available when the desired packet already occurs as a semisimple summand of a known compatible carrier.

Theorem 9.1 (Finite Frobenius separation). *Let $\mathscr{W}_1, \dots, \mathscr{W}_r$ be pairwise nonisomorphic strictly compatible systems whose members are absolutely irreducible, with common algebraic unramified trace values $t_i(v)$ in a number field E. There are r distinct permitted unramified places $v_1, \dots, v_r$ for which*

$$C = (t_i(v_j))_{j,i} \in M_r(E), \qquad \det C \neq 0.$$

Every coefficient-field embedding $\sigma_\lambda : E \hookrightarrow E_\lambda$ therefore sends C to an invertible matrix. Its entries agree with the ordinary representation traces $\mathrm{Tr}(W_{i,\lambda}(\mathrm{Frob}_{v_j}))$ when the selected places satisfy the unramified compatibility convention for that coefficient prime. In particular, places above the residue characteristic of λ are excluded from this ordinary trace comparison.

Proof. Fix one coefficient prime. The classical independence of the characters of pairwise nonisomorphic absolutely irreducible representations and the density of unramified Frobenius conjugacy classes give independent restricted trace functions. Density here concerns the union of the conjugacy classes, not an unsupported assertion about a set of chosen representatives.

For r independent functions, their evaluation linear forms span the r-dimensional coefficient dual: a proper span would leave a nonzero coefficient vector annihilated by every evaluation, contradicting independence. Choose a basis from the evaluations. Its r distinct sample points give an invertible square matrix. The common algebraic traces put that matrix over E. An injective field embedding reflects the nonvanishing of its determinant. All further field embeddings preserve the same nonvanishing. □

Formalization boundary. Characteristic-zero independence is now Lean-checked for actual finite-dimensional irreducible representations of arbitrary monoids. Finiteness of the group and algebraic closedness of the field are not needed for this result. The proof uses the actual monoid algebra and Jacobson density to select constituent actions. Jointly continuous coordinate actions have continuous characters. Coverage in every open normal quotient of a compact totally disconnected group implies density of the conjugacy-saturated samples and hence the finite separator. General arithmetic Frobenius coverage remains unformalized. The system-isomorphism and finite-cyclotomic comparison now proves the bridge from componentwise nonisomorphic systems to nonisomorphic members at the selected coefficient prime, under density on the required good-place overlaps. It also proves the complete restricted separator for a fixed finite cyclotomic Galois group over $\mathbf{Q}$, with arithmetic coverage derived from the proved Dirichlet theorem. The full arithmetic theorem remains partial. Selection is existential and gives no effective upper bound on the selected primes. A common algebraic matrix is still distinct from an ordinary unramified trace comparison at all coefficient primes simultaneously.

System isomorphism and good-place overlaps. The system equivalence used here is componentwise representation isomorphism:

$$\mathscr{W}_i \simeq \mathscr{W}_j \quad \Longleftrightarrow \quad \forall \lambda,\ W_{i,\lambda} \simeq W_{j,\lambda}.$$

For finite-dimensional irreducible representations of any monoid over a characteristic-zero field, the new character-rigidity theorem proves that equality of characters is equivalent to an actual equivariant linear isomorphism. Neither a finite group nor an algebraically closed coefficient field is needed.

Suppose two members are isomorphic at λ_0. Injectivity of the common coefficient embedding gives $t_i(v) = t_j(v)$ at every place good for λ_0. At another coefficient prime λ, this equality compares actual member traces on the intersection of the two good-place sets. Conjugacy density of that intersection and continuity extend the equality to the whole group. Character rigidity then gives an actual isomorphism at λ. Thus the nonisomorphism of systems supplies the required nonisomorphism of members. Equality of optional labels or record fields is not used as a substitute for representation equivalence.

The generic separator now derives this bridge and permits any additional finite set of excluded places. Its coverage premise retains every finite deletion: for each finite excluded set and each open normal quotient, every quotient class contains a conjugate of an allowed sample. This implies density

on each pair of cofinite good-place sets. No all-coefficient-prime common ordinary-trace domain is assumed.

Arithmetic coverage for a fixed cyclotomic extension. Let $n > 0$ and let $L = \mathbf{Q}(\zeta_n)$ be a cyclotomic number field. The canonical isomorphism

$$\mathrm{Gal}(L/\mathbf{Q}) \simeq (\mathbb{Z}/n\mathbb{Z})^\times$$

defines σ_p by $\sigma_p(\zeta_n) = \zeta_n^p$ when $p \nmid n$. For every automorphism σ, finite set $B \subset \mathbb{N}$ and bound b, Lean proves that there is a rational prime $p > b$, with $p \notin B$ and $p \nmid n$, such that $\sigma_p = \sigma$. The prime-existence step uses the proved Dirichlet theorem in the pinned Mathlib dependency.

The arithmetic attachment is checked in this finite cyclotomic case. There is an actual maximal prime $\mathfrak{P}$ of $\mathcal{O}_L$ above (p), its ramification index is one, and σ_p belongs to its decomposition group. For every integral $x \in \mathcal{O}_L$,

$$\overline{\sigma_p(x)} = \overline{x}^{\,p} \quad \text{in } \mathcal{O}_L/\mathfrak{P}.$$

The residue identity is proved on all integral elements using $\mathcal{O}_L = \mathbb{Z}[\zeta_n]$. Existence of $\mathfrak{P}$ is obtained by lying over, rather than assumed. This specifies arithmetic Frobenius, with p-power residue action. The action and unramifiedness statements also hold for every maximal prime above the selected p.

Consequently, for pairwise componentwise nonisomorphic compatible irreducible representation families of this fixed finite Galois group, the common algebraic trace matrix can be selected at distinct rational primes outside any prescribed finite set, with nonzero determinant. Every coefficient embedding preserves its nonvanishing. Actual member trace comparisons retain that member's good-prime condition. No coverage or character-continuity hypothesis is added in this cyclotomic specialization: the prime coverage is proved, and the finite extension's Krull topology is discrete. A concrete conductor-four instance uses the actual field $\mathbf{Q}(\zeta_4)$.

This is a complete restricted arithmetic case of Claim 9.1. It does not establish coverage in arbitrary finite quotients of the absolute Galois group, nor the Hodge–Tate and Weil–Deligne comparisons of Claim 9.2. The source-claim ledger therefore remains seventeen checked and three partial.

Absolute Galois restriction and arithmetic witnesses. Fix a cyclotomic number field $L = \mathbf{Q}(\zeta_n)$ with $n > 0$ and an embedding $j : L \hookrightarrow \overline{\mathbf{Q}}$. The new restriction map

$$q_L : G_{\mathbf{Q}} \longrightarrow \mathrm{Gal}(L/\mathbf{Q}), \qquad j(q_L(\gamma)x) = \gamma(j(x)),$$

is an actual continuous surjective homomorphism with open kernel. Surjectivity is derived by extending automorphisms to the algebraic closure. Pullback along a surjective homomorphism preserves and reflects equivariant linear isomorphisms, invariant subspaces, and irreducibility. These assertions keep the underlying linear maps and submodules and do not assume a finite acting group. In particular, the equivalence relation for systems is preserved and reflected componentwise.

The arithmetic witnesses use the integral closure $\mathcal{A}$ of $\mathbb{Z}$ in $\overline{\mathbf{Q}}$. For each rational prime p, Lean constructs a maximal ideal $\mathfrak{Q}$ of $\mathcal{A}$ above (p) and an actual element $\gamma_p \in G_{\mathbf{Q}}$ such that

$$\gamma_p \in \mathrm{Stab}_{G_{\mathbf{Q}}}(\mathfrak{Q}), \qquad \overline{\gamma_p(a)} = \overline{a}^{\,p} \quad (a \in \mathcal{A}).$$

The existence argument applies Mathlib's proved profinite stabilizer-surjectivity theorem to this actual invariant ring. The residue p-power map is proved bijective by taking p-th roots in $\overline{\mathbf{Q}}$ and showing

that they remain integral when their p-th powers are integral. This constructs an arithmetic Frobenius witness in the prime-ideal decomposition group. It does not assert that an arbitrary global lift belongs to that group.

When $p \nmid n$, the comparison with the finite cyclotomic sample is proved:

$$q_L(\gamma_p) = \sigma_p, \qquad \sigma_p(\zeta_n) = \zeta_n^p.$$

Reduction distinguishes n-th roots of unity at such a prime. Indeed, if $x^n = y^n = 1$ and their reductions agree, the factorization of $x^n - y^n$ gives

$$(x - y) \sum_{i=0}^{n-1} x^i y^{n-1-i} = 0.$$

The second factor reduces to $n\overline{y}^{n-1} \neq 0$, so the domain property gives $x = y$. This proves both Frobenius recognition on the cyclotomic generator and triviality of its inertia action. Consequently, every representation pulled back through q_L is unramified there.

The valuation formulation is checked separately. For any valuation subring $A \subset \overline{\mathbf{Q}}$ with residue characteristic $p \nmid n$, its actual residue-action kernel fixes every n-th root of unity. A supplied element of its decomposition subgroup with p-power residue action restricts to σ_p. These statements use Mathlib's valuation inertia and decomposition subgroups. No identification of the valuation and integral-closure prime models is assumed in the formal comparison.

For a compatible family $\rho_{i,\lambda}$ of representations of the fixed finite group, set $V_{i,\lambda} = \rho_{i,\lambda} \circ q_L$. Suppose the actual absolute-Galois members are irreducible and the systems are pairwise componentwise nonisomorphic. The finite prime separator now yields distinct permitted rational primes p_j, actual prime ideals $\mathfrak{Q}_j$ and arithmetic Frobenius witnesses γ_j as above, outside any prescribed finite set, such that the common algebraic trace matrix has nonzero determinant. Every coefficient embedding preserves this nonvanishing, and

$$\iota_\lambda(t_i(p_j)) = \operatorname{tr}(V_{i,\lambda}(\gamma_j))$$

whenever p_j is good for that coefficient member. The operator and trace values agree for every global lift with the same cyclotomic restriction. Neither Frobenius-witness existence nor quotient coverage is a supplied hypothesis in this restricted arithmetic theorem. The common cyclotomic factorization and the compatible trace data remain explicit hypotheses.

This completes the passage to actual absolute-Galois Frobenius witnesses for the fixed cyclotomic class. It does not establish prime coverage for arbitrary finite Galois extensions. Claim 9.1 therefore remains partial, and the source ledger remains seventeen checked and three partial.

The boundaries are formalized as well. Pullback along a nonsurjective homomorphism can make inequivalent irreducible representations isomorphic. Samples can cover one quotient while missing an open quotient of the full group. Finally, in $\mathbb{Z}_2$, the distinct square roots 1 and -1 have the same residue, so the condition that the root order be a unit cannot be discarded.

General finite-field Frobenius comparison. Let $L/\mathbf{Q}$ now be any finite normal number field, with a chosen embedding $j : L \hookrightarrow \overline{\mathbf{Q}}$. Write $\mathcal{A}$ for the integral closure of $\mathbb{Z}$ in $\overline{\mathbf{Q}}$. The embedding restricts to an injective map $\mathcal{O}_L \to \mathcal{A}$ which intertwines the actual Galois actions. If $\mathfrak{Q} \subset \mathcal{A}$ is maximal above (p), its contraction $\mathfrak{P} \subset \mathcal{O}_L$ is a nonzero maximal ideal above (p), and the induced residue map is injective.

Restriction carries the actual decomposition group at $\mathfrak{Q}$ into that at $\mathfrak{P}$, carries ideal inertia into ideal inertia, and preserves the arithmetic p-power residue action. Thus the absolute Frobenius constructed in the absolute-Galois restriction construction gives a simultaneous finite Frobenius at the contracted prime. This assertion applies to arbitrary finite normal number fields and does not require a cyclotomic generator.

The exceptional primes are controlled by the actual field discriminant:

$$S_L = \{p \text{ rational prime} : p \mid \operatorname{disc}(L)\}.$$

This set is finite. For $p \notin S_L$, every prime of $\mathcal{O}_L$ above (p) is unramified. Lean proves that the actual inertia cardinality is the ramification index. It follows that inertia is trivial and the arithmetic Frobenius at a fixed finite prime is unique as a field automorphism. Neither trivial inertia nor uniqueness is assumed in place of the arithmetic unramifiedness condition.

The choice of absolute prime and Frobenius lift is also controlled. Let $(\mathfrak{Q}_u, \gamma_u)$ and $(\mathfrak{Q}_v, \gamma_v)$ be any two actual arithmetic witnesses at the same rational prime. Transitivity on primes of $\mathcal{A}$ above (p) gives $a \in G_{\mathbf{Q}}$ with

$$\mathfrak{Q}_v = a\mathfrak{Q}_u, \qquad \gamma_v^{-1} a \gamma_u a^{-1} \in I_{\mathfrak{Q}_v}.$$

Consequently, any representation trivial on $I_{\mathfrak{Q}_v}$ has the same trace on the two witnesses. For representations factoring through L, triviality on this actual absolute inertia is derived whenever $p \notin S_L$. The restrictions of all absolute witnesses at such a prime therefore form a single conjugacy class. This conclusion requires only the indicated finite factorization and the discriminant exclusion.

There is a final compatibility between embeddings. For a normal subfield $L \subset \overline{\mathbf{Q}}$, restriction defined through a chosen embedding is conjugate to canonical restriction by one fixed automorphism of L. This identifies their conjugacy classes and lets the arithmetic comparison apply directly to the fixed fields of open normal subgroups of $G_{\mathbf{Q}}$. Those fixed fields are proved to be finite Galois number fields, with the original open normal subgroup as the kernel of restriction.

The remaining prime-existence obligation now has a precise formulation. For every finite Galois subfield L, every finite set B of rational primes, and every $\sigma \in \operatorname{Gal}(L/\mathbf{Q})$, require a prime $p \notin B \cup S_L$ and an actual absolute arithmetic witness γ_p such that

$$q_L(\gamma_p) \sim \sigma.$$

Lean proves that this assertion is equivalent to the cofinite quotient coverage required by the general separator, for any fixed choice of actual Frobenius witnesses. The equivalence derives independence from the witness choices. It does not supply the displayed prime-existence assertion. Arbitrary finite exclusions absorb S_L, and the resulting conditional density theorem preserves the separate good-prime sets of coefficient members. General prime coverage remains unproved, so Claim 9.1 remains partial. The source ledger is still seventeen checked and three partial. This new arithmetic interface has base $\mathbf{Q}$. For the source's general-base instances involving $G_{F,S}$, the analogous actual-prime and norm-power Frobenius attachment and coverage over F, or a proved transfer to the rational-base result, also remain necessary.

Finite deletion can destroy density. In the actual discrete group $C_2 = \{1, a\}$, set $s(0) = a$ and $s(m+1) = 1$. The original samples are surjective and satisfy quotient coverage. Removing index zero leaves only the identity, so both density and quotient coverage fail. The actual rational sign and trivial

characters agree on the remaining samples but differ globally. This checked example explains why ordinary coverage alone cannot justify deleting the bad places in the system comparison.

Theorem 9.2 (Compatible-carrier summand completion)**.** *Suppose a semisimple strictly compatible carrier decomposes as*

$$\mathscr{W} \cong \bigoplus_{i=1}^{r} \mathscr{W}_i^{\oplus c_i},$$

with the $\mathscr{W}_i$ as above. At one coefficient prime λ_0, suppose a semisimple summand has the form

$$V_{\lambda_0} \cong \bigoplus_{i=1}^{r} W_{i,\lambda_0}^{\oplus m_i}, \qquad 0 \le m_i \le c_i.$$

Then

$$\boxed{V_\lambda = \bigoplus_{i=1}^{r} W_{i,\lambda}^{\oplus m_i}}$$

defines a strictly compatible summand at every coefficient prime. The vector (m_i) is uniquely recoverable from finitely many Frobenius traces supplied by the separation theorem.

Proof. Use the same multiplicities in every member of the compatible carrier. Direct sums preserve strict compatibility, and $m_i \le c_i$ makes V_λ a summand of W_λ. At the separating places, the target trace vector is $C\boldsymbol{m}$. Full column rank makes $\boldsymbol{m}$ the unique solution. □

Recovery and realization are different steps. For a certified square separator the coefficient vector is $C^{-1}t$. This is a valid carrier multiplicity vector only when every entry is a nonnegative integer and satisfies its capacity bound $m_i \le c_i$. Those tests and uniqueness of natural multiplicities in characteristic zero are separately Lean-checked, as is transport through a field embedding. Reduction modulo a residue characteristic is not a field embedding and may lose rank. The representation construction and common-polynomial part are now Lean-checked as described below. The full strictly compatible arithmetic statement, including its local conditions, remains partially formalized.

Scope of the supplied-carrier hypothesis. Claim 9.2 supplies the compatible carrier, its decomposition and the compatible constituent systems. Constructing unknown such objects is not required by that conditional theorem. The remaining formal obligation is that finite sums preserve the intended actual local arithmetic structures, together with the arithmetic separator input. The algebraic monodromy results below do not by themselves identify attached Weil–Deligne representations or Hodge–Tate comparison data.

Explicit summands inside a supplied decomposition. Let K be a field, let G be a monoid, and let $\rho_i : G \to \mathrm{End}_K(W_i)$ be actual representations on finite-dimensional spaces, indexed by a finite set I. For natural numbers $m_i \le c_i$, set

$$U_m = \prod_{i \in I} \prod_{k < m_i} W_i, \qquad U_c = \prod_{i \in I} \prod_{k < c_i} W_i.$$

These finite products realize the corresponding finite direct sums. The representation on U_m acts componentwise. Define $j : U_m \to U_c$ by retaining the first m_i copies and filling every remaining coordinate with zero. Define $r : U_c \to U_m$ by restriction to the selected copies. Lean proves

$$rj = 1_{U_m}, \qquad j\rho_m(g) = \rho_c(g)j, \qquad r\rho_c(g) = \rho_m(g)r.$$

The image of j is exactly the subspace whose unused coordinates vanish. Consequently jr is an equivariant idempotent. A supplied equivariant isomorphism $D : W \xrightarrow{\sim} U_c$ gives the split maps $D^{-1}j$ and rD inside the original carrier. The decomposition D is an input. These statements do not construct a decomposition of an unknown arithmetic carrier.

The same formalization proves, for each $g \in G$,

$$\det\big(XI - \rho_m(g)\big) = \prod_{i\in I} \det\big(XI - \rho_i(g)\big)^{m_i}, \qquad \operatorname{Tr}\big(\rho_m(g)\big) = \sum_{i\in I} (m_i : K)\operatorname{Tr}\big(\rho_i(g)\big).$$

Constituents may have different dimensions. Zero multiplicities, zero-dimensional constituents, and the empty index set are included. If at a permitted sample g the constituent polynomials are the images of $P_{i,g} \in E[X]$ under a specified map $E \to K$, the summand polynomial is the image of $\prod_i P_{i,g}^{m_i}$. Applying this independently at each coefficient field preserves a supplied common polynomial family. This does not establish the Hodge–Tate or Weil–Deligne conditions in strict compatibility.

Joint continuity of the constituent actions implies joint continuity of the constructed action. The inclusion and retraction are continuous for the product topologies, and triviality on a supplied subgroup is preserved. Neither continuity nor triviality is inferred for a carrier whose corresponding hypothesis has not been supplied. The maps transported by D are proved algebraically. Their topological interpretation additionally requires the appropriate continuity of D and its inverse.

For the three-character example below, the construction produces an actual three-dimensional summand inside the carrier of dimension seven. At the sample $(0, 1)$ its characteristic polynomial is $(X-1)^2(X+1)$. A separate checked counterexample uses the coordinate inclusion $\mathbf{Q} \to \mathbf{Q}^2$, its coordinate retraction, and the swap involution: the split law holds, but compression sends the swap to zero and therefore fails to preserve its square. Thus selecting whole constituent copies, with the proved equivariance, is essential to this construction.

Algebraic monodromy data on the selected copies. Fix a field K and a nonzero scalar $q \in K^\times$. On each constituent W_i, supply an automorphism F_i and a nilpotent endomorphism N_i with $F_i N_i F_i^{-1} = qN_i$. The scalar q is common to this finite family. The componentwise operators F_m, N_m on U_m satisfy the same relation. F_m is invertible and N_m is nilpotent. The split maps constructed above intertwine both operators. The proof first identifies the independently defined kernel through an equivariant linear isomorphism

$$\ker N_m \simeq \prod_{i\in I} \prod_{k<m_i} \ker N_i.$$

The relation, with $q \neq 0$, proves that both F_i and its inverse preserve $\ker N_i$. Thus $F_i|_{\ker N_i}$ is an actual automorphism, and Lean proves

$$\det(XI - F_m|_{\ker N_m}) = \prod_{i\in I} \det(XI - F_i|_{\ker N_i})^{m_i}.$$

The corresponding kernel dimensions and traces are additive with multiplicity. Common constituent kernel polynomials, when supplied through a coefficient-ring map, give the mapped product polynomial for the summand. Whole-space Frobenius polynomials are not substituted for these kernel polynomials.

The exact special chain has basis $e_0, \dots, e_{n-1}$ and operators

$$Ne_0 = 0, \qquad Ne_j = e_{j-1}\ (j > 0), \qquad Fe_j = aq^{-j}e_j, \qquad a, q \in K^\times.$$

Lean proves $N^n = 0$, and for $n > 0$ also $N^{n-1} \neq 0$ and $\ker N = Ke_0$. Consequently its kernel polynomial is $X - a$, whereas its whole-space polynomial is $\prod_{j=0}^{n-1}(X - aq^{-j})$. The zero-length chain is included as a zero-dimensional space. The assertion $\ker N = Ke_0$ is made only for positive length.

For $n > 1$, replacing N by zero retains exactly the same F and the same whole-space characteristic polynomial, while changing the degree of the kernel polynomial from one to n. Both pairs still satisfy the algebraic monodromy relation. This Lean-checked example shows that whole Frobenius data alone do not determine the monodromy kernel polynomial. It is not asserted to be a counterexample among the intended strictly compatible arithmetic systems.

These statements concern supplied algebraic pairs. No Weil-group or inertia action, Hodge–Tate object, arithmetic comparison, or realization of the pair from a Galois representation is constructed here. The polynomial convention is $\det(XI - F|_{\ker N})$. No identification with an inertia-dependent local Euler factor is asserted. Claim 9.2 remains partial at its full arithmetic scope.

Checked group, inertia and monodromy finite sums. Let K be a field, G a group, and $\nu : G \to K^\times$ a character. The new datum consists of an actual representation r and nilpotent N with $r(g)N = \nu(g)Nr(g)$ for every g. For a supplied subgroup H, define

$$E(D, H) = \ker N \cap V^H.$$

This is the intersection of independently defined kernel and actual invariant subspaces. For normal H, the restricted whole-group representation and its inverse automorphisms are constructed. A change from φ to φh, with $h \in H$, leaves the restricted operator itself unchanged.

For a finite family of finite-dimensional constituents and natural multiplicities, the actual local space of the constructed sum is linearly equivalent to the sum of the constituent local spaces, equivariantly for every group element. Its characteristic polynomials multiply, its dimensions and traces add, and maps intertwining both the group and N restrict to the local spaces. The explicit bounded-copy inclusion and retraction still split there. Finite inertia image and an open inertia kernel are preserved.

Writing $Q_D(T)$ for the reversed local characteristic polynomial, Lean proves

$$Q_D(T) = \det(1 - Tr(\varphi) \mid E(D, H)), \qquad Q_D(0) = 1, \qquad Q_{\bigoplus_i D_i^{\oplus m_i}}(T) = \prod_i Q_{D_i}(T)^{m_i}.$$

The abstract formulas do not need characteristic zero. Normality and finite dimension appear explicitly where used. Arithmetic identification of G, H, ν and φ remains separate. In the geometric-Frobenius convention, $\nu(\varphi)$ is the inverse residue cardinality. It is this unit, rather than the residue cardinality, that enters the earlier special-chain parameter.

An explicit action of $C_2 \times \mathbb{Z}$ has $\nu(\varphi) = 1/3$, $F = \operatorname{diag}(2, 6, 18)$ and $Ne_1 = e_0$, $Ne_2 = e_1$, $Ne_0 = 0$. Trivial inertia gives local dimension one and denominator $1 - 2T$. Scalar sign inertia gives dimension zero and denominator one. The entire F and N are equal in these two examples, and $N^2 \neq 0$. Thus

inertia cannot be omitted. Conversely, unramified chains of lengths one and three have equal Euler denominators while only the first has $N = 0$. Euler factors therefore do not identify complete monodromy data.

The remaining arithmetic comparison is $\mathrm{WD}(\bigoplus_i V_i^{\oplus m_i}) \cong \bigoplus_i \mathrm{WD}(V_i)^{\oplus m_i}$ for the actual attached functor, intertwining the Weil action and monodromy, together with the intended coefficient and Hodge–Tate comparisons. These are not supplied by the abstract datum. Claim 9.2 remains partial at its full arithmetic scope.

Recovered multiplicities determine the semisimple isomorphism type relative to the specified constituents, not a canonical embedding or projector inside a repeated isotypic component. For example, the two projectors $\mathrm{diag}(1,0)$ and $\mathrm{diag}(0,1)$ on a two-dimensional trivial representation are distinct equivariant idempotents with trace one.

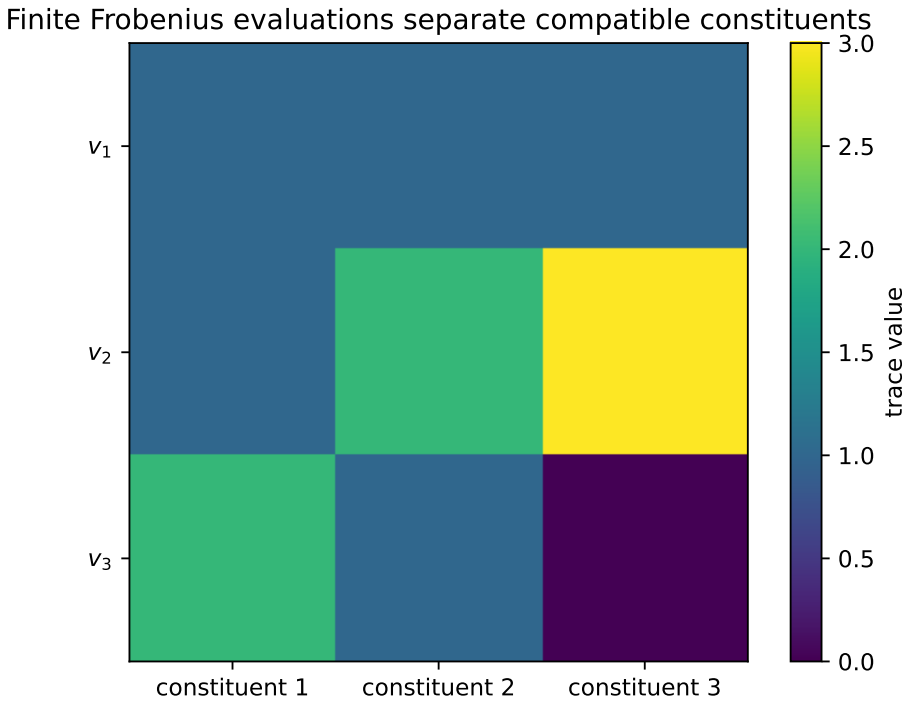

Figure 14. A finite set of trace evaluations separates three compatible constituents and recovers their multiplicities.

Numerical Certificate 9.3 (Multiplicity recovery)**.** The original companion matrix was not retrieved or rerun. A new exact realization uses the trivial character and two independent sign characters of $(\mathbf{Z}/2\mathbf{Z})^2$, evaluated at $(0,0), (1,0), (0,1)$:

$$C = \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \end{pmatrix}, \qquad \det C = 4, \qquad C \begin{pmatrix} 2 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 3 \\ 3 \\ 1 \end{pmatrix}.$$

Lean checks that these are the traces of actual one-dimensional representations, recovers $(2,0,1)$ uniquely, rejects a target whose unique solution is $(1/2,0,0)$, and rejects $(4,0,1)$ under capacities $(3,2,2)$. The separator becomes singular modulo two. These are finite-image representation checks, not fabricated Frobenius data for an arithmetic carrier.

The theorem is substantial only when a suitable compatible carrier and its irreducible compatible constituents are already known. It does not assert that every geometric representation embeds into such a carrier.

Finite-exponential reconstruction and a cubic inverse. Let K be a characteristic-zero field and let (r, N) be supplied group data with nilpotent N and $r(g)N = \nu(g)Nr(g)$. For a supplied scalar map satisfying

$$t(gh) = t(g) + \nu(g)t(h),$$

the formalization constructs

$$\rho(g) = \exp(t(g)N)r(g), \qquad \exp(aN) = \sum_{j=0}^{d-1} \frac{a^j}{j!}N^j \quad (N^d = 0).$$

Lean proves the representation laws, actual finite-copy and split-map compatibility, and joint continuity from continuity of N, r and t with the stated continuous vector-space operations. The monodromy fixed kernel intersected with subgroup invariants is unchanged by this twist. For normal inertia, its restricted action and finite-dimensional Euler denominator agree. Twisting again by $-t$ recovers the datum with N still supplied.

The finite-exponential reconstruction also established an extracted inverse on the explicit class $N^3 = 0$:

$$\log_2 U = (U - I) - \tfrac{1}{2}(U - I)^2, \qquad a^{-1}\log_2(\exp(aN)) = N \quad (a \neq 0).$$

Both exponential/logarithmic inverse identities are checked on the cubic nilpotent and unipotent loci. If a supplied common sample u has $r_D(u) = r_E(u) = I$ and $t(u) \neq 0$, an intertwiner of the reconstructed cubic actions recovers both original group equivariance and monodromy equivariance. The general nilpotence exponential theorem is not restricted to this cubic class, but the extracted inverse in the finite-exponential reconstruction was. The finite logarithmic recovery argument below removes that restriction by using the full finite logarithm.

The rational affine-group example has $u = (1, 1)$, $d = (0, 1/3)$ and

$$\rho(u) = \begin{pmatrix} 1 & 1 & 1/2 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \rho(d) = \operatorname{diag}(1, 3, 9).$$

Reversing the factor order or dropping the quadratic term gives checked failures. For the length-four chain, the quadratic logarithm has erroneous e_3-to-e_0 coefficient $-1/3$, so its cubic restriction is substantive. A zero-parameter sample also fails to recover N.

No arithmetic group, tame cocycle or required sample is constructed by these statements. The attached comparison for every intended representation, coefficient comparisons and Hodge–Tate/period data remain separate. Finite inertia image and an open inertia kernel of r are not asserted to persist under this twist to ρ. Claim 9.2 remains partial.

10 Finite spectral occupancy

System completion produces arithmetic members. It does not prove that a desired packet occurs in a global carrier. In a fixed finite-dimensional semisimple carrier, however, occupancy is an exact projector question.

Let E be a field of characteristic zero and let $T_1, \dots, T_N$ be commuting operators on a finite-dimensional E-vector space A, each diagonalizable over E. Thus the selected spectra split over the coefficient field. Let $a_i \in E$ be a selected target scalar for T_i, possibly absent from its spectrum. Define

$$e_i = \prod_{\mu \in \mathrm{Spec}(T_i) \setminus \{a_i\}} \frac{T_i - \mu I}{a_i - \mu}, \qquad e_T = \prod_{i=1}^{N} e_i,$$

with $e_i = 0$ if a_i is absent.

Theorem 10.1 (Exact finite occupancy trace)**.** *The operator e_T is the projector onto the joint eigenspace*

$$A_T = \{v : T_i v = a_i v \text{ for every } i\}.$$

Moreover,

$$\boxed{\mathrm{Tr}(e_T) = \mathrm{rank}(e_T) = \dim A_T \in \mathbf{Z}_{\geq 0}.}$$

The trace is identified with its unique nonnegative integer preimage under $\mathbf{Z} \hookrightarrow E$. Thus $\mathrm{Tr}(e_T) > 0$ refers to that integer, not to an ordering of an arbitrary field E. The finite packet is occupied exactly when this integer is positive. In positive characteristic the field-valued trace can vanish for a nonzero projector. The rank test, not a positive field trace, must then be used.

Proof. For each operator, its finite set of actual eigenvalues is used without multiplicity. The polynomial

$$p_{i,a}(X) = \prod_{\mu \in \mathrm{Spec}(T_i) \setminus \{a\}} (a - \mu)^{-1}(X - \mu)$$

is used when a occurs, and the zero polynomial otherwise. For an eigenvector $T_i v = bv$, evaluation gives

$$p_{i,a}(T_i)v = \begin{cases} v & b = a, \\ 0 & b \neq a. \end{cases}$$

Because the eigenspaces span A, this proves that $e_i = p_{i,a_i}(T_i)$ maps all of A into the selected eigenspace and fixes that eigenspace pointwise. It therefore proves the individual projector and image assertions, including an absent target.

Polynomials in commuting operators commute. If projections P, Q onto U, W commute, then PQ maps into both U and W, and fixes every vector in $U \cap W$. Induction proves that the actual ordered product e_T is a projection onto A_T. Commutation also makes the result independent of the ordering. An empty list of conditions gives the identity.

For a projection onto a subspace, the direct sum of its image and kernel identifies it with $I \oplus 0$. Thus its trace in E is the natural dimension of its image cast into E. In characteristic zero this cast is injective, so there is a unique natural integer represented by the trace. That integer is positive exactly when the joint eigenspace contains a nonzero vector. □

Naturality and finite hypotheses. If $FT_i = U_i F$ and the source operators split, then $Fe_{T,a} = e_{U,a}F$. This follows first on source eigenvectors and then on their span. In particular, a change of basis conjugates the constructed projector and preserves its trace. Adding conditions decreases the actual joint eigenspace and cannot increase its dimension. These statements do not assume an orthonormal basis or a positive definite inner product.

A specified finite realization. On $\mathbf{Q}^4$, take the diagonal operators with diagonal lists

$$(1,1,1,0), \quad (2,2,0,0), \quad (3,0,0,0), \quad (0,4,4,4)$$

and target scalars $(1,2,3,4)$. All four targets occur individually. Imposing these conditions successively gives actual projector ranks $3,2,1,0$. The last packet is empty despite individual feasibility. The formal code checks these operators, projector formulas, traces and dimensions. This is a newly specified realization, not a claim to have recovered the original companion implementation.

Why the hypotheses cannot be omitted. For

$$P = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad Q = \tfrac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix},$$

each operator is idempotent, but PQ is not idempotent and has trace $1/2$. For the Jordan block $J = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$, the singleton-spectrum Lagrange polynomial is 1, so the formula produces the identity although the eigenspace at 1 is only a line. Both failures are exact formal counterexamples to dropping the corresponding hypotheses, not counterexamples to the theorem with those hypotheses retained.

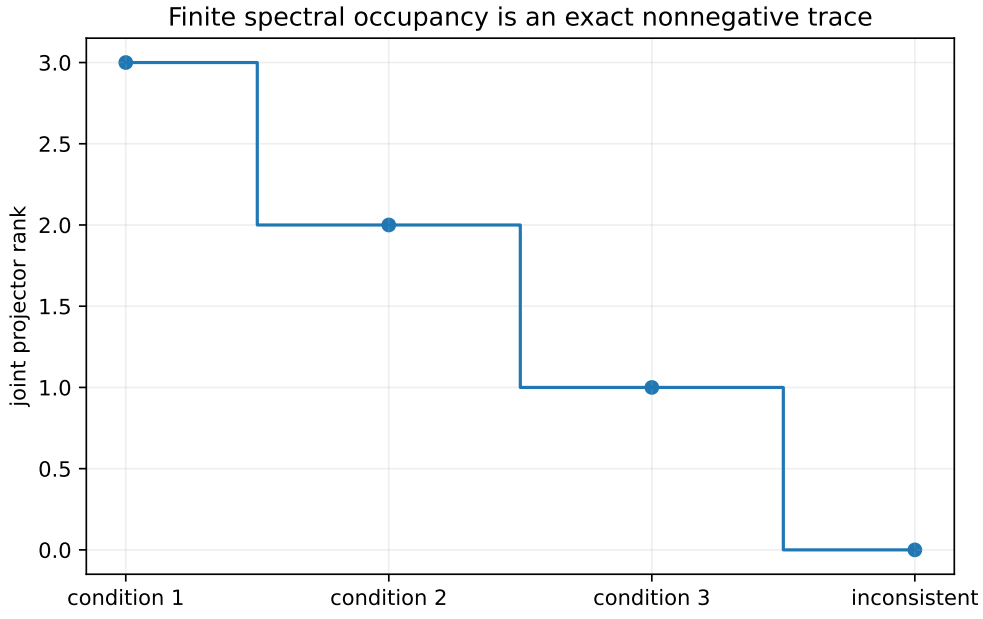

Figure 15. A consistent sequence of finite conditions narrows the carrier from ranks 3 to 2 to 1. One inconsistent condition forces the joint projector to zero.

Conjecture 10.2 (Universal occupancy)**.** For every admissible finite arithmetic packet in the intended global class, there exists a finite-dimensional carrier in which the associated joint projector has positive trace.

This conjecture is not a consequence of the projector formula. The formula measures occupancy exactly once the carrier is fixed. It cannot force the trace to be positive.

11 A conditional system-completion criterion

The preceding results can be assembled without promoting their missing hypotheses to theorems.

Theorem 11.1 (Residual-system completion criterion)**.** *Fix an admissible arithmetic class. Suppose:*

1. *every object has a unique residual root in an exhaustive residual moduli space;*
2. *a common algebraic spine is defined for the desired system;*
3. *every coefficient-prime residual companion exists;*
4. *every companion forest has nonempty finite levels, finite branching, and inverse-limit closed local conditions;*
5. *the required horizontal transports preserve the common spine and the selected local deformation conditions.*

Then the desired strictly compatible arithmetic system exists. If, in addition, the system is a summand of a known compatible carrier, the summand is recovered at every coefficient prime by finitely many Frobenius traces.

Proof. The first four hypotheses give the system by adelic finite-depth completion. The transport hypothesis identifies any roots that are meant to be generated horizontally without changing the prescribed spine. The final assertion is the compatible-carrier summand theorem. □

Corollary 11.2 (Exact location of the remaining existence problem)**.** *Inverse-limit reconstruction alone is not a nonemptiness theorem. The existence requirements must retain both residual companions and liftability through every finite depth:*

$$\boxed{\begin{array}{l}\text{companion existence: } X_{\lambda,1}(\mathfrak{C}) \neq \varnothing \text{ for every } \lambda;\\ \text{finite-depth liftability: } X_{\lambda,m}(\mathfrak{C}) \neq \varnothing \text{ for every } \lambda, m \geq 2;\\ \text{finite occupancy: } \operatorname{Tr}(e_T) > 0 \text{ for every required global packet.}\end{array}}$$

Formal reconstruction does not create a missing residual root, repair an empty higher level, or force global occupancy. Nonempty finite levels with finite branching supply a branch, after which inverse-limit closure reconstructs an admissible object.

An occupied node can have no child. The actual order-two representation with generator

$$A = \begin{pmatrix} 1 & 2 \\ 2 & 3 \end{pmatrix} \pmod 4$$

satisfies $A^2 = I$ and $\det(XI - A) = X^2 - 1$. It has no lift modulo 8 with the same characteristic polynomial. Indeed, every lift has entries congruent to $1, 2, 2, 3$ modulo 4. Trace zero then forces its determinant to be 3 modulo 8, whereas $X^2 - 1$ requires determinant $-1 = 7$ modulo 8. Both

the occupied node and the absence of any next-level matrix or representation with the prescribed polynomial are Lean-checked. Other branches of the same unrestricted involution forest survive, so this example does not contradict finite-branch compactness.

Local properties need their own limit argument. Over a domain, for a nonzero $\pi \in I$, the representations of the additive integer group given by

$$\rho_n(g) = \begin{pmatrix} 1 & \pi^n g \\ 0 & 1 \end{pmatrix}$$

are all nontrivial and converge pointwise in the ideal-adic topology to the trivial representation. The convergence and the failure of limit preservation for nontriviality are formally checked. Thus not every property of approximating integral representations can be asserted for a limit. This example is not claimed to disprove stability for any particular intended Galois local condition.

Complete conditional existence boundary. The eleventh block established the corresponding conditional matrix criterion. The conditional existence-boundary argument now uses the complete common-spine conclusion of Claim 8.2: the returned coefficient-field representations are continuous, have the prescribed common polynomials and coefficient-specific determinants, and satisfy every selected local realization relation under the stated inverse-limit closure hypothesis. All finite reductions belong to the admissible classes.

For each supplied required packet p, let A_p be its finite-dimensional carrier over a characteristic-zero field E_p, and let e_p be the actual joint spectral projector for its finite list of split commuting conditions. No order on E_p is assumed. The source notation $\mathrm{Tr}(e_p) > 0$ means that the unique natural number n_p with $\mathrm{Tr}(e_p) = (n_p : E_p)$ is positive. The checked projector formula identifies n_p with the dimension of the actual joint eigenspace.

An admissible realization here includes continuous coefficient-field members and membership of every finite reduction in its designated admissible class. Under the completion hypotheses and these supplied carrier hypotheses, Lean proves

$$\begin{aligned} &\exists\, \rho,\ (x_p)_p : \quad \rho \text{ is an admissible realization of the full chosen spine}, \quad 0 \neq x_p \in \mathrm{im}(e_p) \text{ for every } p \\ &\quad \Longleftrightarrow \quad \big(\forall \lambda,\ X_{\lambda,1}(\mathfrak{C}) \neq \varnothing\big) \ \wedge\ \big(\forall \lambda,\ \forall m \geq 2, X_{\lambda,m}(\mathfrak{C}) \neq \varnothing\big) \ \wedge\ \big(\forall p,\ n_p > 0\big). \end{aligned}$$

The packet index may be infinite. Each x_p belongs to its own supplied carrier. No common vector across distinct carriers or embedding of the reconstructed system into those carriers is asserted. Neither an unknown carrier nor positive trace is constructed without the corresponding hypotheses.

This completes Claim 11.2 at its conditional source scope, on the same counting basis used for Claim 8.2 in the conditional completion construction. The full arithmetic application premises remain separate. In particular, the criterion does not prove universal occupancy, Hodge–Tate or Weil–Deligne attachment, or the Frobenius recovery clause of Claim 11.1. The latter still depends on the partial Claims 9.1 and 9.2.

Every required packet is necessary. For each omitted index $N \in \mathbb{N}$, consider one-dimensional rational carriers with the identity operator, requiring eigenvalue 0 at N and eigenvalue 1 at every other index. The actual spectral projector has trace 0 at N and trace 1 elsewhere. Lean proves that any predetermined finite sample of packet indices can miss an empty required packet: choose N outside

that sample. The family depends on the omitted index. This does not assert that one fixed family passes every finite prefix while failing global occupancy.

Conjecture 11.3 (Natural finite seed rank)**.** For the admissible residual transport category attached to a fixed arithmetic class, the directed seed rank is finite. A one-seed theorem additionally requires a source component from which every required object is reachable and transports preserving deformation and occupancy data. For a finite condensation DAG, having exactly one source implies that reachability condition. For an infinite category, the existence of a unique source alone does not establish it.

12 Worked finite models

12.1 Smooth branch

For $q = 3$ and formal dimension $d = 2$, the finite levels have cardinalities

$$1, 9, 81, 729, 6561, \dots.$$

The seed zeta function is

$$Z(T) = \frac{T}{1 - 9T}.$$

12.2 Weighted dyadic chart

For weights $(1, 2, 4)$, the counts are

$$1, 2, 8, 32, 256, 2048, \dots.$$

The first coordinate is active immediately, the second one level later, and the third at depth five. The exact rational function generated by the code is

$$Z_{(1,2,4)}(T) = \frac{T(1 - 6T - 8T^2 - 32T^3)}{1 - 8T}.$$

The negative signs in this presentation arise from moving the denominator to $1 - 8T$. Every power-series coefficient is positive.

12.3 Singular branch

For $x^2 = 0$ over a residue field of size three, the counts are

$$1, 3, 3, 9, 9, 27, 27, 81, \dots,$$

and

$$Z(T) = \frac{T + 3T^2}{1 - 3T^2}.$$

The exact branching dimension is $1/2$.

12.4 Directed transport

The finite graph in figure 10 has three source components. The source-component theorem and brute-force enumeration both return the minimum seed count three.

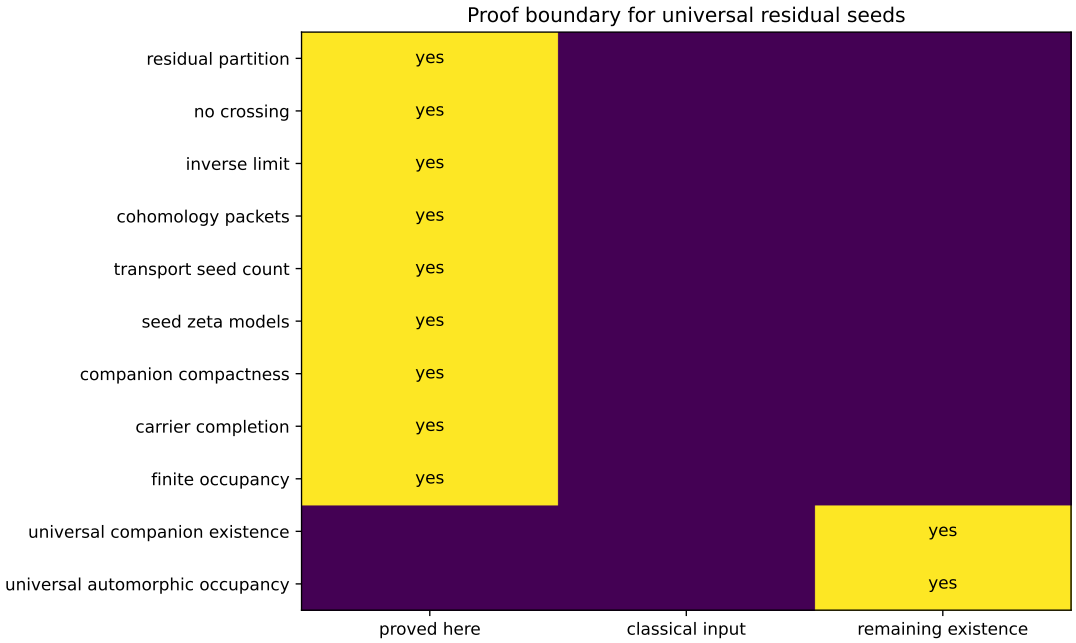

Figure 16. The finite and formal statements proved in this chapter are separated from the two remaining universal existence assertions.

13 Computational certificates

The code uses exact integer, rational, symbolic, and modular arithmetic for all mathematical identities. Floating-point arithmetic is used only to render the figures and to report a regression estimate alongside an exact branching dimension.

Table 1. Selected exact certificates.

Certificate	Result
Residual packet count in the mod-three model	3
Compatible base-five inverse-limit branch	yes
First dyadic sign separation depth	2
Source strongly connected components	3
Brute-force minimum directed seed count	3
Cohomology packet reconstruction residual	0
Compatible common-spine test	passed
Inconsistent spine detected	yes
Recovered carrier multiplicities	$(2, 0, 1)$
Finite occupancy ranks	$(3, 2, 1, 0)$

The complete automated suite contains 28 tests. They cover residual partition, no crossing, inverse-limit digits, weighted and singular zeta coefficients, directed source components, cohomology packets,

companion forests, common-spine consistency, finite Frobenius separation, multiplicity recovery, and exact occupancy projectors.

14 Claim ledger

Statement	Status	Scope or boundary
Residual partition	proved	any moduli functor with well-defined reduction
No crossing	proved	operations trivial at residual depth
Inverse-limit reconstruction	proved	represented complete deformation problem
Finite-branch compactness	proved	finite nonempty levels and finite branching
Smooth and weighted seed zeta formulas	proved	stated formal coordinate models
Singular power zeta and dimension	proved	scalar equation $x^e = 0$
Cohomology packet decomposition	proved	chain projectors commuting with the differential
Directed minimum-seed theorem	proved	finite directed transport graph
Adelic finite-depth completion	proved	common spine, all finite levels occupied, closed local conditions
Compatible-carrier summand completion	proved	known semisimple compatible carrier and finite separation
Finite occupancy trace	Lean checked	supplied commuting split operators and a characteristic-zero trace criterion
Universal residual companions	not proved	requires nonempty root at every coefficient prime
Universal compatible-system completion	not proved	algebraic spine and companion occupancy remain necessary
Universal automorphic occupancy	not proved	requires positive global packet traces
Unrestricted reciprocity	not claimed	belongs to later local and global chapters

15 Conclusion

The residual seed theory becomes precise once vertical and horizontal generation are separated. Positive-depth perturbations can be complete within one formal component. They cannot change the residual root. The universal arithmetic seed is therefore a forest rather than one branch:

$$\boxed{\text{residual roots} \longrightarrow \text{finite deformation levels} \longrightarrow \text{inverse-limit branches.}}$$

Projectors add three useful structures to this forest. They split tangent and obstruction complexes into exact subproblems, they measure delayed dyadic visibility through weights, and they turn finite carrier occupancy into an integer trace. Directed transport adds a fourth: it converts the informal question "how many seeds are needed?" into the source-component count of a condensation graph.

The system-level boundary is now narrow enough to state without ambiguity. One must construct a common algebraic spine, populate every residual companion forest, lift those companions through all depths, and prove positive occupancy of the required global packets. The present chapter proves the formal reconstruction, counting, transport, compactness, carrier, and finite-projector theorems used in that reduction. It does not assert the missing universal existence statements.

A Algorithms implemented in the companion package

A.1 Residual towers

The residual module partitions coordinates modulo p, verifies compatibility

$$x_{m+1} \equiv x_m \pmod{p^m},$$

and reconstructs the digit a_{m-1} by

$$a_{m-1} = \left\lfloor \frac{x_m}{p^{m-1}} \right\rfloor \pmod{p}.$$

For canonical representatives $0 \le x_m < p^m$, set $x_0 = 0$. Compatibility also gives $a_{m-1} = (x_m - x_{m-1})/p^{m-1} \in \{0, \dots, p-1\}$. The floor in the first formula is essential. For example, the compatible base-five residues $4, 19$ give the second digit 3, not the rational number $19/5$. The executable companion uses the same integer floor division.

A.2 Transport condensation

The transport module computes strongly connected components by two depth-first passes, forms the condensation graph, finds all source components, and selects one representative from each. A brute-force subset search is included only as an independent finite certificate.

A.3 Companion forests

For an integral polynomial f, the finite root forest is obtained by exact enumeration of

$$f(x) \equiv 0 \pmod{p^m}$$

and by connecting a child x_{m+1} to its reduction modulo p^m. This is intended for small exact examples, not large deformation rings.

A.4 Cohomology packets

Modular Gaussian elimination computes the ranks of the differentials. For

$$C^{i-1} \xrightarrow{d_{i-1}} C^i \xrightarrow{d_i} C^{i+1},$$

the finite dimension is evaluated as

$$\dim H^i = \dim C^i - \operatorname{rank} d_i - \operatorname{rank} d_{i-1}.$$

Packet subcomplexes are computed separately and checked against the total.

A.5 Finite occupancy

For each commuting semisimple operator, a Lagrange polynomial constructs the exact spectral idempotent. Their product gives the joint packet projector. Symbolic rational arithmetic verifies idempotence and the equality of trace and rank.

B Reproducibility boundary

The companion code is a finite certificate library. It does not construct universal Galois deformation rings, compute general continuous group cohomology, prove representability, discover compatible systems, or evaluate automorphic trace formulas. Those are mathematical inputs or later existence problems. The source package makes the finite examples and displayed counts reproducible. Their computational checks remain distinct from universal proofs.

Further construction details

The following constructions explain the representation, comparison and local arithmetic steps used in the chapter. Appendix D assembles their conditional endpoint. The formal companion keeps the distinct source contracts and verification records separate.

The formal model and its hypotheses. The smooth formal-model classification, its finite point count, its integral digit streams, and its rational seed zeta identity are now checked in Lean. The actual representing-ring algebra isomorphism remains a supplied hypothesis. Neither smoothness nor Galois representability is inferred from numerical counts. All local maps are included in the classification, and locality and actual maximal-ideal-adic continuity are separately proved. Arbitrary choices of parameter representatives do not add phantom maps.

General prescribed-conjugacy prime coverage remains an input. Claims 8.2 and 11.2 retain their conditional hypotheses, including the required residual levels, higher depths and supplied packets. Their nonemptiness and positive trace are not unconditional conclusions. The finite cyclotomic comparison and the fixed quadratic packet give restricted arithmetic realizations. In the latter, the packet characters are trivial on actual valuation inertia at odd primes. Identifying the decomposition group with the full local Galois group remains a separate obligation, and ramification at two is not claimed. The constructions do not identify every packet in the common arithmetic spine or attach all Hodge–Tate and Weil–Deligne invariants. Universal occupancy and natural finite seed rank remain conjectural.

Finite-group comparison with precision loss. Let R be a commutative domain, Γ a finite group, and ρ, τ actual integral matrix representations. Suppose $a = |\Gamma| \neq 0$ in R and $a \mid \pi^e$. An equivariant matrix modulo $(\pi)^{e+k}$ lifts to an integral equivariant matrix with the prescribed reduction modulo $(\pi)^k$. Indeed, lift its entries to A and form

$$S = \sum_{g \in \Gamma} \rho(g) A \tau(g^{-1}).$$

The finite equations imply $S - aA = \pi^{e+k}E$ with E integral. Choose b with $\pi^e = ab$ and put $P = A + b\pi^k E$. Then $aP = S$, so cancellation of $a \neq 0$ proves equivariance. Over a local ring, if π is a nonunit, $k > 0$ and the supplied comparison is invertible, P is an integral unit. Neither completeness nor a finite residue field is needed for this step.

For a DVR, $e = v_\pi(|\Gamma|)$ is derived from the actual group order. The single precision $e + 1$, independent of rank, detects integral isomorphism. It makes reduction injective on integral isomorphism classes, and finite coefficient quotients give finitely many integral classes in fixed rank. This is a formalization of classical finite-group rigidity (Maranda, 1953, Theorem 2), with an explicit proof of the comparison's precision loss.

For complete local coefficients with finite quotients, downward-compatible allowed representations occupied at every precision, and the required finite-group type at depth $e+1$, reconstruction followed by this comparison produces the required integral representation. Continuity is proved for a finite discrete source and for pullback through a fixed continuous map to that source. Occupancy at only one precision is insufficient. The result lifts comparisons between actual integral representations. It does not lift arbitrary quotient representations or supply the missing arithmetic packet interpretation.

For C_2 over $\mathbb{Z}_2$, take

$$\tau(g) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad \rho(g) = \begin{pmatrix} 1 & 2 \\ 0 & -1 \end{pmatrix}, \qquad A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

The matrix A intertwines modulo 4 and its average is $P = \left(\begin{smallmatrix} 1 & -1 \\ 0 & 1 \end{smallmatrix}\right)$. No exact intertwiner can retain A modulo 4, although P retains it modulo 2. The actual trivial and sign representations also agree modulo 2 but are not integrally isomorphic. These checked examples show why residual-only detection and full preservation of the input precision cannot be asserted here.

Lifting a summand inside a supplied finite-group carrier. Let R be a commutative integral domain complete and separated for the (π)-adic filtration. Let Γ be a finite group, and let $\rho : \Gamma \to \mathrm{GL}_n(R)$ be an actual integral representation. Assume that $a = |\Gamma| \neq 0$ in R and $a \mid \pi^e$. For $k > 0$, suppose

$$\bar{E} \in M_n\big(R/(\pi)^{e+k}\big), \qquad \bar{E}^2 = \bar{E}, \qquad \bar{\rho}(g)\bar{E} = \bar{E}\bar{\rho}(g) \quad (g \in \Gamma).$$

There is an actual integral matrix E satisfying

$$E^2 = E, \qquad \rho(g)E = E\rho(g), \qquad E \bmod (\pi)^k = \bar{E} \bmod (\pi)^k.$$

No integral summand or coherent family of quotient projectors is assumed. No local-ring assumption or finiteness of the residue field is needed.

To prove this, apply the preceding averaging correction with both representations equal to ρ. This produces an exact equivariant matrix A with the prescribed reduction at depth k, so that $A^2 - A \in (\pi)^k M_n(R)$. Averaging alone need not preserve idempotence. Use the integral polynomial

$$f(A) = 3A^2 - 2A^3.$$

The identities

$$f(A) - A = (1-2A)(A^2-A), \qquad f(A)^2 - f(A) = (A^2-A)^2(4A^2-4A-3)$$

show that successive corrections preserve the retained reduction and improve the idempotence defect. In these formulas scalar constants denote scalar matrices. The Lean proof establishes at least one additional ideal digit at each step, constructs the resulting compatible family of finite-level matrices, and uses completeness and separatedness to recover E. Every matrix commuting with A commutes with E. There is no division by 2, so the correction also works in residue characteristic 2.

The actual submodules $U = \operatorname{im} E$ and $W = \ker E$ are invariant, and addition gives an equivariant isomorphism

$$U \oplus W \simeq R^n.$$

The inclusion $i : U \hookrightarrow R^n$ and retraction $r(v) = Ev$ are constructed as linear maps and satisfy $ri = 1_U$ and $ir = E$. Their equivariance is proved. Coordinatewise reduction maps U onto $\mathrm{im}(\bar{E} \bmod (\pi)^k)$ and maps W onto $\ker(\bar{E} \bmod (\pi)^k)$. Both equalities are surjectivity statements onto the actual submodules over the finite-level quotient, not merely containment. The same projector defines a summand after pullback through any group homomorphism to Γ.

For $R = \mathbb{Z}_2$ and the sign carrier $\rho(s) = \mathrm{diag}(1, -1)$, the projector

$$\bar{E} = \begin{pmatrix} 1 & 2 \\ 0 & 0 \end{pmatrix} \pmod 4$$

is equivariant and the theorem constructs a nonzero proper equivariant projector retaining its reduction modulo 2. No exact equivariant endomorphism retains this prescribed matrix modulo 4. At the insufficient input depth 1, the projector $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right) \pmod 2$ has no exact equivariant lift retaining its reduction. These are statements about the supplied carrier and prescribed projectors, not about nonexistence of all integral summands.

This construction gives one summand and its complement inside a supplied finite-group carrier. It advances the carrier step in Claim 9.2. It does not identify the intended arithmetic packets, construct the arithmetic Weil–Deligne attachment, establish the Hodge–Tate comparisons, or prove universal occupancy.

Simultaneous projector-family lifting and rigidity. Keep the complete domain, supplied finite-group carrier and group-order hypotheses of the supplied-carrier summand-lifting construction. Let J be any finite label set and $k > 0$. Suppose $(\bar{E}_i)_{i \in J}$ is a complete orthogonal family of equivariant idempotents modulo $(\pi)^{e+k}$. There exists an integral equivariant family $(E_i)_{i \in J}$ satisfying

$$E_i^2 = E_i, \qquad E_i E_j = 0 \ (i \neq j), \qquad \sum_{i \in J} E_i = 1, \qquad E_i \bmod (\pi)^k = \bar{E}_i \bmod (\pi)^k.$$

The loss is at most e, independent of $|J|$ and the ambient matrix rank. There is no local-ring or finite-residue-field hypothesis for existence. The formal theorem also treats empty label sets whenever their input equations can hold.

Average every supplied matrix once. Inductively let C be the complement of the previously lifted projectors and correct the next averaged matrix inside the corner defined by C. The integral polynomial correction preserves the retained reduction and commutation with C and the carrier. Multiplication by C gives the required supported projector. This consumes no further precision. Once every label has been lifted, the complementary idempotent reduces to zero at positive depth. Adic separatedness forces it to vanish, proving the sum-to-identity equation.

The actual invariant images $U_i = \mathrm{im}\, E_i$ give an equivariant linear isomorphism

$$\bigoplus_{i \in J} U_i \simeq R^n, \qquad (v_i)_i \longmapsto \sum_i v_i, \qquad v \longmapsto (E_i v)_i.$$

Lean represents the finite direct sum by the finite product of the image submodules. The existing coordinatewise reduction theorem maps every U_i onto the corresponding reduced projector image. No chosen bases or unproved freeness of the images are used.

For rigidity alone, let R be a commutative local ring, let π be a nonunit, and let E, F be complete equivariant families on the same carrier with $E_i \equiv F_i \pmod{(\pi)^k}$ for every label and $k > 0$. Then

$$U = \sum_{i \in J} F_i E_i, \qquad U \equiv 1 \pmod{(\pi)^k}, \qquad UE_i = F_i U.$$

Reduction reflects invertibility in this setting, so U is an integral unit and $UE_iU^{-1} = F_i$. It commutes with the carrier and induces actual equivariant isomorphisms $\operatorname{im} E_i \simeq \operatorname{im} F_i$. This rigidity theorem requires neither a finite acting group, a domain, nor completeness. More generally a unit-reflecting coefficient map suffices. The combined result proves existence and uniqueness up to this labeled conjugacy. Exact uniqueness of the matrices is false.

For the continuous $\mathbb{Z}_2$ carrier $\rho(s) = \operatorname{diag}(1, -1, 1)$, conjugate the three coordinate projectors by $1 + 2e_{01}$ and reduce modulo 4. They form a complete equivariant family. The general theorem constructs three nonzero integral summands retaining this family modulo 2. No exact equivariant family retains the whole prescribed family modulo 4. Separate checked examples show that independent equivariant idempotent lifts can lose orthogonality, and that distinct complete families with the same reduction can be related by the asserted identity-congruent conjugacy.

The simultaneous projector-family lifting construction completes this finite-group projector-family step. The actual arithmetic packets, Galois-to-Weil–Deligne attachment, coefficient and Hodge–Tate/period comparisons, and arithmetic Frobenius coverage remain outside this result. Universal occupancy remains conjectural.

General finite logarithmic recovery. Let A be a rational algebra, without any commutativity assumption on A. For a unipotent element U and a positive integer d satisfying $(U - 1)^d = 0$, put

$$L_d(U) = \sum_{j=1}^{d-1} \frac{(-1)^{j+1}}{j} (U - 1)^j.$$

The value is independent of the chosen annihilating exponent. The finite logarithm and the nilpotent exponential satisfy

$$L(\exp N) = N, \qquad \exp(L(U)) = U.$$

Both maps preserve every annihilating exponent, and hence preserve the exact nilpotency class of N and $\exp(N) - 1$, or of $U - 1$ and $L(U)$. The Lean finite sum includes its zero-index term with coefficient zero. The displayed mathematical sum starts at one. The formal statements also handle the zero algebra and the exponent-zero case.

The proof evaluates Mathlib's formal power-series inverse identities at constant nilpotent series. Such evaluation is exactly a finite polynomial. For an arbitrary noncommutative ambient algebra, perform the calculation inside the commutative subalgebra generated by the element and then apply its inclusion. No analytic convergence or topology is assumed. The finite logarithm commutes with ring homomorphisms between rational algebras.

Let K be a characteristic-zero field and N an endomorphism with $N^d = 0$. For $t \neq 0$ the actual recovery formula is

$$N = \frac{1}{t} \sum_{j=1}^{d-1} \frac{(-1)^{j+1}}{j} \big(\exp(tN) - 1\big)^j.$$

All coefficients lie in K. The vector spaces need not be finite dimensional, but nilpotence still means that some finite power of the whole operator is zero. A linear map intertwines two nilpotent operators exactly when it intertwines their exponential samples at a common nonzero parameter. Also

$$\ker\bigl(\exp(tN) - 1\bigr) = \ker N.$$

For supplied covariance data and the twisted cocycle of the finite-exponential reconstruction, let $\rho_D(g) = \exp(t(g)N_D)r_D(g)$. If a common element u satisfies $r_D(u) = r_E(u) = 1$ and $t(u) \neq 0$, every intertwiner of ρ_D and ρ_E recovers both the original r-intertwiner and the N-intertwiner. There is no cubic nilpotence restriction. This recovers equivariant projectors for both original components. Reconstructed-action isomorphisms induce actual isomorphisms of the inertia-fixed monodromy kernels. Their local characteristic polynomials agree under the existing finite-dimensional and normal-subgroup hypotheses.

For actual finite original inertia images the common kernel sample is derived. Suppose $u \in H$ satisfies $v(u) = 1$ and $t(u) \neq 0$ and both $r_D(H)$ and $r_E(H)$ are finite. Their sampled actions have positive finite orders a, b. At u^{ab} both original actions are trivial, and

$$t(u^{ab}) = (ab)t(u) \neq 0$$

by the cocycle identity and characteristic zero. Thus the same full intertwiner equivalence holds using the actual finite-image hypotheses, without a separately supplied common trivial-action sample. The initial nonzero cocycle sample and the arithmetic interpretation of the data remain requirements.

Actual affine representations with monodromy chains of every finite length invoke these theorems. In particular a length-six example has $N^5 \neq 0$ and $N^6 = 0$ and is recovered from its actual reconstructed action. The length-four example still defeats the old quadratic logarithm, while the full finite logarithm recovers it.

The sample hypotheses retain substantive content. A zero parameter loses N. For unrestricted supplied algebraic data, one can also absorb $\exp(tN)$ into r and set the new monodromy to zero. The reconstructed representation is unchanged. The absorbed original action fails the required trivial-action sample condition. This is a counterexample in the algebraic datum class, not a failure of uniqueness of arithmetic Weil–Deligne attachment with finite original inertia action.

The finite logarithmic recovery argument removes the general logarithmic-extraction gap from the local algebraic comparison. It does not construct the actual arithmetic attachment, identify every intended packet, prove the coefficient and Hodge–Tate/period comparisons, or prove arithmetic Frobenius coverage.

Interpreted quadratic arithmetic completion. Fix the continuous quotient

$$q : G_{\mathbf{Q}} \longrightarrow C_2$$

obtained by the action on a chosen square root i of -1 in the algebraic closure. Its surjectivity and the equivalence

$$q(\sigma) = 1 \quad \Longleftrightarrow \quad \sigma(i) = i$$

are proved using the existing actual quadratic Galois construction. For a commutative ring B, define the arithmetic packet

$$\mathcal{P}_q(B) = \{\chi : G_{\mathbf{Q}} \longrightarrow B^{\times} \mid \ker q \subseteq \ker \chi\},$$

where the maps are group homomorphisms. Unique descent through the actual surjective map q is derived, rather than supplied. Every member has finite image and is continuous for the coefficient topology, since its descent has the finite discrete domain C_2.

Let R be any commutative ring and B any commutative R-algebra. The coordinate ring $A_R = R[X]/(X^2 - 1)$ represents precisely this specified packet:

$$\mathrm{Hom}_{R\text{-alg}}(A_R, B) \simeq \{x \in B : x^2 = 1\} \simeq \mathrm{Hom}(C_2, B^\times) \simeq \mathcal{P}_q(B).$$

The first map evaluates the coordinate. Its inverse is the quotient universal property. A root is a unit with itself as inverse and determines a character by its value on the generator of C_2. Finally pull back along q. All inverse identities and naturality under coefficient homomorphisms are proved. In particular, the point reductions and actual arithmetic character reductions coincide. There is no invertibility-of-two, reducedness or nontriviality hypothesis on B. No smoothness or étaleness statement at two is used or asserted.

Let $I \subseteq R$ and suppose that R is I-adically complete. Using the checked ring-map reconstruction on the quadratic coordinate ring, Lean proves

$$\mathcal{P}_q(R) \simeq \varprojlim_{m \geq 0} \mathcal{P}_q(R/I^m).$$

The zero-precision quotient is included only for the formal indexing. The inverse constructs an actual arithmetic character, with exactly the prescribed reductions. It is unique, and its continuity is derived from its factorization through the same finite quotient.

There is also a completion theorem without chosen compatible characters. Suppose that R/I^m is finite for every $m \geq 1$, and that $C_m \subseteq \mathcal{P}_q(R/I^m)$ are allowed subsets such that every reduction of an allowed member is allowed. Then

$$\begin{aligned} &\exists \chi \in \mathcal{P}_q(R), \quad \chi \text{ is continuous and } \chi \bmod I^m \in C_m \text{ for all } m \geq 1 \\ &\qquad \Longleftrightarrow \quad C_m \neq \varnothing \text{ for all } m \geq 1. \end{aligned}$$

The root interpretation makes the allowed finite levels genuinely finite. Finite-branch compactness chooses the compatible roots, and the ring reconstruction gives their integral root. Naturality turns this into the required arithmetic character. Surjectivity of transitions and individual liftability of every finite node are not assumed. The root-level theorem needs only the allowed root subsets to be finite.

For $R = \mathbf{Z}_2$, Lean derives finiteness of all positive maximal-ideal quotients and applies this completion theorem. Since $\mathbf{Z}_2$ is a domain, its only roots of $X^2 - 1$ are 1 and -1. Thus the integral packet has exactly two distinct characters: the trivial character and the sign character describing the action on i. They have the same reduction modulo two and distinct reductions modulo four.

The distinction between finite occupancy and continuation is witnessed by an actual finite arithmetic character. The roots modulo eight are $1, 3, 5, 7$. The root 3 defines a member of $\mathcal{P}_q(\mathbf{Z}/8\mathbf{Z})$, but no member of $\mathcal{P}_q(\mathbf{Z}/16\mathbf{Z})$ reduces to it. Indeed the only scalar lifts of 3 are 3 and 11, and both square to 9 modulo sixteen. The formal proof also classifies all roots modulo sixteen and the reductions with children. Consequently a nonempty finite node need not lie on an infinite branch, even in this explicitly interpreted arithmetic packet.

The fixed-quadratic-packet interpretation completes this restricted arithmetic interpretation and its conditional completion. The packet is defined by one fixed quotient. It is not the collection of all quadratic characters of $G_{\mathbf{Q}}$. No local ramification criterion, Hodge–Tate weight, Weil–Deligne attach-

ment, or cross-coefficient local invariant was established by the fixed-quadratic-packet interpretation. The full manuscript still requires its remaining packet identifications and arithmetic comparisons. Universal positive occupancy remains conjectural.

Actual quadratic local conditions and completion. Continue with the fixed packet $\mathcal{P}_q$ above. For a characteristic-zero field K, let

$$j_K : G_K \longrightarrow G_{\mathbf{Q}}$$

be the actual field-induced homomorphism between absolute Galois groups. It includes a chosen embedding of algebraic closures. Let i_K be the image of the chosen square root i under that embedding. Lean proves compatibility with the Galois actions and hence

$$(q \circ j_K)(\sigma) = 1 \quad \Longleftrightarrow \quad \sigma(i_K) = i_K.$$

The fixed-field theorem for the algebraic closure then gives

$$q \circ j_K = 1 \quad \Longleftrightarrow \quad \exists x \in K,\ x^2 = -1.$$

If no such root exists, the local quotient is surjective onto C_2. These are statements about the actual local Galois map, not a supplied arithmetic interpretation of a scalar label.

For every commutative coefficient ring B and $\chi \in \mathcal{P}_q(B)$, define $\chi_K = \chi \circ j_K$. The local character is continuous and commutes with coefficient change. The precise local admissibility condition is

$$\mathrm{LocallyTrivial}_K(\chi) \quad \Longleftrightarrow \quad \chi_K = 1.$$

Descent through the fixed quadratic quotient proves

$$\mathrm{LocallyTrivial}_K(\chi) \quad \Longleftrightarrow \quad \big(\exists x \in K,\ x^2 = -1\big) \ \vee\ \chi = 1.$$

No reducedness, characteristic-zero or domain hypothesis is imposed on B. In particular, the formula applies to the finite coefficient quotients used in completion.

The p-adic square-root criterion is proved for every prime:

$$\big(\exists x \in \mathbf{Q}_p,\ x^2 = -1\big) \quad \Longleftrightarrow \quad p \equiv 1 \pmod 4.$$

A root satisfies $|x|_p^2 = 1$ and is therefore integral. Reduction modulo three rules out a root in $\mathbf{Q}_3$, and reduction modulo four rules out a root in $\mathbf{Q}_2$. At an odd prime, any residue root of $X^2 + 1$ has nonzero derivative and lifts by the pinned Mathlib Hensel theorem. The finite-field square criterion then gives the stated congruence. An explicit Hensel application at the residue root 2 modulo 5 supplies a root in $\mathbf{Z}_5$. Consequently

$$\boxed{\mathrm{LocallyTrivial}_{\mathbf{Q}_p}(\chi) \quad \Longleftrightarrow \quad p \equiv 1 \pmod 4 \ \vee\ \chi = 1.}$$

The arithmetic prime p is independent of the coefficient prime. For the two integral $\mathbf{Z}_2$-valued characters, the sign character is locally trivial exactly at primes congruent to one modulo four. Both distinct global characters are locally trivial at five, while the sign character is nontrivial on the full local Galois groups at three and two.

The inertia theorem uses actual residue actions. For a valuation subring A of an extension field L/K, let D_A be its decomposition subgroup in $\mathrm{Aut}_K(L)$ and put

$$I_A = \ker\bigl(D_A \longrightarrow \mathrm{Aut}(k_A)\bigr),$$

where k_A is the residue field. If 2 is a unit in A, every member of I_A fixes every $y \in L$ with $y^2 = -1$. Indeed $y^{-1} = -y$, so y belongs to A and is a unit there. An automorphism sends y to y or $-y$. Their residues are distinct because 2 and y are units, whereas inertia fixes residues. The second possibility is excluded.

For every prime p, Lean constructs a valuation subring $A \subseteq \overline{\mathbf{Q}_p}$ containing the integral image of $\mathbf{Z}_p$ such that the induced map $\mathbf{Z}_p \to A$ is local. For odd p, two is a unit. The preceding argument applies to every valuation subring containing that integral image, and hence every member of $\mathcal{P}_q(B)$ is trivial on its inertia subgroup after actual local restriction. The existence theorem supplies a locally dominating choice, so this assertion is not vacuous.

This inertia is the actual residue-action kernel inside D_A. No equality $D_A = G_{\mathbf{Q}_p}$ is established in this block. Nor is ramification at two proved: the nontrivial full local character there is a separate result. At three the $\mathbf{Z}_2$-valued sign character is nontrivial on the full local Galois group but trivial on every inertia subgroup covered by the theorem. Thus local triviality and the stated inertia triviality are distinguished by checked arithmetic examples.

The local conditions survive coefficient completion by a proved theorem. For an I-adically separated commutative ring R,

$$\mathrm{LocallyTrivial}_K(\chi) \quad\Longleftrightarrow\quad \mathrm{LocallyTrivial}_K(\chi \bmod I^m) \text{ for every } m \geq 1.$$

If -1 has a square root in K, every packet member satisfies the condition. Otherwise the condition says that the character is globally trivial, and separatedness detects that equality through all reductions. This proves the closure statement for the independently defined arithmetic property.

Suppose now that R is I-adically complete and that every positive quotient R/I^m is finite. Let $C_m \subseteq \mathcal{P}_q(R/I^m)$ be allowed subsets preserved by reduction, and let $(p_s)_{s\in S}$ be any indexed family of arithmetic primes. The index set S need not be finite. Lean proves the simultaneous arithmetic completion criterion

$$\begin{aligned}&\exists \chi \in \mathcal{P}_q(R),\quad \chi \text{ continuous},\quad \chi \bmod I^m \in C_m\ (m \geq 1),\quad \chi_{\mathbf{Q}_{p_s}} = 1\ (s \in S)\\ &\quad\Longleftrightarrow\quad \forall m \geq 1,\ \exists \psi \in C_m,\quad \forall s \in S,\ p_s \equiv 1 \pmod 4 \ \vee\ \psi = 1.\end{aligned}$$

The constructed character also satisfies every odd-prime valuation-inertia condition stated above. Finite-branch compactness selects all finite characters together. No coherent branch or surjective transition maps are assumed. The new local-closure implication is proved, not supplied. Every-level occupancy remains a substantive hypothesis. One nonsplit selected prime forces the completed global character to be trivial.

For the integral dyadic packet, a single detecting precision is also proved: reduction modulo four detects local triviality uniformly in the arithmetic prime. Modulo two does not suffice. The sign character is nontrivial locally at three, while its reduction modulo two is trivial. This is a coefficient-depth failure, distinct from splitting of the arithmetic field.

The quadratic local-condition construction finishes this actual local admissibility and completion step for the fixed quadratic packet. It does not identify all packets in the manuscript's common

arithmetic spine, attach Weil–Deligne objects, or prove coefficient and Hodge–Tate/period comparisons. Identifying the decomposition group with the full local Galois group remains a separate inertia obligation, and ramification at two is not claimed. Universal occupancy and natural finite seed rank remain conjectures.

C Retained residue-counting continuation

The following arguments develop residue counting and the associated norm-image conditions. Their formulas and hypotheses remain distinct from the amended conditional completion in Section D. The formal companion distinguishes the source contracts and their verification status.

Scope and notation. Let K be a number field of degree $d \geq 1$, with ring of integers $\mathcal{O} = \mathcal{O}_K$. Write $\mathrm{N}\, I = \#(\mathcal{O}/I)$ for the absolute norm of a nonzero integral ideal and $n(x) = \mathrm{N}_{K/\mathbb{Q}}(x) \in \mathbb{Z}$ for $x \in \mathcal{O}$. Thus $\mathrm{N}(x) = |n(x)|$. Let ι be the mixed embedding in its Euclidean coordinates, $L(J) = \iota(J)$, and D the actual unit-norm fundamental cone used in the preceding counting block. Its norm function scales by t^d under a positive real dilation t. The full-paper ledger remains **17 checked claims and 3 partial claims**.

Actual additive residues. Fix nonzero integral ideals $M \subseteq J$, and put $q = [J : M] = \#(J/M)$. The formal quotient of ideal lattices is identified with the additive congruence relation $x - a \in M$ on actual elements of J. In particular, the residue label is not an independent parameter attached to a count.

Proposition C.1. *There is a constant $B \geq 0$, depending on K, M, J, such that, for every $a \in J/M$ and every real $t \geq 1$,*

$$\left| \#\{x \in J : x \bmod M = a,\ \iota(x) \in tD\} - \frac{\mathrm{vol}(D)}{q\ \mathrm{covol}(L(J))} t^d \right| \leq B(t^{d-1} + 1).$$

The same constant works for all residues a.

The estimate is proved from the actual boundary charts and the fixed-lattice discrepancy theorem. The index factor comes from the covolume identity $\mathrm{covol}(L(M)) = q\ \mathrm{covol}(L(J))$. For a complex weight $w : J/M \to \mathbb{C}$, summing the estimates gives the leading term

$$\frac{\mathrm{vol}(D) t^d}{q\ \mathrm{covol}(L(J))} \sum_{a \in J/M} w(a),$$

with error at most $B \sum_a |w(a)|(t^{d-1} + 1)$. If the finite sum of weights is zero, only that error remains. Writing $Y = t^d$ gives an error $O(Y^{1-1/d} + 1)$ for the actual norm threshold. These assertions include $d = 1$.

Lean attachment: `ResidueLatticeIdeal`, `ResidueLatticeIdealPoints`, `ResidueLatticeIdealWeights`, and `ResidueLatticeNormCounts`.

The residue norm and its sign. For $m \in \mathbb{N}$, reducing the multiplication matrices of $\mathcal{O}$ modulo m and taking their determinants constructs a monoid homomorphism

$$\overline{n} : \mathcal{O}/m\mathcal{O} \longrightarrow \mathbb{Z}/m\mathbb{Z}, \qquad \overline{n}([x]) = n(x) \bmod m.$$

The construction is proved independent of the integral basis. For $m \neq 0$, its source is finite of cardinality m^d. Consequently $x - y \in m\mathcal{O}$ implies $n(x) \equiv n(y) \pmod{m}$. No surjectivity of $\overline{n}$ is asserted.

The relation to the geometric sign is also proved. If σ ranges over real embeddings and τ over one embedding from each complex pair, then

$$n(x) = \prod_{\sigma} \sigma(x) \prod_{\tau} |\tau(x)|^2.$$

For $x \neq 0$, the second factor is positive. Thus the sign of $n(x)$ is exactly the sign of the real-coordinate product. Cutting D into its positive and negative portions D_+, D_- adds no boundary outside the existing frontier, and both portions retain the proved boundary atlas. They are disjoint and their union is D.

For $\varepsilon \in \{1, -1\}$ define $\overline{n}_\varepsilon(a) = \varepsilon \overline{n}(a)$. On the corresponding sign portion,

$$\mathrm{N}(x) \bmod m = \overline{n}_\varepsilon([x]).$$

The sign cannot be dropped: $-1 \equiv 2 \pmod{3}$, whereas $\mathrm{N}(-1) = 1$ and $\mathrm{N}(2) = 2$ for principal ideals of $\mathbb{Z}$.

The exact ideal filter. Suppose $IJ = (x)$, $n(x)$ has the indicated sign, and $\gcd(\mathrm{N}\, J, m) = 1$. For $c \in \mathbb{Z}/m\mathbb{Z}$,

$$\mathrm{N}\, I \equiv c \pmod{m} \quad \Longleftrightarrow \quad \overline{n}_\varepsilon([x]) = c(\mathrm{N}\, J \bmod m).$$

This gives an actual finite residue target, which is allowed to be empty. The product identity before cancellation does not require coprimality.

Let $[J] = C^{-1}$ in $\mathrm{Cl}(\mathcal{O})$, and let $\mathcal{G}(J)$ denote the actual fundamental-cone generator set. For every predicate $P : \mathbb{R} \to \mathrm{Prop}$ and every real X, the norm-preserving correspondence gives

$$\begin{aligned} &\#\{x \in \mathcal{G}(J) : \mathrm{N}(x) \leq X\, \mathrm{N}\, J,\ P(\mathrm{N}(x))\} \\ &\qquad = \#\mu(K)\, \#\{I \neq 0 : [I] = C,\ \mathrm{N}\, I \leq X,\ P(\mathrm{N}\, I\ \mathrm{N}\, J)\}. \end{aligned}$$

The same norm-preserving equivalence carries arbitrary complex weights. In particular, write $G_{J,\chi}(Y)$ for the sum of $\chi(\mathrm{N}(x) \bmod m)$ over these generators with $\mathrm{N}(x) \leq Y$, and $T_{C,\chi}(X)$ for the corresponding sum over ideals in class C. For multiplicative χ preserving 0 and 1, the exact identity is

$$G_{J,\chi}(X\, \mathrm{N}\, J) = \#\mu(K)\, \chi(\mathrm{N}\, J \bmod m)\, T_{C,\chi}(X). \tag{1}$$

Both signs are included before applying this full roots-of-unity factor. A root of unity can interchange the sign portions, so that factor is not automatically valid for either portion separately.

Lean attachment: `NormResidueArithmetic`, `NormResidueIdealFilter`, `NormSignArithmetic`, `IdealNormFilterAttachment`, and `IdealNormWeightedAttachment`.

Ordinary class characters: an unconditional power saving. The preceding block proved, for every ordinary ideal class C,

$$A_C(X) = c_K X + O_{K,C}(X^{1-1/d}), \qquad c_K = \frac{2^{r_1}(2\pi)^{r_2} R_K}{\#\mu(K)\sqrt{|\Delta_K|}}.$$

Here A_C counts actual nonzero integral ideals, r_1, r_2 count the real and complex places, R_K is the regulator, and Δ_K is the discriminant. For a weight $w : \mathrm{Cl}(\mathcal{O}) \to \mathbb{C}$, define the actual finite ideal sum

$$S_w(X) = \sum_{\substack{I \neq 0 \\ \mathrm{N}\, I \le X}} w([I]).$$

Exact grouping by ideal class gives $S_w(X) = \sum_C w(C) A_C(X)$. If $\sum_C w(C) = 0$, the common leading coefficient cancels, so there is $B_w \ge 0$ such that

$$|S_w(X)| \le B_w X^{1-1/d} \qquad (X \ge 1).$$

For every nontrivial character $\chi : \mathrm{Cl}(\mathcal{O}) \to \mathbb{C}^\times$, the finite character sum is zero. Thus the displayed estimate applies without an additional arithmetic cancellation hypothesis. This conclusion concerns ordinary class characters. It does not identify them with the further norm-residue characters needed for Frobenius separation.

An actual Mellin endpoint. The counting functions are constant on the integer norm steps. Their measurability, and hence that of S_w, is proved from this fact. For zero-sum w, define

$$F_w(h) = (1+h)\int_1^\infty x^{-2-h} S_w(x)\, dx \qquad (h \ge 0).$$

Since $1 - 1/d < 1$, the logarithmic first moment

$$M_w = \int_1^\infty (1 + \log x)\, |x^{-2} S_w(x)|\, dx$$

is finite. Lean proves the explicit estimate $|F_w(h) - F_w(0)| \le h M_w$ for every $h \ge 0$, and therefore $F_w(h) = F_w(0) + O(h)$ as $h \downarrow 0$. The function here is the displayed integral of the actual ideal sum. Its identification with the intended arithmetic Euler product is a separate step.

For a finite family of nontrivial ordinary class characters, suppose functions p, Z satisfy $h\, p(h) \to P \neq 0$, $h\, Z(h) \to Q \neq 0$, and, for all sufficiently small $h > 0$,

$$Z(h) = \left(p(h) \prod_i F_{\chi_i}(h) \right)^e, \qquad e \in \mathbb{N}.$$

The checked real-axis criterion then gives $e = 1$ and $F_{\chi_i}(0) \neq 0$ for every i. The pole limits and product identity remain hypotheses of this application.

Lean attachment: `IdealClassCharacterBound`, `IdealCharacterMellinMeasurable`, `IdealCharacterMellin`, and `IdealCharacterMellinPole`.

An actual unit action on ideal residues. Fix $m > 0$ and a nonzero integral ideal J. Multiplication by $u \in (\mathcal{O}/m\mathcal{O})^\times$ gives a proved permutation of J/mJ. Its inverse follows from $(ab-1)x \in mJ$ when $ab - 1 \in m\mathcal{O}$ and $x \in J$. No surjectivity of $J/mJ \to \mathcal{O}/m\mathcal{O}$ or coprimality condition on J is used. The well-defined residue norm on this quotient satisfies

$$\overline{n}_J(u \cdot a) = \overline{n}(u)\,\overline{n}_J(a).$$

For a multiplicative $\chi : \mathbb{Z}/m\mathbb{Z} \to \mathbb{C}$ preserving 1, an exhibited unit with

$$u \in (\mathcal{O}/m\mathcal{O})^\times, \qquad \chi(\overline{n}(u)) \neq 1 \tag{2}$$

therefore forces

$$\sum_{a \in J/mJ} \chi\big(s\,\overline{n}_J(a)\big) = 0 \qquad (s \in \mathbb{Z}/m\mathbb{Z}).$$

Taking $s = 1, -1$ gives the two finite means needed by the sign-corrected norm weights. Their vanishing follows from the actual permutation.

The assembled ideal norm-character estimate.

Proposition C.2. *Let $C \in \mathrm{Cl}(\mathcal{O})$, let $J \neq 0$ be an integral ideal with $[J] = C^{-1}$, and let $m > 0$. Let $\chi : \mathbb{Z}/m\mathbb{Z} \to \mathbb{C}$ preserve multiplication, 0, and 1. Assume a residue-ring unit satisfying (2), and assume $\chi(\mathrm{N}\,J \bmod m) \neq 0$. Then*

$$T_{C,\chi}(X) = \sum_{\substack{I \neq 0,\ [I]=C \\ \mathrm{N}\,I \leq X}} \chi(\mathrm{N}\,I \bmod m) = O_{K,J,m,\chi}(X^{1-1/d}).$$

More precisely, some $B \geq 0$ bounds its absolute value by $BX^{1-1/d}$ for every real $X \geq 1$.

The assembly identifies the residue sum with the sum over actual generators, recombines the sign portions, and uses $Y = t^d$ to obtain $|G_{J,\chi}(Y)| \leq B_0(Y^{1-1/d} + 1)$. Equation (1) then permits division by the nonzero factor $\#\mu(K)\chi(\mathrm{N}\,J \bmod m)$. The final theorem supplies its finite means and counting estimates internally. For $d = 1$ the exponent is zero and the conclusion is a bounded sum, so the argument does not require $d > 1$.

What remains open. Nontriviality of χ on the larger residue ring does not supply (2): its restriction to the image of the norm on units may be trivial. Witness existence for the intended characters, their remaining norm-image cases, and suitable inverse-class representatives with $\chi(\mathrm{N}\,J) \neq 0$ are still arithmetic obligations. Measurability and the Mellin attachment for these norm-character sums remain to be checked. The compiled Mellin results above concern ordinary class characters. The resulting estimates must also be attached to the required Euler-product identities and prime-occurrence argument. The conditional pole criterion does not supply those identities. Claims 9.1, 9.2, and 11.1 remain partial, including the separate local compatibility obligations. The ledger stays **17 checked / 3 partial**.

Lean attachment: `IdealResidueUnitActionMean`, `NormResidueUnitCounting`, `NormResidueGeneratorAttachment`, `IdealNormCharacterBound`, and `NormResidueCharacterCounting`.

D Conditional occupied-system completion: final checked scope

The current endpoint is `PaperX.ConditionalOccupiedSystemCompletion.conditional_occupied_system_completion`. The twenty internal claims are checked at their amended and conditional source scopes. The assembly theorem uses explicit inputs. Unrestricted companion existence and carrier existence remain separate questions.

D.1 Two conclusions with separate inputs

The first conclusion starts with actual completed source members at every coefficient place, admissibility at every positive depth, reduction-natural horizontal transport, and an inverse-limit-closed target profile. The predecessor theorem `exists_transported_system_of_inverseLimitClosed` constructs a coefficient-indexed target family. Each target member satisfies every declared finite-depth admissibility condition, is related to the source by the exact all-depth relation `TransportedAlong`, and has the declared complete target profile.

The second conclusion starts with a supplied finite compatible family of pairwise nonisomorphic irreducible constituents, a supplied carrier and its explicit constituent-copy decomposition, and a supplied initial subrepresentation with its constituent-copy presentation. Claim 9.1's arithmetic occurrence result supplies a finite set of distinct good primes outside any prescribed finite forbidden set. Its actual Frobenius trace matrix has nonzero determinant. Claim 9.2 then uses this separator to recover the selected multiplicity vector and its summand inside the carrier.

Write ρ_i for the supplied constituents, c_i for the carrier multiplicities and m_i for the selected multiplicities, with $m_i \le c_i$. At a distinguished coefficient place λ, the input presentations have the form

$$V_{\mathrm{car},\lambda} \simeq \bigoplus_i \rho_{i,\lambda}^{\oplus c_i}, \qquad U_{0,\lambda} \simeq \bigoplus_i \rho_{i,\lambda}^{\oplus m_i}.$$

These are actual equivariant presentations. They are not inferred from an unexplained equality of numerical traces. The selected family $\bigoplus_i \rho_{i,\lambda}^{\oplus m_i}$ has a split equivariant inclusion in the carrier. The finite trace sample uniquely determines the multiplicity vector in the declared constituent packet.

The package `CarrierRecoveryAt` also supplies continuity of the selected copies, the common Frobenius characteristic-polynomial product, finite-copy Weil–Deligne and smooth-inertia data, local characteristic and Euler polynomial products, monodromy-kernel dimension and inertia-fixed trace formulas, and genuine semilinear period comparisons with weight-multiplicity sums. The constituent local packets and comparisons are semantic inputs. The conclusion proves their stated finite-copy closure.

D.2 Why the assembly closes

The final proof is a conjunction. The first branch applies the checked inverse-limit-closed horizontal completion theorem to the completed source family. The second branch constructs the finite arithmetic separator and applies the checked compatible-carrier closure theorem. Claim 9.1 constructs its separator independently of the carrier recovery. Claim 9.2 accepts the separator and the compatible-carrier packet. The final source composes these results. It does not use its conclusion to establish either premise.

The two branches do not identify the recovered carrier's supplied local Weil or period structures with restrictions of the transported target family. They remain logically distinct outputs. A simultaneous

all-place carrier statement is obtained by applying the pointwise result at every place when the corresponding carrier presentations are supplied.

D.3 Occupancy and inherited support

Zero multiplicities are permitted by the formal endpoint. A nonzero occupied conclusion additionally requires the manuscript's declared nonzero-multiplicity premise and nonzero constituents. The module-support/Fitting-ideal alternative is logically separate: its checked support formalization is inherited and is not proved again by this final module. No unrestricted companion existence, automorphy, carrier existence, or universal p-adic Hodge comparison follows from this conditional assembly.

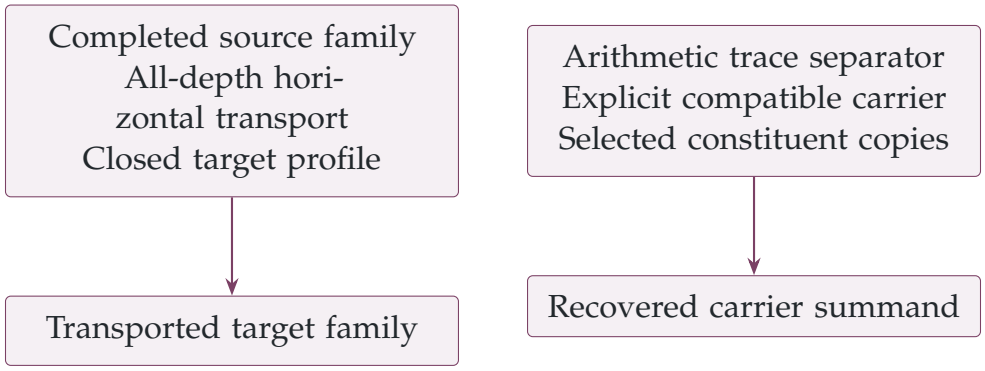
D.4 Evidence tied to this exact source

The recorded verification includes warnings-as-errors builds, matching proof objects and an axiom audit allowing only propext, Classical.choice and Quot.sound. False proofs, placeholders and omitted closure or separator premises were rejected. An injected custom axiom compiled and was detected by the policy audit. The external dependency cache is a trusted input.

D.5 A later attempt with a different scope

The retained stronger residual-system attempt reports 19/20 and `FAIL_CLAIM111_NOT_PROMOTED`, with terminal error `NO_PINNED_LEAN`. No endpoint was promoted by that attempt. It is not a compiler rejection or retraction of the earlier checked conditional theorem. Its criterion begins with finite nonempty companion levels, while the checked conditional endpoint assumes actual completed members. These are different source obligations.

E Worked visual atlas



Plates X.1–X.30 form the worked visual atlas. Their labels, qualified by chapter, identify the same examples throughout the collection.

The atlas develops exact finite models, not substitutes for universal proofs. Its first part separates residual roots, coherent branches, and occupied carrier packets. Its second part studies residue norms, cancellation, Mellin estimates, and the boundary between a finite calculation and arithmetic occurrence. The final plate distinguishes the three source contracts and their mathematical boundaries.

The visual studies connect these examples to the mathematical arguments and to the formal companion.

Two routes to realization

The worked examples connect residual forests, finite occupancy and scalar/Mellin estimates. The conditional occupied-system theorem uses actual completed source members, inverse-limit profile closure, compatible carrier presentations and constituent local comparisons as explicit inputs.

The endpoint proves both outputs. It does not assert that their supplied local structures have been identified. Zero multiplicity is allowed. Nonzero occupancy needs its own input. All-place carrier recovery needs the pointwise presentations at each place.

Reading the examples

The mathematical text gives the arguments and the conditional assembly. The formal companion explains the terminal source, its dependencies and recorded verification. Each plate states the finite data used by its example and the conclusion that those data support.

The target-family and carrier-recovery constructions have different inputs. Their outputs need not be identified. A stronger residual-system contract, retained in the research record, has no promoted endpoint. Its existence requirements must not be substituted for the conditional theorem proved here.

Plate X.1 / READER'S GUIDE

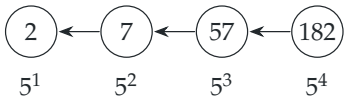
One root is not the whole problem

Main text: §§1–3, 8–11. Conditional contract: Appendix D.

Chapter X separates three questions that can look deceptively similar. Does a residual object exist? Does it extend coherently through every precision? Does the resulting object occur in the required carrier? A successful answer to one question does not supply the next.

A residual root

$x^2 + 1 = 0$ over $\mathbb{F}_2$



one point mod 2

no point mod 4

A coherent branch

$x^2 + 1 = 0$ over $\mathbb{Z}_5$

reductions agree

An occupied packet

1	0
0	0

rank $E = 1$

positivity needs a carrier

Three models to keep in view

The scalar equation $x^2 + 1 = 0$ has the root 1 modulo two, but no root modulo four. Over powers of five, the residues $2, 7, 57, 182$ form the beginning of a compatible branch. Neither fact constructs an automorphic carrier. In a supplied finite carrier, an idempotent such as $\mathrm{diag}(1, 0)$ detects an occupied subspace. It does not explain where that carrier came from.

Read the appendix in three passes. Pages Plates X.3–X.11 explain residual digits, finite counts, and obstruction spaces. Pages Plates X.12–X.20 explain directed transport, common data, and finite occupancy. Pages Plates X.21–X.29 give small exact models for the newer arithmetic continuation and its remaining limits.

> The foundational scalar/Mellin contract covers 17 of 20 records. Claims 9.1, 9.2 and 11.1 need their completed interfaces. The amended conditional assembly covers all twenty under the inputs stated in Appendix D. The finite character examples below do not prove prescribed Frobenius occurrence.

The figures illustrate exact models. Their finite Python checks and formal verification have separate records and scopes.

Plate X.2 / NOTATION BEFORE PICTURES

An atlas of the objects

Main text: Definitions 1.1, 5.1, 6.1, 7.1–7.2, and 8.1.

Keep the coefficient ring, its reduction, and the carrier separate. A residue class is a finite-precision address. A vector in a carrier is a different kind of object, even when both are selected by something called a packet.

Object	What it records	What it does not supply
$\mathcal{O}, \varpi, k$	Complete valuation ring, uniformizer, and residue field k of size q.	A represented deformation functor.
$\bar{x}$	One residual object in the declared moduli problem.	Other residual roots or their transports.
$X_m(\bar{x})$	Admissible objects modulo ϖ^m reducing to $\bar{x}$.	A lift of every individual member.
$(x_m)_m$	A branch satisfying $x_{m+1} \bmod \varpi^m = x_m$.	A global object without the stated reconstruction hypotheses.
w_i	A coordinate constrained to begin in $\varpi^{w_i}\mathcal{O}$.	A classification of all singular deformation rings.
$Z(T)$	The formal series $\sum_{m\geq 1} \#X_m T^m$.	The cardinality of the inverse limit.
$C^\bullet, d$	Cochains and a differential with $d^2 = 0$.	Its arithmetic identification with a Galois problem.
G	The graph of supplied admissible residual transports.	A proof that a proposed arithmetic edge exists.
$\mathscr{C}$	Common algebraic polynomials and declared local data.	A member realizing those data at every prime.
$C\boldsymbol{m} = \boldsymbol{b}$	A finite trace system for carrier multiplicities.	Integrality, positivity, or available capacity automatically.
$e_T V$	The joint eigenspace inside an existing finite carrier V.	Nonzero occupancy for every desired joint label.

Three indices that must not be conflated

The depth m counts retained digits. A coordinate index i selects a parameter or a packet. A coefficient place λ selects a different local field. Increasing m at one λ neither changes i nor constructs the member at another λ.

> **Read this as:** Specify the ambient object before applying a projector, a reduction, a rank, or a counting formula. The same symbol can refer to quite different spaces.

Plate X.3 / RESIDUAL PARTITION

Higher digits cannot change the root

Main text: Theorems 2.1–2.2 and Corollary 2.3.

Work in $\mathbb{Z}/27\mathbb{Z}$. Every element has a unique form $x = 3q + r$ with $r \in \{0,1,2\}$ and $q \in \{0,\dots,8\}$. The row below is the residual root. The column contains all the remaining information at this precision.

$x = 3q + r \pmod{27}$: columns are higher-digit addresses q

	0	1	2	3	4	5	6	7	8
$r = 0$	0	3	6	9	12	15	18	21	24
$r = 1$	1	4	7	10	13	16	19	22	25
$r = 2$	2	5	8	11	14	17	20	23	26

Adding 3 moves within one row. Adding 1 can change the row.

Read the operation, not just the arrow

An operation $x \mapsto x + 3h$ preserves r, because its correction vanishes modulo three. Repeated corrections of this form can visit every column in a row, but can never enter another row. By contrast, adding one changes the residual class. It is therefore not a positive-depth perturbation in this model.

For example, the addresses $1, 4, 7, 10, \dots, 25$ may be deeply connected by higher-digit changes. They remain disjoint from the addresses reducing to zero. In a genuine deformation problem, the same conclusion applies to operations whose reduction is the identity, not to every operation that happens to be called a deformation.

$$\operatorname{red}(x + 3h) = \operatorname{red}(x), \qquad \mathcal{M}(A) = \bigsqcup_{\bar{x}} \mathcal{M}_{\bar{x}}(A).$$

> **Read this as:** Vertical completeness can fill one entire residual fiber without reaching a single point in a different fiber.

All 27 addresses and their finite corrections are checked by integer reduction. Passing to an infinite perturbation stream additionally requires the convergence condition recorded in the formal no-crossing statement.

Plate X.4 / INVERSE-LIMIT RECONSTRUCTION

A branch fixes digits permanently

Main text: Theorem 3.2 and the compatible-digit example in §3.

The rational number $1/4$ is a five-adic integer. Its normalized residues are obtained by solving $4x_m \equiv 1 \pmod{5^m}$, not by taking decimal approximations. At the first six depths they are $4, 19, 94, 469, 2344, 11719$.

	5^0	5^1	5^2	5^3	5^4	5^5	
$x_1 = 4$	4	—	—	—	—	—	
$x_2 = 19$	4	3	—	—	—	—	$4x_m - 1 = 3 \cdot 5^m$
$x_3 = 94$	4	3	3	—	—	—	
$x_4 = 469$	4	3	3	3	—	—	
$x_5 = 2344$	4	3	3	3	3	—	digits already fixed never change
$x_6 = 11719$	4	3	3	3	3	3	

Compatibility is stronger than independent solvability

The residues satisfy both

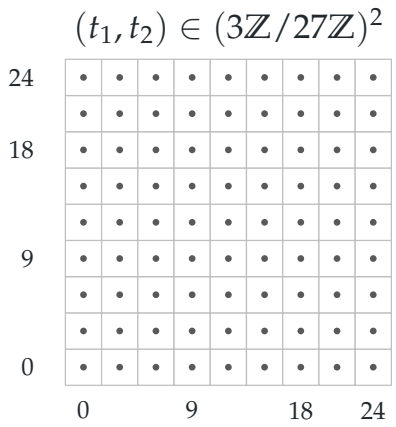
$$x_{m+1} \equiv x_m \pmod{5^m}, \qquad 4x_m - 1 = 3 \cdot 5^m.$$

The latter identity shows that the residual error tends to zero in the five-adic norm. The stabilized digit sequence is

$$\frac{1}{4} = 4 + 3 \cdot 5 + 3 \cdot 5^2 + 3 \cdot 5^3 + \cdots \quad \text{in } \mathbb{Z}_5.$$

This series is not convergent in the ordinary real norm. The topology is part of the statement. To view the branch as a positive-depth coordinate above the residual root 4, use $t = x - 4 \in 5\mathbb{Z}_5$.

An inverse-limit point is the entire compatible family, not its last displayed approximation. The six rows are a finite window. The displayed exact formula supplies a branch at every depth in this particular example. In the represented deformation theorem, compatibility reconstructs maps on all ring elements, with multiplication, continuity, and locality retained.



> **Read this as:** A later approximation may append a digit. It may not revise a digit already certified by reduction.

Plate X.5 / ACTUAL FINITE POINTS

A smooth chart has independent choices

Main text: Proposition 3.4 and Theorem 6.2.

Take $R = \mathbb{Z}_3[[t_1, t_2]]$ and coefficient-preserving local maps to $\mathbb{Z}/27\mathbb{Z}$. Locality forces both parameters into the maximal ideal. Each therefore has nine possible values, $0, 3, 6, \ldots, 24$.

$$9 \times 9 = 81 \text{ points}$$

$$(t_1, t_2) \mapsto (t_1, t_2) \bmod 9$$

Each parent has $3^2 = 9$ children.

The chart hypothesis supplies independent digits.

Why the exponent is $d(m-1)$

At depth m, the image of the maximal ideal contains 3^{m-1} elements. Two independent parameters give $3^{2(m-1)}$ points. The grid displays all 81 points at depth three, not a random sample. Reduction to depth two maps each coordinate to one of $0, 3, 6$, and every parent has nine children.

$$\#X_m = 3^{2(m-1)}, \qquad Z(T) = \sum_{m \geq 1} \#X_m T^m = \frac{T}{1 - 9T}.$$

Counting all 27^2 parameter assignments at depth three would ignore locality. Counting only tangent directions would describe the first layer but not all later layers. The power-series presentation explains why these choices stay independent through every precision.

This is a coordinate model with a proved presentation. A general deformation ring can impose equations among the parameters, changing the counts and causing branches to die. The next pages retain the same depth convention while changing the allowed coordinates or adding a singular equation.

> **Read this as:** The smooth count is not a universal rule for deformation spaces. Its independence comes from the actual formal power-series chart.

Plate X.6 / WEIGHTED DYADIC CHARTS

Weights delay visibility

Main text: Proposition 5.3, Theorem 6.3, and §12.2.

Over $\mathbb{Z}_2$, require three coordinates to lie in $2\mathbb{Z}_2$, $2^2\mathbb{Z}_2$, and $2^4\mathbb{Z}_2$. At depth m, coordinate i has $\max(m - w_i, 0)$ free binary digits. A zero in the table means only one allowed residue: zero.

	$m=1$	$m=2$	$m=3$	$m=4$	$m=5$	$m=6$	$m=7$
$w_1 = 1$	0	1	2	3	4	5	6
$w_2 = 2$	0	0	1	2	3	4	5
$w_3 = 4$	0	0	0	0	1	2	3
count	1	2	8	32	256	2048	16384

Cell = number of free binary digits, not first separation depth.

The two different thresholds

A coordinate of weight w_i first becomes nontrivial when $m = w_i + 1$. By contrast, the first separation depth of two distinct fixed values a, b is $v_2(a - b) + 1$. Thus 1 and -1 separate at depth two, because their difference has valuation one. Neither threshold is simply the printed coordinate label.

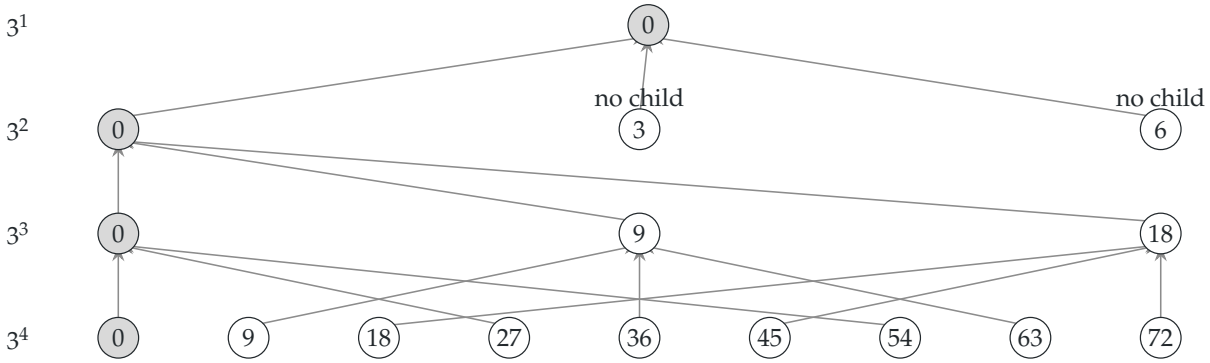
For weights $(1, 2, 4)$,

$$N(m) = 2^{\max(m-1,0)+\max(m-2,0)+\max(m-4,0)}.$$

The first counts are $1, 2, 8, 32, 256, 2048$. Once all three coordinates are active, every additional precision digit multiplies the count by eight. Separating the initial levels from that geometric tail gives

$$Z(T) = \frac{T(1 - 6T - 8T^2 - 32T^3)}{1 - 8T}.$$

Negative coefficients in the numerator do not mean negative numbers of points. Expanding the whole rational expression gives positive coefficients.



> **Read this as:** Weights change the finite-depth delay. After activation, this chart still has three independent digit streams.

Plate X.7 / SINGULAR POWER SEEDS

Many approximate roots, one limit

Main text: Theorem 6.4 and Corollary 6.6.

Now impose $x^2 = 0$ modulo 3^m. The condition is exactly $2v_3(x) \geq m$, so the roots are the multiples of $3^{\lceil m/2 \rceil}$ in that quotient. Their number is $3^{m-\lceil m/2 \rceil}$.

More finite roots, but only the zero stream persists through every precision.

Count vertices and count branches separately

There are three roots modulo nine: $0, 3, 6$. But the only roots modulo 27 are $0, 9, 18$, and all three reduce to zero modulo nine. The other two vertices at the previous level have no children. Counting them as permanent branches would be incorrect.

$$\#X_m = 1, 3, 3, 9, 9, 27, \ldots, \qquad Z(T) = \frac{T + 3T^2}{1 - 3T^2}.$$

The count-growth exponent is $\lim_m \log_3(\#X_m)/m = 1/2$. Nevertheless, a compatible branch reconstructs $x \in \mathbb{Z}_3$ with $x^2 = 0$. Since $\mathbb{Z}_3$ has no nonzero nilpotent, the only such branch is the zero branch.

More generally, $x^e = 0$ has count $q^{m-\lceil m/e \rceil}$ and count-growth exponent $1 - 1/e$. These exponents describe finite thickenings. They do not assert that the set of complete roots has a fractional geometric dimension or more than one point.

> **Read this as:** The seed zeta function counts finite-level solutions. It is not a generating function for distinct infinite branches.

Plate X.8 / A SCALAR COMPANION MODEL

One equation, several local outcomes

Main text: Theorem 8.2, Corollary 8.3, and Example 8.4.

Consider the fixed scalar equation $x^2 + 1 = 0$ in $\mathbb{Z}/p^m\mathbb{Z}$. The following are exact counts for five primes and three depths. The coefficient rings and the scalar nature of the unknown are fixed throughout this page.

	$p = 2$	$p = 3$	$p = 5$	$p = 7$	$p = 13$
$m = 1$	1	0	2	0	2
$m = 2$	0	0	2	0	2
$m = 3$	0	0	2	0	2

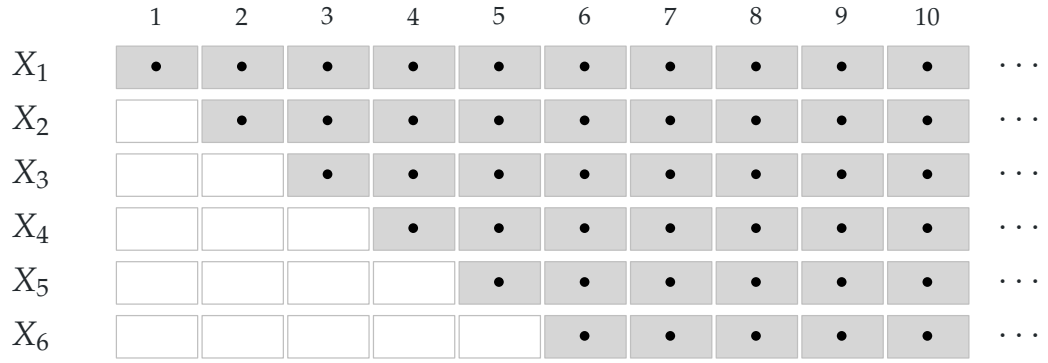
Counts of $x \in \mathbb{Z}/p^m\mathbb{Z}$ with $x^2 + 1 = 0$.

Where failure occurs matters

At $p = 3$ and $p = 7$, no residual root exists. At $p = 2$, the residual root exists but dies immediately: every odd square is one modulo four. At $p = 5$ and $p = 13$, the two residual roots are simple, and the usual one-digit equation gives one child above each root at every depth.

At five, one branch begins $2, 7, 57, 182$. The other is its negative modulo each power of five. Arbitrarily many digits in either branch cannot supply the absent scalar root over $\mathbb{Z}_3$. Nor can one root modulo two satisfy the hypothesis that every finite level is nonempty.

The chapter's system-completion theorem uses a supplied common algebraic spine, finite nonempty levels at every coefficient place, coherent reductions, and closed local conditions. The scalar example isolates why these are substantive requirements. It is not a disproof of a companion theorem whose coefficients may be enlarged or whose objects are higher-dimensional representations.



> **Read this as:** A residual root, roots at all depths, and roots at every required coefficient place are three distinct tests.

Plate X.9 / AN INFINITE-LEVEL COUNTERMODEL

Why finiteness enters compactness

Main text: Theorem 3.3 and its finite-branching hypotheses.

Let $X_m = \{n \in \mathbb{Z} : n \geq m\}$, with the inclusion $X_{m+1} \hookrightarrow X_m$ as transition map. Every level is nonempty. Every vertex has at most one child. Yet there is no compatible infinite branch.

$X_m = \{n \in \mathbb{N} : n \geq m\}$; every reduction is an inclusion.

The missing hypothesis is not surjectivity

Compatibility would force all coordinates of a branch to be one fixed integer n. Membership at every level would then require $n \geq m$ for every m, which is impossible. Each vertical column in the drawing eventually ends. A finite window always contains columns extending beyond it, but no single column survives all windows.

There is no contradiction with finite-branch compactness: these levels are infinite. Attaching a common artificial root would give that root infinitely many children. The finitely branching rooted-tree argument therefore does not apply.

In the chapter, finite nonempty levels and actual total reduction maps provide compactness even when some vertices die and some transition maps are not onto. One can retain only vertices with descendants at arbitrarily large depths. Finiteness makes that surviving part nonempty and permits compatible choices.

$$X_m \neq \varnothing \text{ for all } m \quad \not\Longrightarrow \quad \varprojlim_m X_m \neq \varnothing \quad \text{without the compactness hypotheses.}$$

> **Read this as:** Arbitrarily long finite paths are not automatically one infinite path. The finite-level hypothesis prevents escape to new roots.

Plate X.10 / A TWO-PACKET COCHAIN COMPLEX

See cycles, boundaries, and classes

Main text: Theorem 4.2 and the finite-complex example.

Over $\mathbb{F}_5$, use bases (e_0, e_1), (u_0, u_1, u_2, u_3), and (f_0, f_1) in degrees zero, one, and two. The only nonzero differential values are $d_0 e_0 = u_0$ and $d_1 u_1 = f_0$. Consequently $d_1 d_0 = 0$.

$d_0 : C^0 \to C^1$

	e_0	e_1
u_0	1	0
u_1	0	0
u_2	0	0
u_3	0	0

$d_1 : C^1 \to C^2$

	u_0	u_1	u_2	u_3
f_0	0	1	0	0
f_1	0	0	0	0

$$d_1 d_0 = 0$$

$$H^0 = \langle [e_1] \rangle$$

$$H^1 = \langle [u_2], [u_3] \rangle$$

$$H^2 = \langle [f_1] \rangle$$

Packet A is exact. Packet B has zero differentials and carries all cohomology.

Passing to the quotient

In degree one, the cycles are $\operatorname{span}(u_0, u_2, u_3)$, but u_0 is a boundary. Thus the cohomology is represented by u_2, u_3, not by every vector killed by d_1. In the other degrees the surviving classes are e_1 and f_1.

$$\dim(H^0, H^1, H^2) = (1, 2, 1).$$

Packet A contains e_0, u_0, u_1, and f_0. It is exact and contributes $(0, 0, 0)$. Packet B contains e_1, u_2, u_3, and f_1, with zero differentials, and contributes $(1, 2, 1)$. Adding the packet cohomologies reconstructs the total.

The projectors must be specified in every degree and commute with the differential. Their existence is not a consequence of the printed dimensions. Identifying this finite complex with the actual continuous cohomology of an arithmetic deformation problem would also require a separate comparison.

> **Read this as:** Resolve the differential first, then pass from cycles to classes. Counting packet dimensions alone does not compute cohomology.

Plate X.11 / THE CHAIN-MAP CONDITION

An arbitrary cut need not descend

Main text: Theorem 4.2 and the scope of the cohomology splitting.

Retain the previous complex. The valid A-packet projectors are $P^0 = \operatorname{diag}(1,0)$, $P^1 = \operatorname{diag}(1,1,0,0)$, and $P^2 = \operatorname{diag}(1,0)$. They satisfy $d_r P^r = P^{r+1} d_r$.

valid P^1_A invalid Q^1 $d_0 P^0_A - Q^1 d_0$

1	0	0	0
0	1	0	0
0	0	0	0
0	0	0	0

0	0	0	0
0	1	0	0
0	0	0	0
0	0	0	0

1	0
0	0
0	0
0	0

e_0 is retained at the source but its image u_0 is deleted at the target.

All displayed degreewise maps are idempotent. The differential test distinguishes them.

A boundary can cross an incompatible cut

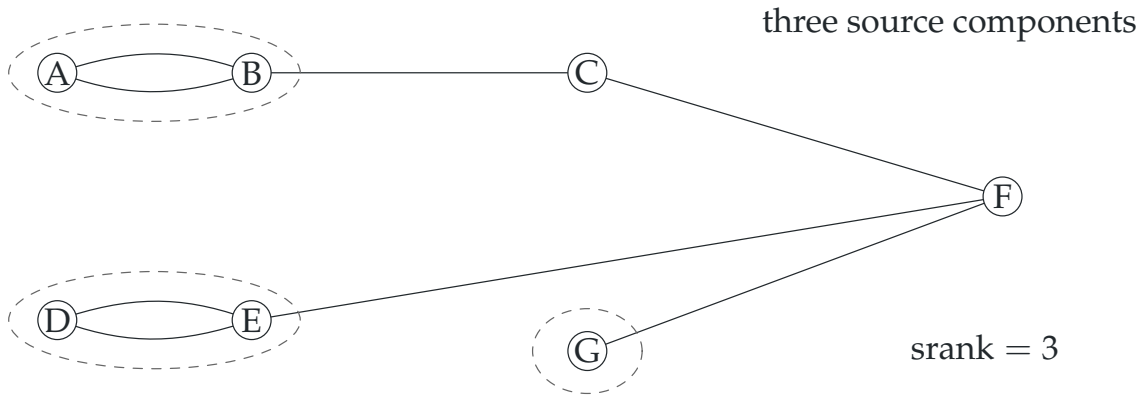
Replace the degree-one projector by $Q^1 = \operatorname{diag}(0,1,0,0)$ while keeping P^0. Then

$$d_0 P^0 e_0 = u_0, \qquad Q^1 d_0 e_0 = 0, \qquad (d_0 P^0 - Q^1 d_0) e_0 = u_0 \neq 0.$$

The selected degree-zero component is sent outside the selected degree-one component. There is no subcomplex with these cuts, so the cohomology packet theorem cannot be applied to them. Both matrices remain perfectly valid idempotents. The failure is compatibility with the differential.

This example separates two kinds of obstruction. The nonzero matrix above obstructs this proposed decomposition. A nonzero class in H^2 may obstruct a lift only after the deformation problem and its obstruction map have been identified. One should not equate every failed projector commutator with an arithmetic obstruction class.

The exact checks verify both commuting diagrams for the valid family and reject the altered family. They also enumerate the finite kernels and images, so the dimension comparison is not inferred from the drawing.



> **Read this as:** A projector on each vector space is not yet a projector on the complex. The differential must respect the chosen packets.

Plate X.12 / DIRECTED TRANSPORT

How many starting seeds are necessary?

Main text: Theorem 7.3 and the seven-root example.

The arrows below are the entire supplied transport graph. Vertices joined by paths in both directions form strongly connected components. The components $\{A, B\}$, $\{D, E\}$, and $\{G\}$ have no incoming edge from outside themselves.

A minimum set meets each dashed source component.

A lower bound and a construction

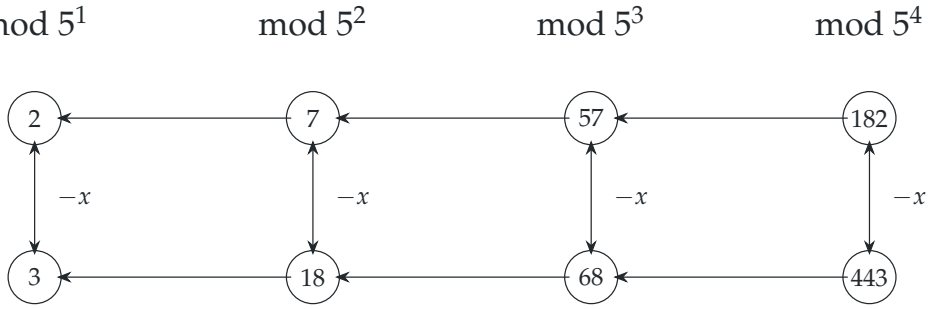
Any seed set reaching every vertex must meet all three source components. Otherwise there is no path into the omitted source. Conversely, one representative from each source reaches C and F as well. The directed seed rank is therefore three.

There are precisely four minimum seed sets:

$$\{A, D, G\}, \quad \{A, E, G\}, \quad \{B, D, G\}, \quad \{B, E, G\}.$$

The example checks this by exhaustive enumeration of all 2^7 subsets, independently of the strongly connected component calculation. Adding an admissible edge cannot increase the required seed count. In particular, adding $F \to G$ makes G reachable from the other sources, reducing the count to two.

The graph theorem is exact for the graph supplied. It does not establish that a proposed twist, induction, or arithmetic transfer preserves a determinant, local condition, or occupancy theorem. Those facts justify the arrows before graph optimization begins.



> **Read this as:** Count source components, not all components and not all vertices. But do not add an arithmetic arrow merely because it would improve the count.

Plate X.13 / ONE REVERSIBLE EXAMPLE

A transport must work at every depth

Main text: Definition 7.1 and the reduction-compatibility requirement.

For the two roots of $x^2 + 1 = 0$ modulo powers of five, negation is an actual reversible transport. It preserves the equation, is its own inverse, and commutes with reduction.

Negation commutes with reduction. Translation by 1 fails already at $2 \mapsto 3 \mapsto 4 \bmod 5$.

One successful input is not a natural transformation

At every depth m,

$$N_m(x) = -x \pmod{5^m}, \qquad r_{m+1,m} N_{m+1} = N_m r_{m+1,m}.$$

The two compatible branches beginning at 2 and 3 are exchanged. Because $2 \not\equiv 3 \pmod 5$, this transport changes the residual root. It is horizontal rather than a positive-depth correction.

Translation by one is a useful false control. Modulo five it takes the root 2 to the root 3, but takes the root 3 to 4, which is not a root. A single successful arrow between selected points does not define an operation on the whole deformation problem.

Even negation is admissible only for the equation and conditions stated here. An extra condition that fixes the residual root at 2 would not be preserved. Likewise, a representation-theoretic dual or twist needs its own compatibility checks for the chosen local data and carrier.

> **Read this as:** A transport is a family of maps respecting equations and reductions. A convenient pair of endpoints is not enough.

Both branches are computed by exact one-digit lifting. Negation is checked on all roots at the displayed depths. Its universal reduction identity follows directly from ring homomorphism laws.

Plate X.14 / THE ARITHMETIC SPINE

Common coefficients, different residues

Main text: Definition 8.1 and Theorem 8.2.

A common spine records algebraic data before reducing at a coefficient prime. For a small model, take the one polynomial

$$P(T) = T^2 - 5T + 6 = (T - 2)(T - 3) \in \mathbb{Z}[T].$$

Its reductions at five and seven look different, but they come from the same coefficients.

$$P(T) = T^2 - 5T + 6 = (T - 2)(T - 3)$$

coefficient images under the declared maps

	T^2	T	1
$\mathbb{Z}$	1	-5	6
$\mathbb{F}_5$	1	0	1
$\mathbb{F}_7$	1	2	6

Different residue rows come from the same algebraic polynomial.

Agreement means descent from supplied data

Modulo five the polynomial is $T^2 + 1$. Modulo seven it is $T^2 + 2T + 6$. The roots 2 and 3 are the reductions of the same integer roots in both places. The coefficient lists are not required to be equal as raw residues in different rings.

The chapter's common spine is larger: it includes characteristic polynomials at the permitted arithmetic places and the specified determinant, weight, and local labels. Requiring every finite member to match those reductions is a compatibility condition on existing objects. It is not a construction of the objects.

Finite agreement also leaves ambiguity. Adding 35 to an integer coefficient changes neither its residue modulo five nor its residue modulo seven. Thus two finite coefficient observations do not determine a unique global polynomial without a height bound or further exact information. Conversely, one arbitrarily chosen family of local objects need not descend to an algebraic spine.

> **Read this as:** The common spine is input shared across coefficient places. It is not created by comparing unrelated residue labels after the fact.

Plate X.15 / CHARACTERS BEFORE ARITHMETIC PRIMES

A finite trace matrix can separate types

Main text: Theorem 9.1; retained scalar/Mellin continuation: arithmetic-system separation.

Use the three irreducible characters of S_3: trivial, sign, and standard. On the identity, a transposition, and a three-cycle, their values form the matrix below. Rows are samples. Columns are constituent types.

C: actual S_3 character table

	trivial	sign	standard
1	1	1	2
(12)	1	−1	0
(123)	1	1	−1

$$\boldsymbol{m} = \begin{pmatrix} 2 \\ 0 \\ 1 \end{pmatrix} = \boldsymbol{b} = \begin{pmatrix} 4 \\ 2 \\ 1 \end{pmatrix}$$

$$\det C = 6$$

$$C^{-1}\boldsymbol{b} = (2, 0, 1)^T$$

Class representatives are finite group elements, not a proof that suitable Frobenius primes occur.

What full rank implies

Since $\det C = 6$, these samples distinguish every rational multiplicity vector. A target with two trivial constituents, no sign constituent, and one standard constituent has

$$\boldsymbol{m} = \begin{pmatrix} 2 \\ 0 \\ 1 \end{pmatrix}, \qquad \boldsymbol{b} = C\boldsymbol{m} = \begin{pmatrix} 4 \\ 2 \\ 1 \end{pmatrix}.$$

Solving $C\boldsymbol{m} = \boldsymbol{b}$ recovers the unique rational vector. The standard character is not introduced as an arbitrary list: the checks construct matrices for a transposition and a three-cycle, verify their group relations, and obtain their traces.

This finite example explains the linear algebra after separating samples are available. For the arithmetic theorem, the samples must be genuine unramified Frobenius classes with the required compatibility and allowed-prime conditions. Selecting abstract group elements does not construct such primes.

The scalar/Mellin construction supplies a separator assembly conditional on arithmetic coverage. The checked source Claim91ConstructedClosure discharges that interface for its rational-base contract. Neither result follows from the finite character table displayed here.

> **Read this as:** Invertibility answers reconstruction from these samples. Arithmetic occurrence answers whether the required samples can be taken at actual primes.

Plate X.16 / INTEGRAL, NONNEGATIVE, WITHIN CAPACITY

A solution is not yet a summand

Main text: Theorem 9.2 and its multiplicity-recovery example.

Keep the same separating matrix C and suppose the available carrier has capacities $\boldsymbol{c} = (2,1,1)$. A recovered vector describes a sum of selected constituents of that carrier only if each entry is an integer and $0 \le m_i \le c_i$.

trace data $\boldsymbol{b}$	$C^{-1}\boldsymbol{b}$	capacity $(2,1,1)$
$(4,2,1)$	$(2,0,1)$	allowed
$(1,0,0)$	$(\frac{1}{6},\frac{1}{6},\frac{1}{3})$	nonintegral
$(2,-2,-1)$	$(-1,1,1)$	negative
$(5,3,2)$	$(3,0,1)$	over capacity

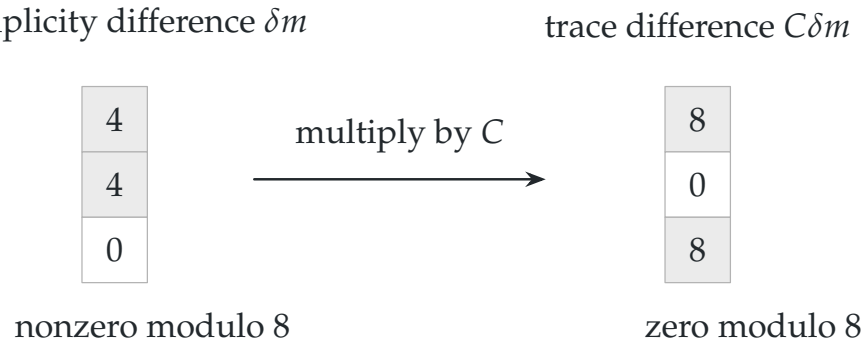
Three independent rejection tests

The trace vector $(1,0,0)$ gives $(1/6,1/6,1/3)$, so it fails integrality. The vector $(2,-2,-1)$ gives $(-1,1,1)$, which is integral but not nonnegative. The vector $(5,3,2)$ gives $(3,0,1)$, which exceeds the available capacities. In each case the linear equation itself has a unique rational solution.

The accepted example $\boldsymbol{b} = (4,2,1)$ recovers $(2,0,1)$. When compatible constituent families are already supplied, the same admissible multiplicities define the corresponding direct sum at every coefficient place. This is the finite algebraic core of summand transport.

It does not supply a compatible family for an arbitrary object, construct all local attachments, or ensure that a carrier contains the desired representation. The carrier theorem requires explicit constituent-copy presentations and supplied local comparisons.

> **Read this as:** Invert the trace matrix, then check the representation-theoretic constraints. A unique vector in a field need not be a realizable multiplicity vector.



All accepted and rejected vectors are solved over exact rationals. The code rejects the wrong cases by their stated reason, not by a floating-point tolerance.

Plate X.17 / EXACT PRECISION LOSS

Separation can consume a digit

Main text: The finite trace-recovery discussion in §9.

The character matrix has determinant six, so its inverse contains a factor of two in the denominator. That arithmetic fact is visible as a loss of one binary digit in trace reconstruction.

Modulo 16, the traces separate them. $v_2(\det C) = v_2(6) = 1$.

A concrete ambiguity modulo eight

The multiplicity difference $\delta\boldsymbol{m} = (4, 4, 0)$ is nonzero modulo eight, but

$$C\,\delta\boldsymbol{m} = (8, 0, 8) \equiv 0 \pmod 8.$$

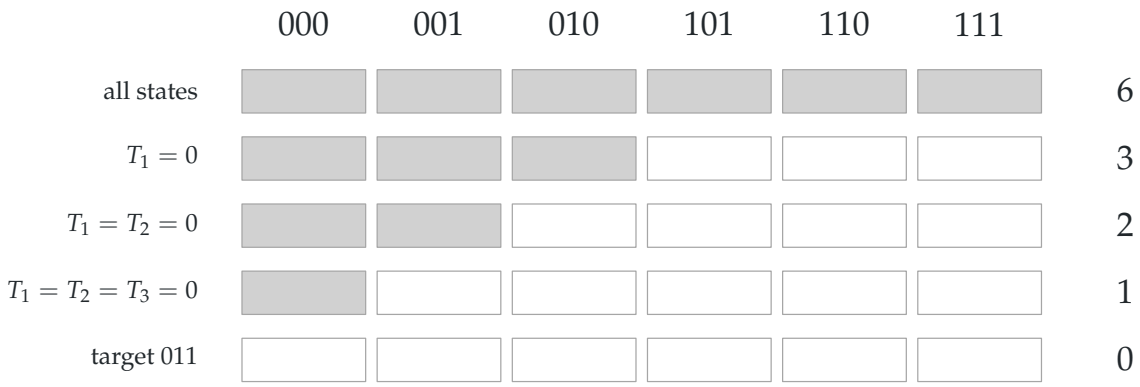
Thus traces known modulo eight do not distinguish those two residue vectors. The same trace difference is nonzero modulo sixteen, so one more trace digit resolves this ambiguity.

More generally, the kernel of C modulo 2^n has exactly two elements:

$$(0, 0, 0), \qquad (2^{n-1}, 2^{n-1}, 0).$$

To see this, the second equation gives $m_1 = m_2$. The third gives $m_3 = 2m_1$. The first then gives $6m_1 = 0$. Three is a unit modulo 2^n, leaving precisely the displayed possibilities.

Conversely, $C\delta\boldsymbol{m} \equiv 0 \pmod{2^{n+1}}$ implies $6\delta\boldsymbol{m} \equiv 0 \pmod{2^{n+1}}$ by the adjugate identity, hence $\delta\boldsymbol{m} \equiv 0 \pmod{2^n}$. Capacity bounds can remove ambiguity earlier in a particular carrier, but do not change this universal linear precision calculation.



> **Read this as:** Full rank over characteristic zero is not the same as invertibility over every residue ring. Denominator valuations determine the needed extra precision.

Plate X.18 / EXACT JOINT PROJECTORS

Pairwise occupancy can still fail jointly

Main text: Theorem 10.1 and the finite occupancy models.

Let a six-dimensional rational carrier have the joint eigenvalue labels shown below for three commuting diagonal operators T_1, T_2, T_3. Each coordinate is zero or one. Selecting a zero uses $I - T_i$. Selecting a one uses T_i.

Each pair of requirements from 011 is occupied. Their triple intersection is empty.

The full conjunction is a different test

For target $(0,0,0)$, successive conditions reduce the ranks from 6 to 3, then 2, then 1. The joint projector is nonzero, so that label is occupied in this carrier.

For target $(0,1,1)$, every pair of conditions is occupied: $(0,1,0)$ witnesses the first two, $(0,0,1)$ the first and third, and $(1,1,1)$ the second and third. But the triple itself is absent. Multiplying all three selectors gives the zero matrix.

$$E_{\boldsymbol{a}} = \prod_{i=1}^{3} \begin{cases} I - T_i, & a_i = 0, \\ T_i, & a_i = 1. \end{cases} \qquad \operatorname{Tr}(E_{\boldsymbol{a}}) = \operatorname{rank}(E_{\boldsymbol{a}}).$$

The checks compute all eight joint projectors, their pairwise orthogonality, and their sum. The sum is the identity even though two labels are absent: those two projectors are simply zero.

> **Read this as:** A formula for a projector does not force its image to be nonzero. Occupancy must be tested on the complete set of required conditions.

Plate X.19 / TRACE AND SEMISIMPLICITY

Why the hypotheses are needed

Main text: Theorem 10.1 and the checked false controls following it.

The finite occupancy theorem uses a split semisimple commuting family in characteristic zero. Two matrices show why neither the coefficient condition nor semisimplicity should disappear from the statement.

I_5 over $\mathbb{F}_5$

1	0	0	0	0
0	1	0	0	0
0	0	1	0	0
0	0	0	1	0
0	0	0	0	1

rank 5, trace 0

$N^2 = 0$

0	1
0	0

only eigenvalue 0

$\dim \ker N = 1$

sole-eigenvalue product $= I_2$

Keep characteristic zero for trace detection, and split semisimplicity for the Lagrange formula.

Trace zero need not mean an empty image

On $\mathbb{F}_5^5$, the identity is an idempotent of rank five, but its field-valued trace is $5 = 0$ in $\mathbb{F}_5$. Rank and localization still detect its nonzero image. A characteristic-zero integer trace cannot be silently transferred to this setting.

An eigenvalue label need not select ordinary eigenvectors

For the nilpotent matrix $N = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, the only eigenvalue is zero. A Lagrange selector that multiplies over all other eigenvalues is an empty product, hence I. Its image has dimension two, while $\ker N$ has dimension one. The selector does not project onto the ordinary eigenspace.

The whole two-dimensional space is the generalized zero-eigenvalue packet. Chapter XII's Artin-packet treatment is designed to retain such nilpotent structure. That is a different target from Chapter X's split semisimple joint-eigenspace formula.

> **Read this as:** A correct theorem in one coefficient category is not a theorem in all categories. Changing from ordinary eigenspaces to generalized packets also changes the object being detected.

Plate X.20 / CLOSEDNESS OF THE LOCAL CONDITIONS

A condition must survive the limit

Main text: Theorems 8.2 and 11.1; the inverse-limit closure hypotheses.

In $\mathbb{Z}_3$, every term of the sequence $x_k = 3^k$ is nonzero. Yet $x_k \to 0$ in the three-adic topology. The property "nonzero" is not closed, so a limit of objects satisfying it can lose that property.

	3^0	3^1	3^2	3^3	3^4	3^5	3^6
$a_k = 3^0$	1	0	0	0	0	0	0
$a_k = 3^1$	0	1	0	0	0	0	0
$a_k = 3^2$	0	0	1	0	0	0	0
$a_k = 3^3$	0	0	0	1	0	0	0
$a_k = 3^4$	0	0	0	0	1	0	0
$a_k = 3^5$	0	0	0	0	0	1	0

Every a_k is nonzero. Every fixed finite digit window eventually reads only zeros.

Polynomial conditions behave differently

For a continuous polynomial f, if a convergent sequence satisfies $f(x_k) = 0$ for every k, then continuity gives $f(x) = 0$ at its limit. More generally, a compatible residue branch satisfying $f(x_m) \equiv 0 \pmod{3^m}$ reconstructs an exact root once the complete ring and its reduction maps have been identified.

The sequence 3^k here is *not* presented as a compatible branch of nonzero residues modulo 3^k: those particular residues are zero. It is a convergent sequence of nonzero elements of the complete ring. The distinction prevents an incorrect finite-level interpretation of the picture.

In an arithmetic application, local conditions may be given by quotient equations, integral structures, or other data. The completion theorem requires a proof that the chosen condition is preserved by the limit under construction. The word "admissible" does not itself provide that proof.

> **Read this as:** Compatibility reconstructs an object. Closedness is what carries the declared equations or conditions to that object.

The finite diagram displays the retreat of the first nonzero digit. The convergence assertion follows from $|3^k|_3 = 3^{-k}$, not from extrapolating a finite numerical plot.

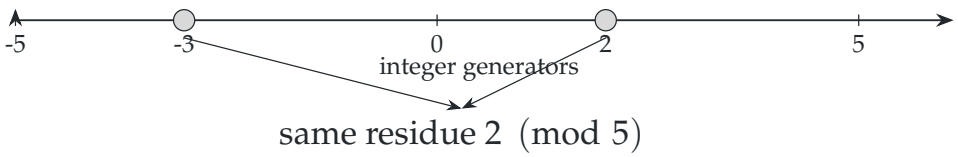


Plate X.21 / ELEMENTS VERSUS IDEALS

The sign of a norm is arithmetic data

Main text: §9, arithmetic residue-counting continuation; signed-norm comparison.

Even in the number field $\mathbb{Q}$, congruent generators need not have congruent absolute norms. The integers 2 and -3 are congruent modulo five. Their signed field norms are congruent, but their absolute values are not.

$$N_{\mathbb{Q}/\mathbb{Q}}(-3) = -3 \qquad N_{\mathbb{Q}/\mathbb{Q}}(2) = 2$$

same residue 2 $\pmod 5$

$$N((-3)) = 3 \qquad N((2)) = 2$$

The ideal norm is positive. Passing to absolute values must retain the real sign.

A counterexample over the integers

For $K = \mathbb{Q}$,

$$N_{K/\mathbb{Q}}(2) = 2, \qquad N_{K/\mathbb{Q}}(-3) = -3 \equiv 2 \pmod 5,$$

whereas

$$N((2)) = 2, \qquad N((-3)) = 3 \not\equiv 2 \pmod 5.$$

Here $N((a))$ is the positive index of the ideal (a), equal to $|a|$. The determinant norm of an element is signed. Taking absolute values is not a ring operation and does not commute with reduction in this example.

The retained scalar/Mellin continuation counts the two real norm signs separately before reassembling its generator-to-ideal sums. Its exact comparison also includes the roots-of-unity multiplicity and the norm of the chosen inverse-class representative. Omitting those factors would change the arithmetic sum, not merely its normalization.

The finite-field norm on the following pages is a determinant in a finite algebra. It has no ordering or absolute-value sign. Its role is to control residue characters before the separate real-lattice counting argument.

> **Read this as:** Do not infer an ideal-norm residue from a generator congruence without accounting for the sign in the element-to-ideal comparison.

Plate X.22 / THE QUOTIENT ALGEBRA $\mathbb{F}_{25}$

A norm is a determinant you can compute

Main text: §9; retained scalar/Mellin continuation: actual quotient determinant norms.

Use $A = \mathbb{F}_5[u]/(u^2 - 2)$. Since two is not a square modulo five, this quotient is a field with 25 elements. Every element is uniquely $a + bu$, with $a, b \in \mathbb{F}_5$.

$$N(a + bu) = a^2 - 2b^2 \pmod 5$$

	$b=0$	$b=1$	$b=2$	$b=3$	$b=4$
$a=0$	0	3	2	2	3
$a=1$	1	4	3	3	4
$a=2$	4	2	1	1	2
$a=3$	4	2	1	1	2
$a=4$	1	4	3	3	4

$$u^2 = 2 \text{ in } \mathbb{F}_{25}$$

$$M_{a+bu} = \begin{pmatrix} a & 2b \\ b & a \end{pmatrix}$$

$$\#N^{-1}(0) = 1$$

$$\#N^{-1}(r) = 6 \text{ for } r \neq 0$$

All 25 elements are shown. Every nonzero element is a unit.

Coordinates, multiplication, and norm agree

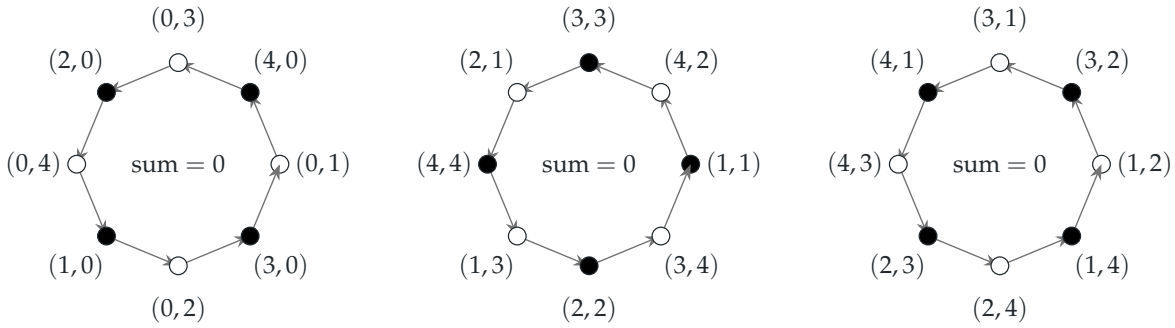
In the basis $(1, u)$, multiplication by $a + bu$ has matrix

$$M_{a,b} = \begin{pmatrix} a & 2b \\ b & a \end{pmatrix}, \qquad N(a + bu) = \det M_{a,b} = a^2 - 2b^2 \pmod 5.$$

The table shows every norm value. Only the zero element has norm zero. Each nonzero norm value has exactly six preimages. This makes the later character cancellation visible without estimating any sums.

The checks enumerate all 25 matrices, verify the determinant formula, and verify norm multiplicativity on every pair of field elements. They also change to a different invertible basis and check that conjugating the multiplication matrix leaves its determinant unchanged.

This model is the reduction of the quadratic integer algebra $\mathbb{Z}[\sqrt{2}]$ modulo five. Its finite arithmetic illustrates the determinant construction used in the continuation. It is not a computation of all ideal classes or a general ideal-counting theorem.



> **Read this as:** A quotient norm is built from the actual multiplication operator. Its basis independence is a determinant identity, not a choice of convenient coordinates.

Plate X.23 / A NONSCALAR UNIT WITNESS

Permutation forces a zero mean

Main text: §9; retained scalar/Mellin continuation: norm-residue lattice mean cancellation.

Let χ be the quadratic character modulo five, extended by $\chi(0) = 0$. In the field on the preceding page, choose $v = 2u$. Its norm is $N(v) = 2$, so $\chi(N(v)) = -1$.

Multiply by $v = 2u$. Its norm is 2, so $\chi(N(vz)) = -\chi(N(z))$.

Filled node: $+1$. Open node: -1. The omitted zero element has weight 0.

The whole sum is paired with its negative

Multiplication by v permutes the 25 elements. Norm multiplicativity gives

$$\sum_{z \in A} \chi(N(z)) = \sum_{z \in A} \chi(N(vz)) = -\sum_{z \in A} \chi(N(z)).$$

The sum is an integer, so it is zero. The origin contributes zero. The other 24 elements fall into three cycles of length eight under multiplication by v. The character signs alternate around each cycle.

The same reasoning works with a complex root of unity $\chi(N(v)) \neq 1$: subtracting the two equal sums gives $(1 - \chi(N(v)))S = 0$. The essential inputs are an actual permutation, a multiplicative norm, and a nontrivial character value. They are not consequences of drawing an alternating cycle.

In the arithmetic continuation the quotient is the actual additive module J/mJ associated with an ideal representative. This finite-field example isolates the cancellation mechanism while keeping that broader module and lattice comparison separate.

> **Read this as:** The witness is one unit that changes the character value. Once it exists, the permutation cancels the entire finite mean.

Plate X.24 / THE EXACT SCALAR TEST

A nontrivial character may still be exceptional

Main text: §9. Scalar/Mellin construction: scalar-power and nonscalar-witness boundaries.

A scalar $a \in \mathbb{F}_5^\times$ acts on a degree-d algebra with determinant a^d. Therefore the scalar cancellation route tests $\chi(a^d)$, not merely $\chi(a)$.

	$d=1$	$d=2$	$d=3$	$d=4$	$d=5$	$d=6$
trivial	no	no	no	no	no	no
quartic	yes	yes	yes	no	yes	yes
quadratic	yes	no	yes	no	yes	no
conjugate quartic	yes	yes	yes	no	yes	yes

For $\chi_k(2) = i^k$, a witness exists exactly when $kd \not\equiv 0 \pmod 4$.

A failed sufficient test is not an impossibility theorem

Let $\chi_4(2) = i$ generate the character group of $\mathbb{F}_5^\times$, and write $\chi_k = \chi_4^k$. Since 2 generates the unit group,

$$\exists a : \chi_k(a^d) \neq 1 \quad \Longleftrightarrow \quad kd \not\equiv 0 \pmod 4.$$

For the quadratic character $k = 2$ and degree $d = 2$, every scalar test is trivial. Yet page Plate X.23 supplies the nonscalar witness $2u$, proving cancellation in that specific algebra. Scalar exceptional does not mean exceptional for every possible quotient unit.

Conversely, the quartic character $k = 1$ works in degree two even though $\gcd(2,4) \neq 1$. Thus the simpler degree–totient coprimality criterion is sufficient, not necessary. With degree three, every nontrivial character passes because exponentiation by three permutes the units.

The retained scalar/Mellin continuation states its public hypothesis in the weaker exact scalar-power form. It does not claim to construct a nonscalar witness for every scalar-exceptional arithmetic character.

> **Read this as:** Test the character after the degree-power map. Nontriviality before that map can disappear after it.

Plate X.25 / A CRT MODEL FOR REPRESENTATIVE CHOICE

Avoid finitely many primes constructively

Main text: §9; retained scalar/Mellin continuation: finite-prime avoidance and automatic representatives.

A representative needed by an arithmetic argument often has to avoid a prescribed finite collection of primes. A small integer version asks for

$$x \equiv 1 \pmod 2, \qquad x \equiv 2 \pmod 3, \qquad x \equiv 4 \pmod 5.$$

There is exactly one solution modulo 30: $x = 29$.

0	1	2	3	4	5
6	7	8	9	10	11
12	13	14	15	16	17
18	19	20	21	22	23
24	25	26	27	28	29

Choose one residue in each quotient

$$a \equiv 1 \pmod 2$$

$$a \equiv 2 \pmod 3$$

$$a \equiv 4 \pmod 5$$

$$a = 29, \quad \gcd(29, 30) = 1$$

Shaded values avoid 2, 3, and 5 simultaneously.

Avoidance and ideal class are different constraints

The selected residues are nonzero modulo each forbidden prime, so $\gcd(29, 30) = 1$. The eight units modulo 30 are displayed separately. They all avoid the primes, but only one also satisfies the three specific residue prescriptions.

The continuation proves an ideal-theoretic analogue with more structure: in every prescribed inverse ideal class it constructs a nonzero integral representative whose norm is coprime to the nonzero modulus. That removes a representative-choice assumption from the public norm-character bound. It does not remove the remaining character, lattice, or Frobenius-occurrence obligations.

The integer CRT calculation is an illustration, not a proof of the ideal-class representative theorem. In particular, enumerating integers cannot impose a nontrivial ideal class. The full construction uses prime-ideal avoidance and its source comparison to the class group.

> **Read this as:** A finite avoidance argument supplies an admissible representative. It does not by itself make the arithmetic object being counted, or the desired Frobenius class, occur.

All 30 residue classes are tested exactly. The unique CRT result and the unit count are independent finite outputs of the check script.

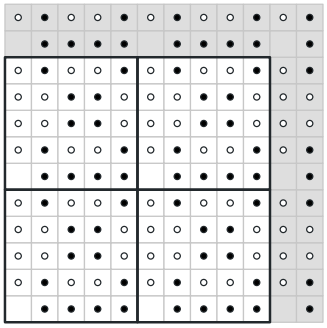


Plate X.26 / A FULL LATTICE-BOX CALCULATION

Cancellation leaves a boundary problem

Main text: §9; retained scalar/Mellin continuation: additive residue counts and norm-character bounds.

Extend the function $f(a,b) = \chi(a^2 - 2b^2 \bmod 5)$ periodically to $\mathbb{Z}^2$. Every complete 5×5 residue tile has sum zero by the finite-field calculation. Only incomplete tiles can contribute to a box sum.

$$[0,12)^2 \cap \mathbb{Z}^2$$

four full 5×5 cells

100 bulk points: sum 0

44 boundary points

actual total $S_{12} = 1$

$|S_L| \le L^2 - (L - (L \bmod 5))^2$ for this square-lattice model.

Separate bulk cancellation from boundary size

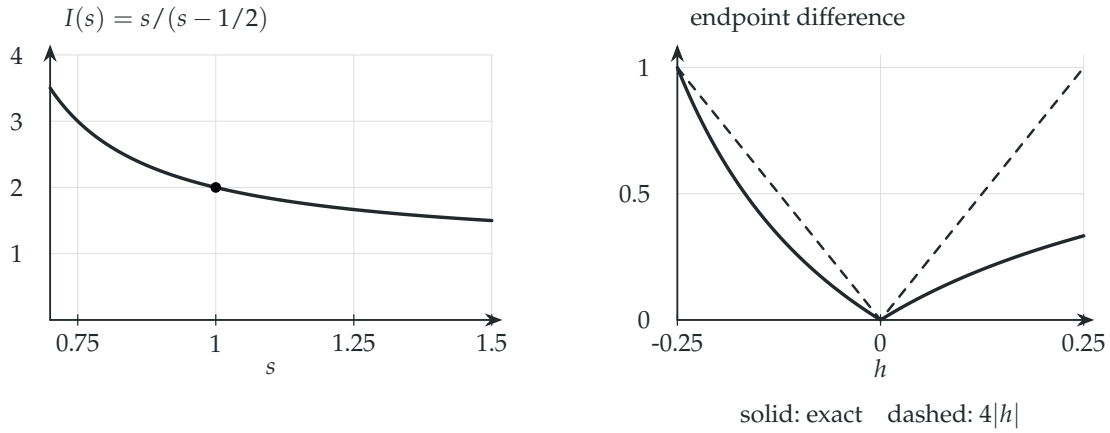
For $0 \le a, b < 12$, four complete tiles fill a 10×10 square and contribute zero. The remaining 44 points lie in the two boundary strips. Their exact sum is one. Since $|f| \le 1$, a bound of 44 follows without needing that final cancellation.

For a general positive integer L, write $L = 5q + r$, $0 \le r < 5$. The complete tiled square has side $L - r$, so

$$|S_L| \le L^2 - (L-r)^2 = 2Lr - r^2 \le 8L.$$

The area is $X = L^2$, giving a bound proportional to the square root of the area in this square model. The proof is the exact tile decomposition. Checking many L values is only a regression check of the implementation.

Number-field ideal sums involve different regions, lattice indices, signs, and generator multiplicities. Their $X^{1-1/d}$ exponent cannot be justified simply by relabeling this square picture as an ideal-norm ball.



> **Read this as:** A zero finite mean removes the bulk. The remaining estimate depends on the actual geometry of the region and its boundary.

Plate X.27 / A MELLIN ENDPOINT MODEL

Analytic consequences of a power-saving bound

Main text: §9; retained scalar/Mellin continuation: summatory measurability and first-order Mellin control.

Use the explicit envelope $A(x) = x^{1/2}$ for $x \geq 1$. It is not an ideal-counting function. It is a model showing why a power saving can make a Mellin expression regular at $s = 1$.

Compute the endpoint rather than just naming it

For real $s > 1/2$,

$$I(s) = s \int_1^\infty A(x) x^{-s-1}\,\mathrm{d}x = \frac{s}{s-1/2}.$$

At $s = 1 + h$ this gives

$$I(1+h) - I(1) = -\frac{h}{h+1/2}, \qquad |I(1+h) - I(1)| \leq 4|h| \quad (|h| \leq 1/4).$$

The derivative at one is -2. The logarithmic moment is finite as well: $\int_1^\infty x^{-3/2} \log x\,\mathrm{d}x = 4$. These are explicit calculations. The drawn curve does not establish differentiability or convergence.

The continuation performs the corresponding analytic steps for its actual summatory functions, with their explicit measurability and growth hypotheses. The arithmetic Euler-product identity, nonzero pole residues, and the required prescribed-prime divergence remain separate. Regularity of one Mellin transform does not construct all of those inputs.

> **Read this as:** An analytic estimate controls a function already tied to arithmetic data. It is not a substitute for proving that tie.

Plate X.28 / THE REMAINING FROBENIUS STEP

Finite splitting data are not a density theorem

Main text: Theorem 9.1. Latest continuation: GeneralArithmeticCoverage and ArithmeticSystemSeparation.

For the quadratic polynomial $X^2 + 1$, reduction modulo an odd prime either gives two roots or no roots. This finite scan displays both behaviors. It is a useful model for the distinction between splitting and nonsplitting classes.

odd primes p

3	5	7	11	13	17	19	23
0	2	0	0	2	2	0	0

roots of $x^2 + 1$ in $\mathbb{F}_p$

two factorization types
already appear in this finite list

repeat one class

1	1	2
1	1	2
1	1	2

three rows, rank one

Finite character separation needs enough different evaluations, not just more evaluations.

Existence must survive arbitrary exclusions

The continuation's missing general coverage proposition asks for an actual unramified rational prime in a prescribed conjugacy class, outside any prescribed finite forbidden set, together with the corresponding absolute Frobenius witness. A list of small primes does not establish that quantifier.

The finite character argument on page Plate X.15 also needs samples that jointly separate the constituents. Repeating the identity-class row $(1, 1, 2)$ of the S_3 table gives rank one no matter how often it is repeated. Many samples are not necessarily informative samples.

The later checked rational-base separator composes its constructed arithmetic coverage theorem with finite linear algebra. The earlier scalar/Mellin route retained a coverage premise. The displayed scan certifies neither route: it is a finite example, not an occurrence theorem.

> **Read this as:** A separating group element, a witnessed Frobenius at one prime, and a new prime after every finite exclusion are distinct levels of evidence.

The scan exhaustively checks scalar roots for the shown primes. No density, infinitude, or general prescribed-conjugacy statement is inferred from it.

Plate X.29 / SCALAR ABSENCE VERSUS REPRESENTATION EXISTENCE

Changing coefficients changes the problem

Main text: Example 8.4 and the declared coefficient categories in §§8–9.

Over $\mathbb{F}_3$, no scalar solves $x^2 + 1 = 0$. But the matrix

$$A = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \in M_2(\mathbb{F}_3) \quad \text{satisfies} \quad A^2 + I = 0.$$

And over $\mathbb{F}_9 = \mathbb{F}_3[u]/(u^2 + 1)$, the scalars u and $-u$ solve the same polynomial.

Scalar over $\mathbb{F}_3$	Matrix over $\mathbb{F}_3$	Scalar over $\mathbb{F}_9$
$x = 0, 1, 2$	$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$	$u^2 = -1$
$x^2 + 1 = 1, 2, 2$		roots $u, -u$
no solution	$A^2 + I = 0$	coefficient extension

Fix the coefficient field, dimension, and point category before declaring an occupancy failure.

Three outputs with different types

The failed scalar problem over $\mathbb{F}_3$, the successful matrix problem over $\mathbb{F}_3$, and the successful scalar problem over $\mathbb{F}_9$ are not contradictory answers. They have different allowed objects. The matrix is multiplication by u in the $\mathbb{F}_3$-basis $(1, u)$ of the extension field.

This also has a characteristic-zero analogue. The matrix with the same entries gives a rational two-dimensional representation of a cyclic group of order four. Its scalar eigenvalues require a field containing a square root of -1. No one-dimensional rational eigencharacter is created by writing the two-dimensional matrix.

Accordingly, the scalar companion failure on page Plate X.8 is a counterexample only to the fixed scalar problem. It is not a counterexample to a representation problem that permits coefficient extension or a different dimension. Those permissions must be declared before comparing fibers across primes.

> **Read this as:** An empty fiber is meaningful only after its coefficient ring and object type are fixed. Do not repair an empty fiber by silently changing either.

Plate X.30 / FINAL READER'S CHECKLIST

Read the evidence at its actual scope

Main text: Appendix D. Formal guide: statement register, dependency sources, and replay boundary.

The three contracts have different hypotheses. Their coverage counts do not make them interchangeable.

Record	What it establishes
Base 17/20	Scalar/Mellin contract. Claims 9.1, 9.2 and 11.1 remain partial in that contract.
Checked 20/20	The amended conditional occupied-system assembly. Completed source members, closed target profiles, compatible carrier presentations, and local comparisons remain explicit inputs.
Stronger 19/20	A stronger residual-system contract with an unproved terminal endpoint. It does not recheck or replace the conditional assembly.

Two conclusions, not an unstated identification

The terminal theorem constructs a transported target family and independently recovers a summand of the supplied carrier. To identify them requires an explicit comparison. The carrier result is pointwise at an arbitrary coefficient place. Recovering carriers at every place needs the relevant presentations there. Zero multiplicity is allowed. Nonzero occupancy needs a separate nonzero premise.

What the examples verify

The appendix supplies reproducible finite examples and exact Python checks. A plotted pixel does not decide a congruence, rank, determinant, root or character sum. The formal companion states the scope of the Lean verification. Sources and supporting records accompany the volume.

> **Read this as:** A completed conditional theorem is a theorem with its hypotheses, not a claim that every arithmetic application supplies them.

CHAPTER XI

Tame and Wild Packet Geometry

For local Langlands

The preceding chapter separates the arithmetic objects supplied as inputs from those obtained conditionally. Local packet geometry sharpens the realization questions.

Tame and wild packet geometry organizes the local arithmetic constructions. The research companions retain both restricted progress and the unresolved obligations of Conjecture 66.

Scope

Conjecture 66 remains open. Its unresolved requirements concern general arithmetic realization, H5 for the same candidate, corrected full-character occurrence and actual native data under the stronger contract.

The final chapter gives a conditional route through patching support and Hecke compatibility. The open realization obligations remain separate.

Abstract. Let K be a nonarchimedean local field. We resolve several finite layers that occur inside the local Langlands correspondence for general linear groups. Frobenius semisimple Weil Deligne parameters first split into irreducible Weil atoms and finite monodromy chains. In the tame case, character projectors show that every irreducible atom is one transitive Frobenius orbit, and Mackey theory gives an exact greatest common divisor and least common multiple rule for tensor packets. Regular finite field characters produce primitive cuspidal projectors and finite Gauss phases. For wild data, projective intertwiners recover an alternating commutator form. Its radical free quotient determines a finite Heisenberg representation, and maximal isotropic averaging gives an exact selector. We prove a restricted one break bridge: an equivariant symplectic isometry between a declared Galois envelope and a type side quotient induces the Heisenberg comparison uniquely up to scalar, while one cyclic phase condition removes the remaining ambiguity. Odd residue characteristic is governed by finite Weil phases. Residue characteristic two requires a quadratic refinement and its Arf invariant. A matrix holonomy theorem then gives the exact gluing criterion on a finite transport graph. The general arithmetic packet realization is stated as Conjecture 66. Detailed ordinary proofs give restricted arithmetic realizations in all odd prime-power ranks and in all dyadic ranks for the stated increasing-break families. The complete comparison of pair local factors remains a conditional input for the same arithmetic candidate.

A route through Chapter XI

This chapter presents the finite packet theory and retains the detailed restricted arithmetic constructions. Two separate research companions explain the later progress toward Conjecture 66. They do not replace this chapter's proved statements or turn its conditional comparison into an existence theorem.

The mathematical text and its companions

Reader	Route and purpose
Mathematical text	Finite tame and wild theory, restricted arithmetic constructions, and the exact realization/comparison boundary.
Core visual guide	Geometric route through the mathematical text. The original arithmetic examples retain their stated scope.
Formal companion	Formal statements, literal excerpts and evidence lineage. The guide distinguishes the selected source census, compiler replay and arithmetic hypotheses.
Progress paper	Toward Arithmetic Packet Realization. Connected proofs, failed routes, conductor conventions and conditions on native markings.
Research visual atlas	Arithmetic Packet Realization. Thirty-two worked plates accompany the progress paper.

The endpoint is a quantified construction problem

Conjecture 66 asks for an actual arithmetic witness for each admitted source with its supplied H1–H4 datum. The comparison proposition then uses H5 for that same realized candidate. The formal companion distinguishes this conjecture from the differently numbered statements in the source registers.

The research contract in Section 1 and Plate XI.1 make the quantifiers explicit. Supplying finite operators does not construct an arithmetic representation. Likewise, proving a factor identity for a different candidate does not identify the packet's realizer.

How to use the links

The reading links connect the mathematical text, visual studies, research companions and formal companion. Section and result numbers are local to the named treatment. Plate references include the chapter number, so Plate XI.32 identifies the corresponding visual plate.

Scope and research routes

Question	Route beyond the core statement
Parameter, full character and recovery	Progress Sections 7–10 and Plates XI.6–XI.10. The full character, central character and noncompact completion remain fixed.
Monomial, Clifford and occurrence routes	Progress Part II. The original character route is excluded under its hypotheses. A different corrected character passes a scalar test, but occurrence in the same candidate is still open.
Conductor and capacity	Progress Sections 22–25 and Plates XI.11–XI.19. Swan, ordinary conductor and epsilon exponent for an additive character are named separately. Equal numerical invariants need not give equal quotient capacity.
Native markings and allowed repairs	Progress Sections 26–29 and Plates XI.20–XI.29. A freely transported marking is different from a prescribed native marking. Finite corrections require their stated inputs and permission to change the relevant map.
Remaining arithmetic certificate	Progress Section 30 and Plates XI.30–XI.32. General realization, H5, corrected-character occurrence and the stronger native certificate remain separate tasks.

The construction and its limits

The breakwise phase product uses its moving symplectic spaces. The type-side pairing fixes a prime-field character, and the tame comparison retains the boundaries for the rank-one conductor and the Gauss sum of the trivial character. Interaction carriers are distinguished from minimal character orbits.

The detailed construction appendices give ordinary proofs under their stated type-theory hypotheses. The selected Henniart–Lemaire induction inputs [20] retain their characteristic, rank and normalization conditions. They do not establish H5 or corrected-character occurrence. The formal companion identifies the actual compiler and axiom coverage.

1 Introduction

The local Langlands correspondence for $\mathrm{GL}_n(K)$ is an established theorem. It matches irreducible smooth representations of $\mathrm{GL}_n(K)$ with Frobenius semisimple Weil Deligne representations of dimension n. Its proof and normalization draw on global methods, harmonic analysis, types, local factors, and the geometry of Shimura varieties [19, 17, 8]. This chapter asks a narrower structural question. Which parts of the local correspondence admit finite packet coordinates whose projectors, transfers, phases, and gluing laws can be proved directly?

The answer has a sharp division. The tame layers are explicit. A tame irreducible Weil representation is induced from a character of an unramified extension. Its inertia restriction is one Frobenius orbit. Regular characters of elliptic finite field tori give cuspidal blocks through the Deligne and Lusztig construction [13]. Their tensor products are controlled by a greatest common divisor and least common multiple decomposition. The corresponding cycle orientation and finite Gauss phases can be computed exactly. These features are closely related to the tame lifting and essentially tame correspondence of Bushnell and Henniart [4, 5, 6, 7, 9].

Wild data are different. The restriction to wild inertia need not split into cyclic characters. On the type side, simple character theory produces finite symplectic quotients and Heisenberg representations [11]. Canonical beta extensions fix a phase ambiguity in the extension to the normalizer [2, 14]. On the Galois side, higher ramification gives a canonical filtration and strong numerical constraints [10]. The missing construction is not another finite matrix calculation. It is a choice free passage from an arbitrary wild inertia atom to a finite symplectic envelope that agrees with the type side quotient.

We therefore separate three levels of assertion. First, this chapter proves finite algebraic theorems about tame orbits, Heisenberg groups, twisted group algebras, finite Weil phases, and transport graphs. Second, it proves a restricted one break bridge once a normal wild datum and an equivariant symplectic identification are declared. Third, it records the exact additional input needed to pass from that restricted bridge to an independent construction of all wild atoms.

The finite Heisenberg theory used here is classical. We use the Stone von Neumann theorem, finite Weil representations, and standard projective representation theory [15, 25, 26, 22, 16]. The contribution is the way these results are arranged into one comparison diagram and the matrix holonomy theorem that controls finite gluing. In residue characteristic two, the alternating form does not determine the phase. A quadratic refinement and its Arf invariant are required. The underlying quadratic form theory is standard [24].

Local factors provide the final test. Henniart showed that pair epsilon factors characterize the local correspondence in the required range [18]. The tame packet calculations below recover exact local polynomials and finite Gauss phases for the declared tame atoms. They do not supply the complete pair factor comparison for arbitrary wild atoms. This boundary is retained throughout this chapter.

Arithmetic realization and identification of an actual candidate are separate problems. The realization endpoint is conjecture 66. The restricted constructions are developed in section 19 and the detailed construction appendices. They have ordinary mathematical proofs with retained internal reviews. Their formal coverage is stated separately in the formal companion.

The accompanying sources include detailed proofs, construction notes, proof reviews and research records. These documents distinguish established results, conditional results, and the remaining obligations associated with Conjecture 66.

This chapter is organized as follows. Weil Deligne chains appear in section 2. Tame Frobenius packets, finite field cuspidal projectors, tensor refinement, and Gauss phases are developed in sections 3 to 6. Finite Heisenberg groups and projective commutator envelopes appear in sections 7 and 8. The restricted one break Galois envelope and its comparison with the type side are treated in

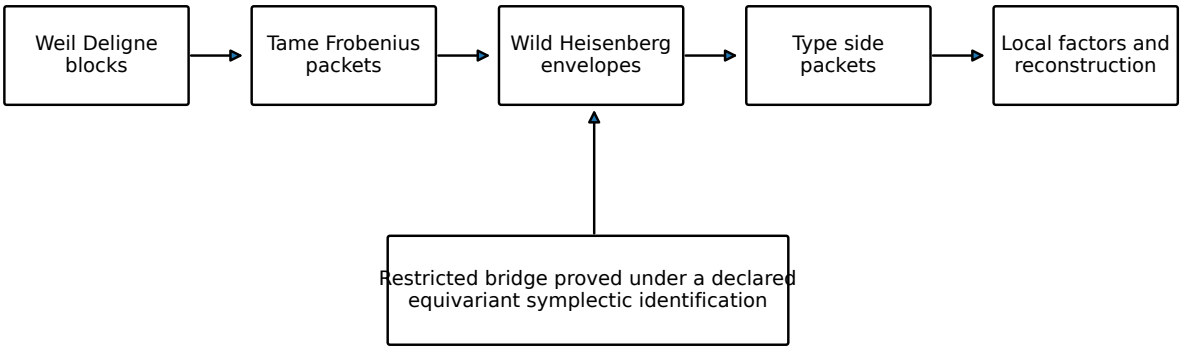

Figure 1. The finite theorem layers and the remaining wild boundary.

sections 9 to 11. Odd and dyadic phase data are separated in sections 12 and 13. Matrix holonomy and breakwise reconstruction appear in sections 14 and 15. The boundary for local factors appears in section 16. Examples and scope follow in sections 17 and 18. Section 19 and the appendices develop the restricted arithmetic constructions. The separate progress paper reconciles subsequent routes, corrections and remaining obligations without replacing these source records.

2 Weil Deligne chains

Let W_K be the Weil group of K, let I_K be inertia, let P_K be wild inertia, and choose a geometric Frobenius lift Φ. A Weil Deligne representation is a pair (r, N) with

$$r(w)Nr(w)^{-1} = |w|_K N.$$

Standard Fact 2.1 (Indecomposable monodromy blocks)**.** Every Frobenius semisimple Weil Deligne representation is a direct sum of blocks

$$\mathrm{Sp}_m(\tau),$$

where τ is an irreducible Weil representation and the nilpotent operator is one Jordan chain of length m.

This standard decomposition reduces the construction of a local correspondence to two tasks. One must understand irreducible Weil atoms, then one must attach the correct generalized Steinberg chain. The second task is formal once the first is known.

Definition 2.2 (Monodromy packet chain)**.** Let $V_0, \dots, V_{m-1}$ be copies of the space of τ. Put

$$V = \bigoplus_{j=0}^{m-1} V_j.$$

A monodromy packet chain is a nilpotent operator N with

$$N(V_j) \subseteq V_{j-1}$$

for $j > 0$, with $N(V_0) = 0$, together with a Frobenius operator whose conjugation scales N by q^{-1}.

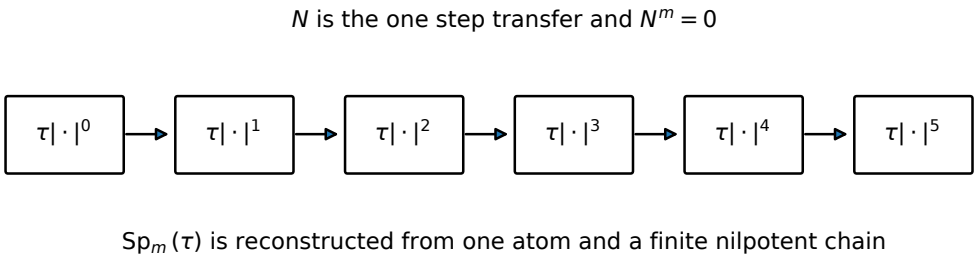

Figure 2. A Weil Deligne chain is reconstructed from one atom and finitely many nearest neighbor transfers.

Proposition 2.3 (Exact block reconstruction)**.** *Let P_j be the projector onto V_j. Then*

$$N = \sum_{j=1}^{m-1} P_{j-1} N P_j, \qquad N^m = 0.$$

Every power N^r is the sum of the packet paths of length r along the chain.

Proof. The projectors resolve the identity. Since N maps only from V_j to V_{j-1}, every block except the displayed nearest neighbor blocks vanishes. A product of r nonzero blocks moves down exactly r levels. No path of length m exists, so $N^m = 0$. □

Proposition 2.4 (Scalar covariance model)**.** *Let*

$$F = \mathrm{diag}(1, q, q^2, \dots, q^{m-1})$$

and let $N_{j-1,j} = 1$. Then

$$FNF^{-1} = q^{-1}N.$$

Proof. The only nonzero entry in column j and row $j-1$ is multiplied by $q^{j-1}q^{-j} = q^{-1}$ under conjugation. □

Theorem 2.5 (Formal atomic reconstruction)**.** *Assume that every irreducible Weil representation τ has been assigned a supercuspidal representation σ_τ, compatibly with isomorphism and unramified twist. Then the rules*

$$\mathrm{Sp}_m(\tau) \longmapsto \mathrm{St}_m(\sigma_\tau)$$

and normalized parabolic induction determine a candidate correspondence on all Frobenius semisimple Weil Deligne parameters.

Proof. Decompose the parameter into indecomposable monodromy blocks. Replace each Weil atom by its assigned supercuspidal atom and each monodromy chain by the corresponding generalized Steinberg block. Order the resulting essentially square integrable factors in Langlands order and take the unique irreducible quotient. The multiset of indecomposable Weil Deligne blocks is intrinsic, so the result does not depend on the chosen display. □

Remark 2.6. Theorem 2.5 is a reconstruction theorem. It does not produce the atomic assignment $\tau \mapsto \sigma_\tau$, and it does not prove the required local factor identities.

3 Tame Frobenius packets

Assume that P_K acts trivially. After passing to a finite quotient, tame inertia is cyclic. Let t generate a quotient of order M, and put $\zeta_M = \mathrm{e}^{2\pi i/M}$. For $j \in \mathbb{Z}/M\mathbb{Z}$, define

$$P_j = \frac{1}{M} \sum_{a=0}^{M-1} \zeta_M^{-ja} r(t)^a.$$

Proposition 3.1 (Tame character projectors)**.** *The operators P_j are pairwise orthogonal idempotents whose sum is the identity. Frobenius permutes them by*

$$\Phi P_j \Phi^{-1} = P_{qj}.$$

Proof. The first assertion is the Fourier idempotent calculation for a cyclic group. For the geometric Frobenius convention of section 2, the relation is $\Phi^{-1} t \Phi = t^q$. Equivalently, $\Phi t \Phi^{-1} = t^{q^{-1}}$, with inverse taken modulo M since $\gcd(q, M) = 1$. Conjugating the Fourier sum and changing its summation index therefore gives $\Phi P_j \Phi^{-1} = P_{qj}$. The inverse Frobenius convention reverses the label direction while preserving the same orbits. □

Theorem 3.2 (Tame orbit induction)**.** *Let τ be an irreducible complex representation of W_K with trivial wild inertia. Then the nonzero tame character packets form one transitive Frobenius orbit of length f. If K_f/K is the unramified extension of degree f, there is a character ξ of W_{K_f} such that*

$$\boxed{\tau \cong \mathrm{Ind}_{W_{K_f}}^{W_K} \xi.}$$

Proof. The nonzero tame packets are permuted by Frobenius. A union of Frobenius orbits is stable under W_K, so irreducibility forces one orbit. Choose one packet V_θ. Its stabilizer is $W_{K_f} = \langle I_K, \Phi^f \rangle$. A nonzero proper stable subspace of V_θ would generate a nonzero proper W_K stable subspace after summing its Frobenius translates. Thus V_θ is irreducible for the stabilizer. Inertia acts on it by the scalar character θ, and the remaining action is generated by Φ^f. The stabilizer action on this packet is therefore one dimensional. Induction reconstructs the complete orbit. □

Corollary 3.3 (Dimension and regularity)**.** *The dimension of τ equals the Frobenius orbit length of its tame inertia character. The inducing character is regular, meaning that no smaller positive power of Frobenius fixes it.*

Proof. The induced representation has one line for every Frobenius translate of the chosen character. A shorter orbit would produce a proper stabilizer and contradict the minimality of f. □

Proposition 3.4 (Dual and self dual tame packets)**.** *For a tame atom*

$$\tau_\xi = \mathrm{Ind}_{W_{K_f}}^{W_K} \xi,$$

we have

$$\tau_\xi^\vee \cong \mathrm{Ind}_{W_{K_f}}^{W_K} \xi^{-1}.$$

The atom is self dual exactly when

$$\xi^{-1} = \xi^{\Phi^j}$$

for some $j \in \mathbb{Z}/f\mathbb{Z}$.

Proof. Duality commutes with finite index induction, giving the first statement. Two regular induced tame atoms are isomorphic exactly when their inducing characters lie in the same Frobenius orbit. Applying this to ξ and ξ^{-1} gives the criterion. □

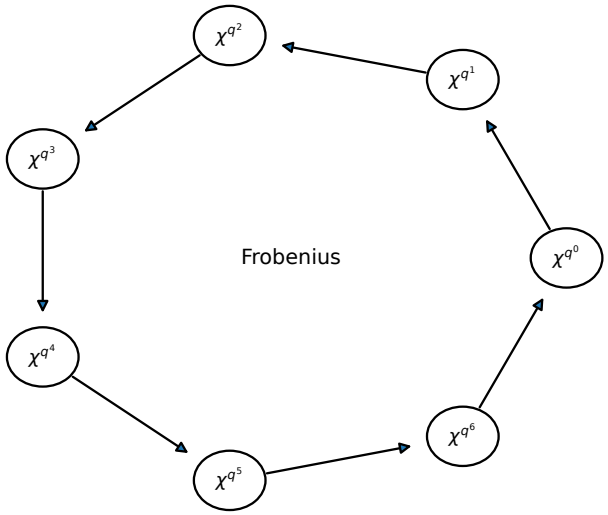

Figure 3. A tame irreducible atom is one transitive Frobenius orbit.

Proposition 3.5 (Unramified twist)**.** *Let ν be an unramified character of W_K. Then*

$$\tau_\xi \otimes \nu \cong \operatorname{Ind}_{W_{K_f}}^{W_K} \left(\xi\, \nu|_{W_{K_f}} \right).$$

The tame inertia orbit is unchanged. If the original Frobenius cycle has closing scalar a, the twisted cycle has closing scalar

$$a\nu(\Phi)^f.$$

Proof. The tensor identity follows from the projection formula for induction. Since ν is trivial on inertia, it does not change any tame character packet. It multiplies every Frobenius step by $\nu(\Phi)$, so a closed cycle of length f gains the factor $\nu(\Phi)^f$. □

3.1 Regular orbit counts

Characters of $\mathbb{F}_{q^n}^\times$ are indexed by exponents modulo $q^n - 1$, and Frobenius acts by multiplication by q.

Proposition 3.6 (Möbius orbit count)**.** *The number of regular Frobenius orbits of length n is*

$$\boxed{c_n(q) = \frac{1}{n} \sum_{d \mid n} \mu(d) \left(q^{n/d} - 1 \right).}$$

Proof. For every divisor $r \mid n$, the characters fixed by Frob^r are exactly those descending to $\mathbb{F}_{q^r}^\times$, and there are $q^r - 1$ of them. Möbius inversion gives the number of characters of exact orbit length n. Division by n gives the number of orbits. □

Example 3.7 (Degree four over $\mathbb{F}_2$)**.** The regular exponent orbits modulo fifteen are

$$(1, 2, 4, 8), \qquad (3, 6, 12, 9), \qquad (7, 14, 13, 11).$$

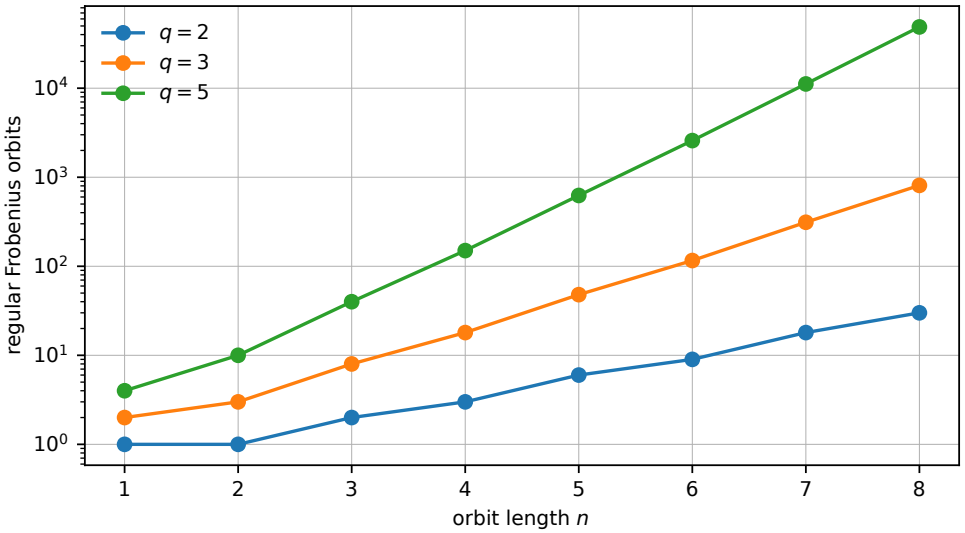

Figure 4. Regular Frobenius orbit counts for three residue field sizes.

The formula gives

$$\frac{1}{4}\big((2^4-1)-(2^2-1)\big)=3.$$

4 Finite field cuspidal projectors

Let

$$G_n=\mathrm{GL}_n(\mathbb{F}_q),\qquad T_n\cong\mathbb{F}_{q^n}^{\times}$$

with T_n an elliptic maximal torus.

Standard Fact 4.1 (Regular elliptic torus characters)**.** A regular character $\theta : T_n \to \mathbb{C}^{\times}$ determines an irreducible cuspidal representation κ_θ of G_n. Frobenius conjugate characters determine isomorphic representations, and every irreducible cuspidal representation of G_n occurs in this way.

This is the finite field input from Deligne and Lusztig theory [13]. We use standard finite group character theory for the central idempotents [28, 21]. Once κ_θ is known, its block is selected by a central idempotent.

Proposition 4.2 (Primitive cuspidal idempotent)**.** *Let χ_θ be the irreducible character of κ_θ, and let $d_\theta=\chi_\theta(1)$. Then*

$$e_\theta=\frac{d_\theta}{|G_n|}\sum_{g\in G_n}\chi_\theta(g^{-1})g$$

is the primitive central idempotent selecting the κ_θ block in $\mathbb{C}[G_n]$.

Proof. On an irreducible representation of character ψ, the central element acts by a scalar. Taking traces shows that the scalar is

$$\frac{d_\theta}{|G_n|\,\psi(1)}\sum_{g\in G_n}\chi_\theta(g^{-1})\psi(g).$$

Character orthogonality makes this scalar one for $\psi=\chi_\theta$ and zero otherwise. The element is therefore central, idempotent, and primitive. □

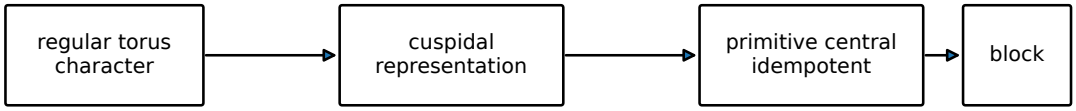

Figure 5. A regular torus character determines a cuspidal block and its primitive central projector.

Proposition 4.3 (Parabolic annihilation)**.** *Let $P = LU$ be a proper parabolic subgroup of G_n, and put*

$$e_U = \frac{1}{|U|} \sum_{u \in U} u.$$

If κ_θ is cuspidal, then

$$\boxed{e_U e_\theta = e_\theta e_U = 0.}$$

Proof. The operator e_U projects onto the subspace of U fixed vectors. A cuspidal representation has no nonzero fixed vector under the unipotent radical of a proper parabolic. Thus e_U acts by zero on the κ_θ block. Since e_θ is central, both products vanish. □

4.1 Depth zero reconstruction and cycle orientation

The depth zero construction inflates a finite cuspidal representation to $\mathrm{GL}_n(\mathcal{O}_K)$, extends it to the standard compact modulo center subgroup, and then compactly induces it to $\mathrm{GL}_n(K)$. This is classical type theory [11, 8].

The induced tame Weil atom has an elementary cycle invariant. In an orbit basis $e_0, \dots, e_{n-1}$, write

$$\tau(\Phi) e_j = e_{j+1}$$

for $j < n - 1$, and

$$\tau(\Phi) e_{n-1} = a e_0.$$

Proposition 4.4 (Frobenius cycle polynomial)**.** *The Frobenius transfer matrix has characteristic polynomial*

$$X^n - a$$

and determinant

$$\boxed{\det \tau(\Phi) = (-1)^{n-1} a.}$$

Proof. The matrix is the companion matrix of $X^n - a$. Its only nonzero determinant term is the closed n cycle. That cycle has sign $(-1)^{n-1}$, and the closing edge contributes a. □

Corollary 4.5 (Unramified orientation character)**.** *The sign $(-1)^{n-1}$ is the orientation of the closed Frobenius packet cycle. It is unchanged by rescaling the individual orbit basis vectors.*

Proof. A basis rescaling conjugates the transfer matrix by a diagonal matrix, so the determinant and characteristic polynomial remain unchanged. □

5 Tensor refinement of tame atoms

Let

$$\tau_\xi = \operatorname{Ind}_{W_{K_n}}^{W_K} \xi, \qquad \tau_\eta = \operatorname{Ind}_{W_{K_m}}^{W_K} \eta,$$

where K_n/K and K_m/K are unramified. Put

$$d = \gcd(n,m), \qquad L = \operatorname{lcm}(n,m).$$

Theorem 5.1 (Greatest common divisor and least common multiple packets)**.** *There is a decomposition*

$$\boxed{\tau_\xi \otimes \tau_\eta \cong \bigoplus_{i=0}^{d-1} \operatorname{Ind}_{W_{K_L}}^{W_K} \left(\xi_{L,n}\eta_{L,m}^{\Phi^i}\right),}$$

where $\xi_{L,n}$ and $\eta_{L,m}$ are the norm lifts to K_L.

Proof. Apply Mackey decomposition [23]. The double cosets

$$W_{K_n} \backslash W_K / W_{K_m}$$

are the orbits of simultaneous translation on $\mathbb{Z}/n\mathbb{Z} \times \mathbb{Z}/m\mathbb{Z}$. There are d orbits, each of length L. The stabilizer of a point in each orbit is W_{K_L}. The second character is shifted by the chosen Frobenius representative. Summing the induced terms over the double cosets gives the decomposition. □

Corollary 5.2 (Packet count and dimension)**.** *The tensor product has d induced interaction packets, each with carrier dimension and Frobenius coset-cycle length L. The interaction character may have a shorter inertia orbit, in which case a packet may split further into irreducible atoms. The total dimension is preserved because*

$$dL = nm.$$

Proof. The double coset calculation in theorem 5.1 gives exactly d summands, and every stabilizer is W_{K_L}, so every induced packet has dimension L. The identity $dL = nm$ follows from the definitions of greatest common divisor and least common multiple. □

5.1 Exponent coordinates

Represent the residue characters by exponents

$$a \pmod{q^n - 1}, \qquad b \pmod{q^m - 1}.$$

Proposition 5.3 (Refined exponent formula)**.** *The ith interaction packet on $\mathbb{F}_{q^L}^\times$ has exponent*

$$\boxed{c_i = a\frac{q^L - 1}{q^n - 1} + bq^i\frac{q^L - 1}{q^m - 1} \pmod{q^L - 1}.}$$

It is trivial on tame inertia exactly when $c_i = 0$.

Proof. Norm lifting a character exponent from $\mathbb{F}_{q^n}^\times$ to $\mathbb{F}_{q^L}^\times$ multiplies the exponent by $(q^L - 1)/(q^n - 1)$. The Frobenius shift multiplies the second exponent by q^i. Multiplication of characters adds exponents. Triviality is equivalent to the resulting exponent being zero modulo $q^L - 1$. □

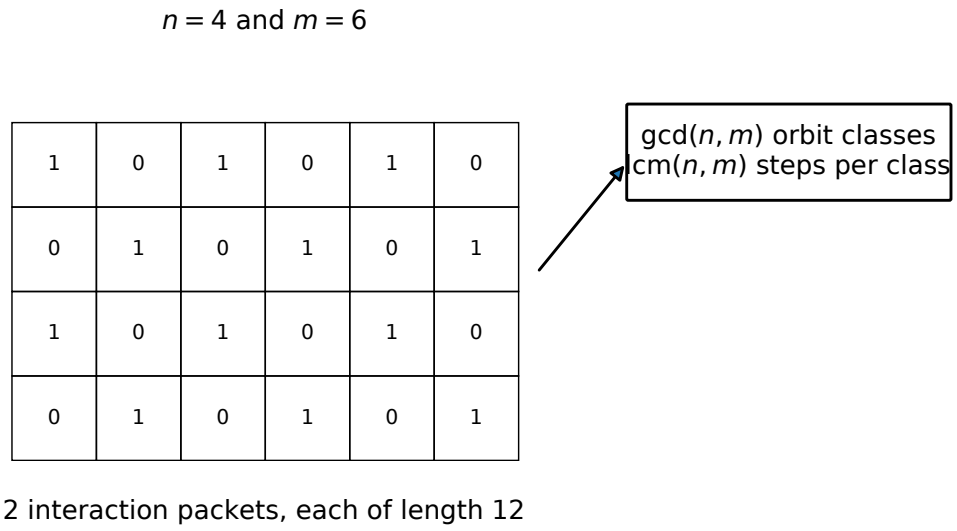

Figure 6. Tensor refinement gives as many packets as the greatest common divisor, each with carrier dimension equal to the least common multiple.

5.2 Tame local polynomials

Let V be one interaction packet. If its inertia character is nontrivial, then $V^{I_K} = 0$. If the inertia character is trivial, Frobenius acts on the invariant packet by a companion cycle.

Proposition 5.4 (Local polynomial of one tame packet)**.** *Suppose an interaction packet has orbit length r and closing scalar a. Its local polynomial is*

$$\det\left(I - u\Phi \mid V^{I_K}\right) = \begin{cases} 1 - au^r, & \text{if the inertia character is trivial,} \\ 1, & \text{otherwise.} \end{cases}$$

Proof. For nontrivial inertia, the invariant space is zero. In the trivial case, Frobenius on the invariant packet is the companion matrix of $X^r - a$. Substituting $X = u^{-1}$ and multiplying by u^r gives $1 - au^r$. □

Corollary 5.5 (Tame tensor local factor)**.** *The local factor of the tame tensor product is the product of*

$$(1 - a_i u^{r_i})^{-1}$$

over precisely those refined packets whose inertia exponent vanishes.

Proof. The invariant space is the direct sum of the invariant refined packets, and determinant is multiplicative on direct sums. □

Proposition 5.6 (Trivial tensor packet criterion)**.** *For every refined interaction packet, let r_i be its cycle length and a_i its closing scalar. The dimension of the W_K fixed space in $\tau_\xi \otimes \tau_\eta$ equals the number of packets satisfying both*

$$c_i = 0 \qquad \text{and} \qquad a_i = 1.$$

Proof. A nonzero fixed vector must lie in an inertia trivial packet, so $c_i = 0$. On that packet, Frobenius is a companion cycle with characteristic polynomial $X^{r_i} - a_i$. Its fixed space is the eigenspace for eigenvalue one. This eigenspace is one dimensional exactly when $a_i = 1$, and it is zero otherwise. Summing over the refined packets proves the formula. □

Corollary 5.7 (Tame Hom test)**.** *For irreducible tame atoms,*

$$\dim \mathrm{Hom}_{W_K}(\tau_\xi^\vee, \tau_\eta)$$

is zero or one, and it is one exactly when the refined tensor packet test in proposition 5.6 finds one trivial packet.

Proof. The Hom space is the fixed space of $\tau_\xi \otimes \tau_\eta$. Schur's lemma gives dimension zero or one, and proposition 5.6 gives the packet criterion. □

5.3 Tame conductor

Proposition 5.8 (Conductor of a nontrivial tame atom)**.** *Let τ be an irreducible tame Weil representation of dimension $n > 1$. Then*

$$\mathrm{Swan}(\tau) = 0, \qquad \dim \tau^{I_K} = 0, \qquad \mathrm{Art}(\tau) = n.$$

Proof. Wild inertia acts trivially, so the Swan conductor is zero. An inertia fixed vector would generate a nonzero Frobenius stable sum of trivial character packets. Irreducibility would then make inertia act trivially on all of τ. An irreducible representation of the quotient generated by Frobenius would be one dimensional, contrary to $n > 1$. The Artin conductor is therefore

$$\dim \tau - \dim \tau^{I_K} + \mathrm{Swan}(\tau) = n.$$

□

6 Finite Gauss phases

Let $k = \mathbb{F}_q$, let $\psi : k \to \mathbb{C}^\times$ be a nontrivial additive character, and let $\chi : k^\times \to \mathbb{C}^\times$ be a multiplicative character. Define

$$G(\chi, \psi) = \sum_{x \in k^\times} \chi(x)\psi(x).$$

The standard theory of Gauss and Jacobi sums will be used in the form recorded in [12, 1].

Proposition 6.1 (Gauss magnitude)**.** *If χ is nontrivial, then*

$$\boxed{|G(\chi, \psi)| = q^{1/2}.}$$

Proof. Compute

$$|G(\chi, \psi)|^2 = \sum_{x,y \in k^\times} \chi(xy^{-1})\psi(x - y).$$

Write $x = ty$. The inner sum over y equals $q - 1$ when $t = 1$ and equals -1 otherwise. Since $\sum_{t \in k^\times} \chi(t) = 0$, the result is q. □

Definition 6.2 (Normalized Gauss phase)**.** For nontrivial χ, define

$$\gamma(\chi, \psi) = q^{-1/2} G(\chi, \psi).$$

Then $|\gamma(\chi, \psi)| = 1$.

Proposition 6.3 (Duality of Gauss phases)**.** *For nontrivial χ,*

$$\boxed{\gamma(\chi, \psi)\gamma(\chi^{-1}, \psi) = \chi(-1).}$$

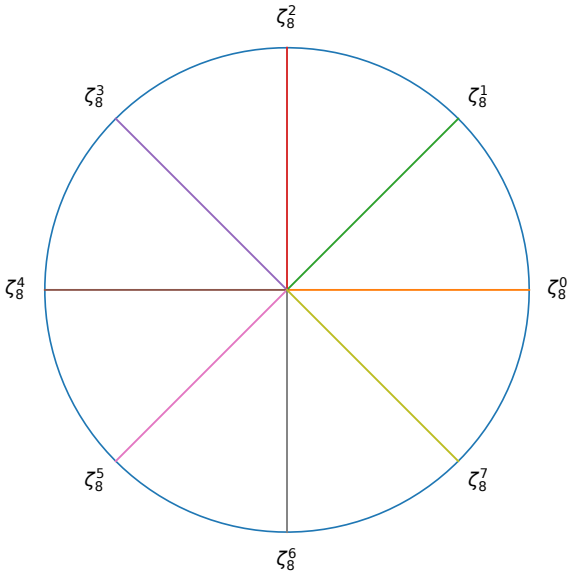

Figure 7. Normalized finite Gauss sums lie on the unit circle.

Proof. The standard Gauss identity gives

$$G(\chi,\psi)G(\chi^{-1},\psi) = \chi(-1)q.$$

Divide by q. □

Standard Fact 6.4 (Hasse and Davenport lifting)**.** Let k_r/k be the extension of degree r. Lift χ by the norm and ψ by the trace. Then the lifted Gauss sum satisfies the Hasse and Davenport product relation, with a sign determined by the chosen additive character normalization.

Remark 6.5. Finite Gauss phases reproduce the finite field part of tame and depth zero normalization. They do not by themselves give the full epsilon factor of a general wild pair.

7 Finite Heisenberg packets

Let p be odd. Let X be an r dimensional vector space over $\mathbb{F}_p$, and put

$$V = X \oplus X^*.$$

Define the alternating form

$$b\big((x,\xi),(y,\eta)\big) = \eta(x) - \xi(y).$$

Let $Z = \mathbb{F}_p$, and define the Heisenberg group

$$\mathfrak{H}(V) = V \times Z$$

with multiplication

$$(v,z)(w,t) = \left(v+w, z+t+\frac{1}{2}b(v,w)\right).$$

Fix the additive character

$$\psi(z) = \mathrm{e}^{2\pi i z/p}.$$

Definition 7.1 (Schrödinger operators)**.** On $\mathcal{H} = \mathbb{C}^X$, define

$$\big(\rho(x,\xi,z)f\big)(u) = \psi\left(z + \xi(u) + \frac{1}{2}\xi(x)\right) f(u+x).$$

Theorem 7.2 (Finite Schrödinger representation)**.** *The map $\rho : \mathfrak{H}(V) \to \mathrm{GL}(\mathcal{H})$ is a representation. It is irreducible, its center acts by ψ, and*

$$\dim \mathcal{H} = p^r = \sqrt{|V|}.$$

Proof. A direct calculation gives

$$\rho(v,z)\rho(w,t) = \rho\left(v+w, z+t+\frac{1}{2}b(v,w)\right).$$

Translations by X and multiplications by characters from X^* generate the full matrix algebra on $\mathbb{C}^X$. Indeed, the character multipliers give all diagonal projectors by finite Fourier inversion, and translations move each coordinate line to every other coordinate line. The commutant is therefore scalar, so the representation is irreducible. The dimension is $|X| = p^r$. □

Proposition 7.3 (Character support)**.** *The character of the Schrödinger representation satisfies*

$$\boxed{\operatorname{Tr}\rho(v,z) = \begin{cases} p^r\psi(z), & v = 0, \\ 0, & v \neq 0. \end{cases}}$$

Proof. If the translation component x is nonzero, the operator permutes the standard basis without a fixed point, so its trace is zero. If $x = 0$ but $\xi \neq 0$, the trace is

$$\psi(z)\sum_{u\in X}\psi(\xi(u)) = 0.$$

When $x = \xi = 0$, the operator is the scalar $\psi(z)$. □

Standard Fact 7.4 (Finite Stone von Neumann theorem)**.** For a finite Heisenberg group with nondegenerate commutator form and a fixed nontrivial central character, there is one irreducible representation up to isomorphism. Its dimension is the square root of the order of the symplectic quotient.

The standard fact follows from the twisted group algebra argument in section 8. It is also the finite form used in the classical Weil representation literature [15, 26].

7.1 Maximal isotropic selectors

Let $L \subseteq V$ be maximal isotropic. Choose a subgroup lift $\widetilde{L} \subseteq \mathfrak{H}(V)$ on which the central coordinate is zero.

Proposition 7.5 (Isotropic averaging projector)**.** *The operator*

$$P_L = \frac{1}{|L|}\sum_{\ell\in\widetilde{L}}\rho(\ell)$$

is an orthogonal projector. In the Schrödinger model with $L = X$, it has rank one and selects the constant functions.

Proof. The lifted isotropic subgroup is abelian, so group averaging is an idempotent. Every operator in the average is unitary, and the subgroup is closed under inversion, so the average is self adjoint. For $L = X$, the average is the translation average

$$(P_L f)(u) = \frac{1}{|X|}\sum_{x\in X} f(u+x),$$

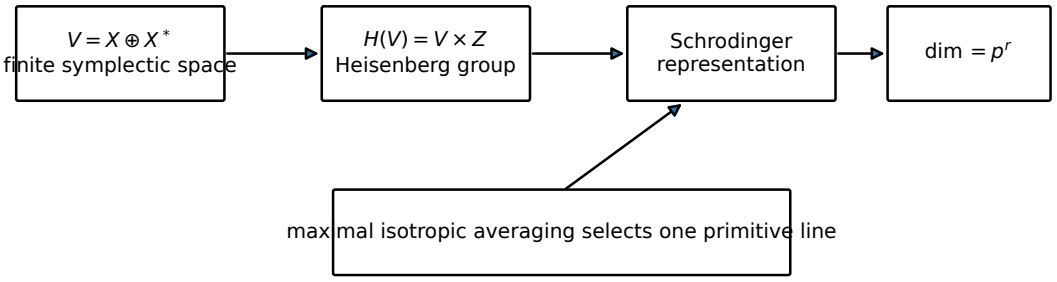

Figure 8. The finite Heisenberg packet and its maximal isotropic selector.

which is the constant function with value equal to the mean of f. Its range is one dimensional. □

Corollary 7.6 (Primitive line selector)**.** *Every maximal isotropic subgroup selects a one dimensional fixed line in the irreducible Heisenberg representation.*

Proof. The projector rank equals its trace. The identity element contributes p^r, while every nonidentity element of the lifted isotropic subgroup is noncentral and has trace zero by proposition 7.3. Since $|L| = p^r$, we get

$$\operatorname{Tr} P_L = \frac{p^r}{p^r} = 1.$$

Thus the projector has rank one. □

8 Twisted group algebras and commutator envelopes

Let A be a finite abelian group, and let

$$c : A \times A \to \mathbb{C}^\times$$

be a normalized two cocycle. The twisted group algebra $\mathbb{C}^c[A]$ has basis $(u_a)_{a \in A}$ and multiplication

$$u_a u_b = c(a,b) u_{a+b}.$$

Define the commutator bicharacter

$$b_c(a,b) = c(a,b)c(b,a)^{-1}.$$

Proposition 8.1 (Scalar choice invariance)**.** *Replacing u_a by $\lambda_a u_a$, with $\lambda_a \in \mathbb{C}^\times$, changes c by a coboundary and leaves b_c unchanged.*

Proof. The new cocycle is

$$c'(a,b) = \lambda_a \lambda_b \lambda_{a+b}^{-1} c(a,b).$$

The scalar coboundary factor is symmetric in a and b, so it cancels from $c'(a,b)c'(b,a)^{-1}$. □

Proposition 8.2 (Alternating commutator form)**.** *The map b_c is an alternating bicharacter. Its radical*

$$R = \{a \in A : b_c(a, x) = 1 \text{ for every } x \in A\}$$

is a subgroup, and b_c descends to a nondegenerate alternating bicharacter on A/R.

Proof. Associativity of the twisted product gives multiplicativity of scalar commutators in each variable. We have $b_c(a, a) = 1$ and $b_c(b, a) = b_c(a, b)^{-1}$. The radical is the kernel of the homomorphism from A to its character group defined by $a \mapsto b_c(a, \cdot)$. The induced pairing on the quotient is nondegenerate by construction. □

Theorem 8.3 (Nondegenerate twisted group algebra)**.** *Assume that b_c is nondegenerate. Then $|A|$ is a square, and*

$$\boxed{\mathbb{C}^c[A] \cong M_{\sqrt{|A|}}(\mathbb{C}).}$$

Consequently, $\mathbb{C}^c[A]$ has one irreducible module up to isomorphism, of dimension $\sqrt{|A|}$.

Proof. Let

$$z = \sum_{a \in A} z_a u_a$$

be central. Commuting with u_x gives

$$z_a b_c(x, a) = z_a$$

for every x. Nondegeneracy forces $z_a = 0$ for every nonzero a. Thus the center is $\mathbb{C}$. To prove semisimplicity directly, choose a linear projection P onto a submodule of a finite dimensional $\mathbb{C}^c[A]$-module and form

$$\overline{P} = \frac{1}{|A|} \sum_{a \in A} u_a P u_a^{-1}.$$

Every summand maps into the submodule and is the identity there. Conjugation by any u_x permutes the summands: the cocycle scalars cancel between each operator and its inverse. Hence $\overline{P}$ is an equivariant projection, and its kernel is an invariant complement. The algebra is therefore semisimple. Its center $\mathbb{C}$ permits only one simple factor. A finite dimensional central simple algebra over $\mathbb{C}$ is a full matrix algebra. Its dimension is $|A|$, so the matrix size is $\sqrt{|A|}$. □

Corollary 8.4 (Radical free envelope)**.** *For an arbitrary scalar projective action of A, the quotient*

$$\boxed{A^{\mathrm{symp}} = A/\operatorname{rad} b_c}$$

is the maximal quotient detected by noncommuting projective intertwiners. If A is an elementary abelian p group, then A^{symp} is a symplectic $\mathbb{F}_p$ space.

Proof. Every radical element commutes with all projective generators, so it contributes only central data. Quotienting by the radical leaves the nondegenerate commutator form. In the elementary abelian case, multiplicative values in the group of pth roots can be written as an alternating bilinear form over $\mathbb{F}_p$. □

Remark 8.5. The envelope depends only on the projective representation. It does not by itself prove that a given wild inertia representation carries a canonical finite quotient with the required projective action.

9 A restricted one break Galois envelope

We now isolate a finite Clifford setting in which the quotient projective action is defined on a multiplicity space. This avoids assigning a quotient action directly to arbitrary representatives of G/N.

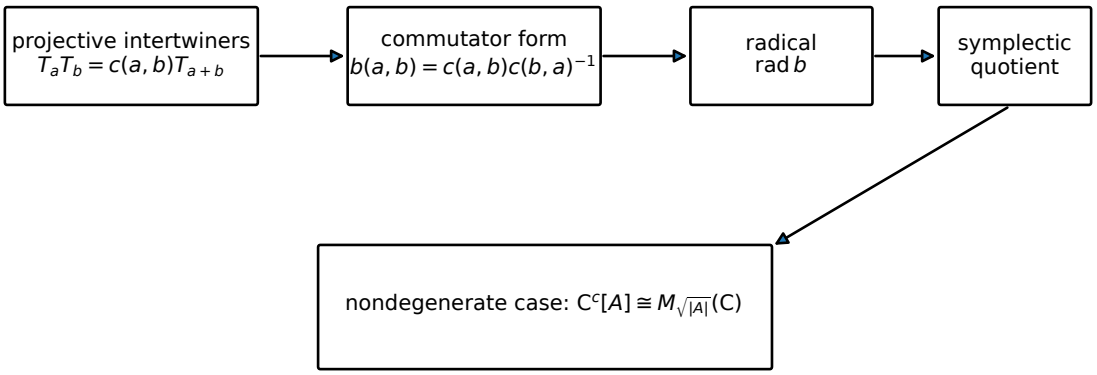

Figure 9. Projective intertwiners determine a radical free symplectic envelope.

Definition 9.1 (One break Clifford datum)**.** A one break Clifford datum consists of finite groups and representations

$$N \triangleleft G, \qquad A = G/N, \qquad \Pi : G \to \mathrm{GL}(\mathcal{X}), \qquad \rho : N \to \mathrm{GL}(W),$$

with the following properties.

(1) The quotient A is a finite elementary abelian p group.
(2) The representations Π and ρ are irreducible.
(3) The isomorphism class of ρ is fixed by G.
(4) The restriction of Π to N is ρ isotypic.
(5) The quotient records one declared ramification break.

The multiplicity space is

$$M_\rho = \mathrm{Hom}_N(W, \mathcal{X}).$$

The isotypic condition gives an N equivariant evaluation isomorphism

$$W \otimes M_\rho \longrightarrow \mathcal{X}.$$

Choose a section $s : A \to G$. For every $a \in A$, choose an intertwiner I_a from ρ to its conjugate by $s(a)$. Under the evaluation isomorphism, there is a unique operator T_a on M_ρ such that

$$\Pi(s(a)) = I_a \otimes T_a.$$

The operators T_a form a projective representation of A.

Proposition 9.2 (Clifford multiplicity action)**.** *The projective equivalence class of the action $(T_a)_{a\in A}$ is independent of the section, the intertwiners, and the chosen isotypic evaluation isomorphism. The projective action is irreducible.*

Proof. Changing an intertwiner I_a by a scalar changes T_a by the inverse scalar. Changing the isotypic evaluation isomorphism conjugates all T_a by one element of $\mathrm{GL}(M_\rho)$. Changing the section multiplies

$s(a)$ by an element of N. That factor is absorbed by the ρ action on W, leaving a scalar change on the multiplicity operator by Schur's lemma. Thus all choices give projectively equivalent actions.

If a nonzero proper subspace of M_ρ were stable under all projective operators T_a, then its tensor product with W would give a nonzero proper G stable subspace of $\mathcal{X}$. This contradicts irreducibility of Π. □

Definition 9.3 (Clifford cocycle class)**.** Choose scalars $c(a,b)$ such that

$$T_a T_b = c(a,b) T_{a+b}.$$

The cohomology class

$$[c_\rho] \in H^2(A, \mathbb{C}^\times)$$

is the Clifford cocycle class of the datum.

Proposition 9.4 (Intrinsic commutator pairing)**.** *The pairing*

$$b_\rho(a,b) = c(a,b)c(b,a)^{-1}$$

is independent of every choice in definition 9.1. It is an alternating bicharacter

$$b_\rho : A \times A \to \mu_p.$$

Proof. The projective equivalence class is intrinsic by proposition 9.2. Conjugation does not change scalar commutators, and scalar changes alter the cocycle by a coboundary. The commutator pairing is therefore unchanged by proposition 8.1. Its alternating and bilinear properties follow from proposition 8.2. Since every element of A has order p, every value has order dividing p. □

Definition 9.5 (One break symplectic envelope)**.** The one break symplectic envelope is

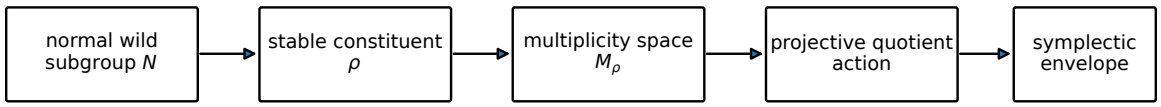
$$\boxed{V_\rho = A / \operatorname{rad} b_\rho.}$$

Theorem 9.6 (Nondegenerate one break packet)**.** *If b_ρ is nondegenerate, then*

$$\mathbb{C}^{c_\rho}[A] \cong \operatorname{End}(M_\rho), \qquad \dim M_\rho = \sqrt{|A|}.$$

Proof. The projective action gives a nonzero representation of the twisted group algebra on M_ρ. The algebra is a full matrix algebra by theorem 8.3. Its unique irreducible module has dimension $\sqrt{|A|}$. The projective multiplicity action is irreducible by proposition 9.2, so it is that module. □

Proposition 9.7 (Isomorphism invariance)**.** *The cocycle class and the equivariant isometry class of V_ρ depend only on the isomorphism class of the one break Clifford datum.*



Proof. An isomorphism of data transports the restriction, the multiplicity space, and its projective quotient action. It therefore transports the cocycle class, the commutator pairing, its radical, and the quotient. □

Proposition 9.8 (Tame stabilizer action)**.** *Suppose a finite group C acts by automorphisms of the one break Clifford datum. Then C acts on V_ρ by symplectic automorphisms.*

Proof. The automorphism action transports the intrinsic projective multiplicity representation. It therefore preserves the scalar commutator pairing and its radical. The induced action on the quotient is symplectic. □

Corollary 9.9 (Heisenberg representation attached to one break)**.** *Fix a nontrivial central character. The envelope V_ρ determines one irreducible finite Heisenberg representation up to isomorphism.*

Proof. Apply the finite Stone von Neumann theorem to the nondegenerate symplectic quotient. □

The construction is intrinsic for the declared one break Clifford datum, up to equivariant isometry.

Figure 10. The restricted one break construction is made on the Clifford multiplicity space.

Remark 9.10. The group cohomology class records the extension obstruction for the multiplicity action. General background on projective representations and group cohomology can be found in [22, 3]. The theorem remains restricted because the finite quotient and the one break isotypic datum are assumed rather than constructed from arbitrary wild inertia.

10 The type side symplectic quotient

Let θ be a maximal simple character for $\mathrm{GL}_n(K)$, with compact open subgroups

$$H^1_\theta \subseteq J^1_\theta \subseteq J_\theta.$$

The quotient

$$V_\theta = J^1_\theta / H^1_\theta$$

is regarded as a finite vector space over $\mathbb{F}_p$, where p is the residue characteristic. Fix a nontrivial additive character $\psi_0 : \mathbb{F}_p \to \mu_p \subset \mathbb{C}^\times$, where μ_p is the group of p-th roots of unity. The simple-character commutator takes values in μ_p. Since ψ_0 is injective, the equation

$$\psi_0\big(h_\theta(\bar{x}, \bar{y})\big) = \theta([x, y])$$

uniquely defines the $\mathbb{F}_p$-valued commutator pairing h_θ. We use the same identification of μ_p with the additive group of $\mathbb{F}_p$ on the Galois side when comparing the two symplectic spaces.

Standard Fact 10.1 (Type side Heisenberg quotient)**.** The pairing h_θ is nondegenerate and alternating. There is one irreducible representation η_θ of J^1_θ containing θ, and its dimension is

$$\sqrt{\left|J^1_\theta / H^1_\theta\right|}.$$

This is part of the simple character and Heisenberg representation theory used in the construction of types [11]. The extension of η_θ from J^1_θ to J_θ is not unique before a normalization is chosen.

Standard Fact 10.2 (Canonical beta extension)**.** The canonical beta extension is obtained from a primary extension together with finite symplectic and tame orientation corrections. The construction is functorial in the declared simple character data and removes the remaining extension ambiguity.

The normalization and its relation to finite Weil representations are developed in [2, 14]. This chapter uses this theorem as type side input. It does not rederive simple character theory.

Proposition 10.3 (Type side projective commutator)**.** *The projective action of J_θ / J_θ^1 on the Heisenberg representation preserves the commutator form on V_θ. Any two choices of projective lifts give the same alternating form.*

Proof. Conjugation by J_θ preserves θ, so it preserves the commutator pairing defined from $\theta([x, y])$. Two choices of projective lifts differ by scalars. The scalar commutator is therefore unchanged by proposition 8.1. □

11 The restricted Galois to type bridge

The full bridge would construct an intrinsic Galois envelope for every wild atom and identify it canonically with V_θ. We prove the comparison after the required symplectic identification has been supplied.

Definition 11.1 (Bridge datum)**.** A restricted bridge datum consists of

(1) a one break Galois envelope (V_ρ, b_ρ)
(2) a type side quotient (V_θ, h_θ)
(3) an equivariant symplectic isometry
$$\iota : V_\rho \longrightarrow V_\theta$$
for a finite cyclic stabilizer $C = \langle c \rangle$
(4) the same nontrivial central character on the two Heisenberg groups
(5) when $p = 2$, compatible quadratic refinements and an isomorphism of the resulting Heisenberg central extensions lifting ι.

Theorem 11.2 (Restricted Heisenberg bridge)**.** *A restricted bridge datum determines an isomorphism between the two Heisenberg representations, unique up to a nonzero scalar. More precisely, there is an invertible map*
$$U : \mathcal{H}_\rho \longrightarrow \mathcal{H}_\theta$$
such that
$$U\omega_\rho(h) = \omega_\theta(\iota_H(h))U$$
for every Heisenberg element h, and every other such map is a scalar multiple of U.

Proof. When p is odd, the symplectic isometry and the common central character induce the standard isomorphism ι_H of the two Heisenberg groups. When $p = 2$, the required lift of ι is part of the bridge datum because the alternating form alone does not determine the central extension. Pulling the type side representation back through ι_H gives an irreducible Heisenberg representation with the same central character as the Galois side representation. The finite Stone von Neumann theorem gives an isomorphism. Schur's lemma gives uniqueness up to scalar. □

The stabilizer actions need not agree after choosing U. Their discrepancy is scalar because both actions implement the same automorphisms of the irreducible Heisenberg representation.

Proposition 11.3 (Cyclic discrepancy character)**.** *Assume that the two projective stabilizer actions have been linearized to honest representations of the cyclic group C. Then there is a character*
$$\delta : C \to \mathbb{C}^\times$$

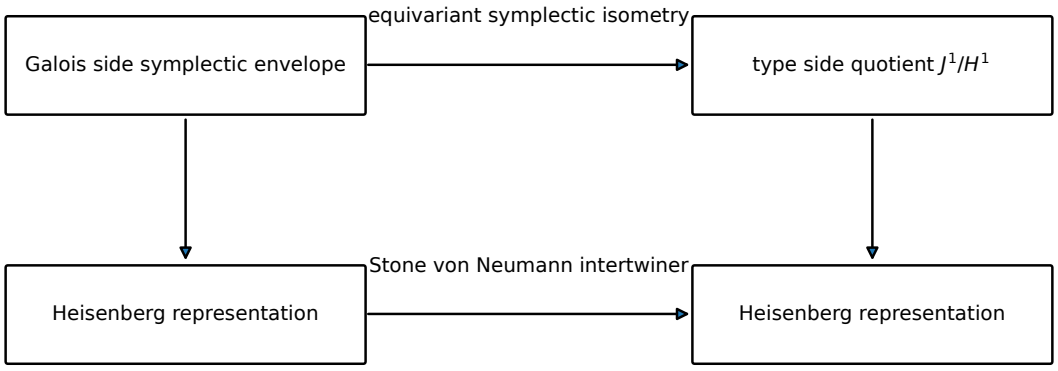


Figure 11. An equivariant symplectic isometry reduces the finite comparison to one scalar cyclic phase.

such that

$$U\Omega_\rho(g) = \delta(g)\Omega_\theta(g)U$$

for every $g \in C$.

Proof. For each g, the operator

$$\Omega_\theta(g)^{-1}U\Omega_\rho(g)U^{-1}$$

commutes with the type side Heisenberg representation. It is therefore scalar. Since both stabilizer actions are honest representations, multiplication of group elements shows that the scalars form a character. □

Lemma 11.4 (Linearization over a cyclic stabilizer)**.** *Every finite dimensional projective representation of a finite cyclic group over* $\mathbb{C}$ *is projectively equivalent to an honest representation.*

Proof. Let $C = \langle c \rangle$ have order m, and let T be a lift of the projective generator. Since $c^m = 1$, the operator T^m is scalar. Choose $\lambda \in \mathbb{C}^\times$ with $\lambda^m T^m = I$. Replacing T by λT gives an honest cyclic representation. □

Theorem 11.5 (One phase closes the cyclic bridge)**.** *In a restricted bridge datum, choose linearizations of the cyclic stabilizer actions. If the two actions have the same scalar phase on the generator c, then the Heisenberg intertwiner can be chosen to intertwine the full semidirect product action.*

Proof. By proposition 11.3, the discrepancy is a character δ. Equality of the generator phase gives $\delta(c) = 1$. Since c generates C, the character is trivial. The chosen map U then intertwines every stabilizer element as well as the Heisenberg group. □

Corollary 11.6 (Bridge uniqueness)**.** *When the semidirect product representation is irreducible, the completed bridge is unique up to scalar.*

Proof. Any two completed bridges differ by an endomorphism commuting with the semidirect product representation. Schur's lemma applies. □

Remark 11.7. The theorem does not construct ι. It proves that, once an equivariant symplectic isometry exists, the remaining finite comparison is one dimensional for a cyclic stabilizer.

12 Odd residue characteristic phases

Let p be odd, let (V, b) be a finite symplectic $\mathbb{F}_p$ space of dimension $2r$, and let

$$g \in \mathrm{Sp}(V)$$

have no fixed vector. Fix one of the standard finite Weil normalizations used in the literature [15, 25, 16].

Standard Fact 12.1 (Fixed point free Weil trace)**.** Under the declared normalization,

$$\boxed{\mathrm{Tr}\,\omega(g) = \left(\frac{-1}{p}\right)^r \left(\frac{\det(g-I)}{p}\right).}$$

Here $\left(\frac{\cdot}{p}\right)$ denotes the quadratic character of $\mathbb{F}_p^\times$.

Definition 12.2 (Odd finite Weil phase)**.** For fixed point free g, define

$$\Phi_p(g, V) = \left(\frac{-1}{p}\right)^r \left(\frac{\det(g-I)}{p}\right).$$

Proposition 12.3 (Symplectic invariance)**.** *If*

$$\iota : (V, b) \longrightarrow (V', b')$$

is a symplectic isometry and $g' = \iota g \iota^{-1}$, then

$$\Phi_p(g, V) = \Phi_p(g', V').$$

Proof. The dimensions agree, and conjugate matrices have the same determinant of $g - I$. □

Proposition 12.4 (Orthogonal multiplicativity)**.** *Suppose*

$$V = V_1 \perp \cdots \perp V_s$$

and g preserves every summand. If no $g|_{V_j}$ has a fixed vector, then

$$\boxed{\Phi_p(g, V) = \prod_{j=1}^{s} \Phi_p(g|_{V_j}, V_j).}$$

Proof. The half dimensions add, and

$$\det(g - I \mid V) = \prod_j \det(g - I \mid V_j).$$

The quadratic character is multiplicative. □

Corollary 12.5 (Characteristic polynomial certificate)**.** *Let*

$$P_g(X) = \det(XI - g \mid V).$$

Then

$$\boxed{\Phi_p(g, V) = \left(\frac{-1}{p}\right)^r \left(\frac{P_g(1)}{p}\right).}$$

Proof. Since $\dim V$ is even,

$$\det(g - I) = \det(I - g) = P_g(1).$$

□

Proposition 12.6 (Fixed and moving decomposition)**.** *Assume that $g \in \mathrm{Sp}(V)$ has order prime to p. Then*

$$V = \ker(g - I) \perp \mathrm{im}(g - I).$$

The restriction of the symplectic form to $\mathrm{im}(g - I)$ is nondegenerate, and $g - I$ is invertible on that moving summand.

Proof. The order hypothesis makes g semisimple, so

$$V = \ker(g - I) \oplus \mathrm{im}(g - I).$$

If $x \in \ker(g - I)$ and $y = (g - I)z$, then

$$b(x, y) = b(x, gz) - b(x, z) = b(g^{-1}x, z) - b(x, z) = 0.$$

Thus the two summands are orthogonal. Nondegeneracy on each summand follows from nondegeneracy on V. The last statement is immediate from the direct sum decomposition. □

Definition 12.7 (Moving phase)**.** Under the hypotheses of proposition 12.6, define

$$\Phi_p^{\mathrm{mov}}(g, V) = \Phi_p\left(g|_{\mathrm{im}(g-I)}, \mathrm{im}(g - I)\right).$$

Proposition 12.8 (Hyperbolic phase formula)**.** *Let U be a finite dimensional $\mathbb{F}_p$ space, let $a \in \mathrm{GL}(U)$ have no eigenvalue one, and let g act on*

$$H(U) = U \oplus U^*$$

by

$$g = (a, (a^{-1})^*).$$

Then

$$\boxed{\Phi_p(g, H(U)) = \left(\frac{\det a}{p}\right).}$$

Proof. Put $d = \dim U$. We have

$$\det\big((a^{-1})^* - I\big) = (-1)^d (\det a)^{-1} \det(a - I).$$

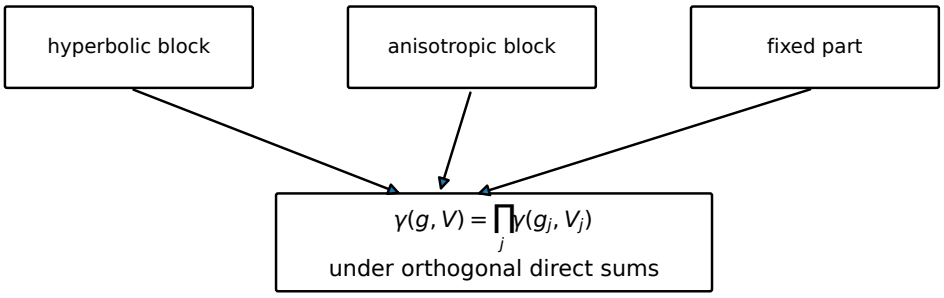
Hence

$$\det(g - I) = (-1)^d (\det a)^{-1} \det(a - I)^2.$$

Multiplying its quadratic character by the normalization factor $(\frac{-1}{p})^d$ cancels the sign and the square. Since a quadratic character equals its inverse, the result is $(\frac{\det a}{p})$. □

Corollary 12.9 (Phase only bridge test)**.** *Two odd characteristic moving packets have the same normalized phase whenever their moving half dimensions agree and the determinants of $g - I$ lie in the same square class.*

Proof. Apply the definition of Φ_p. □



Remark 12.10. When g has fixed vectors, one first separates the fixed part and applies the formula to the moving quotient. Additional normalization data may enter the full trace on the fixed part.

13 Dyadic quadratic refinements

Let (V, b) be a symplectic vector space over $\mathbb{F}_2$. The alternating form alone is not enough to determine the finite phase.

Definition 13.1 (Quadratic refinement)**.** A quadratic refinement of b is a map

$$q : V \to \mathbb{F}_2$$

In odd characteristic the normalized finite Weil phase is controlled blockwise.

Figure 12. Odd finite Weil phases multiply across orthogonal atomic blocks.

satisfying

$$q(x+y)-q(x)-q(y)=b(x,y).$$

Proposition 13.2 (Affine space of refinements)**.** *If one quadratic refinement exists, then the set of all quadratic refinements is an affine space over V^*.*

Proof. The difference of two refinements has zero polar form, so it is additive and hence linear over $\mathbb{F}_2$. Conversely, adding a linear form does not change the polar form. □

Definition 13.3 (Arf invariant)**.** Choose a symplectic basis $(e_i,f_i)_{i=1}^r$. Define

$$\operatorname{Arf}(q)=\sum_{i=1}^{r} q(e_i)q(f_i)\in\mathbb{F}_2.$$

Standard Fact 13.4 (Arf invariance and classification)**.** The value in definition 13.3 is independent of the symplectic basis. Two nondegenerate quadratic refinements of one finite symplectic space are isometric exactly when their Arf invariants agree.

This is the classical classification of nonsingular quadratic forms over $\mathbb{F}_2$ [24].

Theorem 13.5 (Dyadic Gauss sign)**.** *Let $\dim V=2r$, and let q be nondegenerate. Then*

$$\boxed{\sum_{x\in V}(-1)^{q(x)}=(-1)^{\operatorname{Arf}(q)}2^r.}$$

Proof. Orthogonally decompose (V,q) into two dimensional nonsingular planes. On a plane with Arf invariant zero, the four values of $(-1)^q$ sum to 2. On a plane with Arf invariant one, they sum to -2. The total sum is the product of the plane sums. The parity of the number of anisotropic planes is the Arf invariant. □

Corollary 13.6 (Orthogonal dyadic multiplicativity)**.** *For an orthogonal sum*

$$(V,q)=(V_1,q_1)\perp(V_2,q_2),$$

we have

$$\operatorname{Arf}(q)=\operatorname{Arf}(q_1)+\operatorname{Arf}(q_2)$$

and the normalized Gauss sign is the product of the two normalized signs.

Proof. Take symplectic bases of the two summands and concatenate them. The Gauss sum factors as a product over the Cartesian decomposition. □

Proposition 13.7 (The form alone does not determine the phase)**.** *On every nonzero symplectic $\mathbb{F}_2$ space, there are quadratic refinements of both Arf invariants. Their polar forms agree, but their normalized Gauss signs are opposite.*

Proof. On a symplectic plane, the standard hyperbolic refinement has Arf invariant zero. Adding a suitable nonzero linear form produces a refinement with Arf invariant one. Orthogonally adjoining a fixed refinement on the complement gives the two choices in every positive even dimension. The signs differ by theorem 13.5. □

Proposition 13.8 (Translation of quadratic refinements)**.** *For $v \in V$, put*

$$q_v(x) = q(x) + b(v, x).$$

Then

$$\boxed{\operatorname{Arf}(q_v) = \operatorname{Arf}(q) + q(v).}$$

Proof. Using the quadratic identity,

$$q_v(x) = q(x + v) + q(v).$$

Therefore

$$\sum_x (-1)^{q_v(x)} = (-1)^{q(v)} \sum_x (-1)^{q(x)}.$$

Compare the signs in theorem 13.5. □

Theorem 13.9 (Number of dyadic refinements)**.** *Let $\dim V = 2r$. The number of quadratic refinements with Arf invariant zero is*

$$\boxed{2^{r-1}(2^r + 1),}$$

and the number with Arf invariant one is

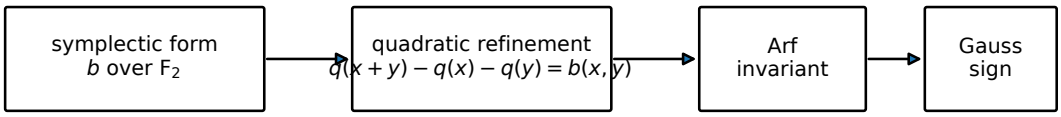
$$\boxed{2^{r-1}(2^r - 1).}$$

Proof. Every refinement is q_v for a unique $v \in V$, because b identifies V with V^*. By proposition 13.8, the Arf invariant changes according to $q(v)$. Let Z and O be the numbers of zeros and ones of q. Then

$$Z + O = 2^{2r}$$

and theorem 13.5 gives

$$Z - O = (-1)^{\operatorname{Arf}(q)} 2^r.$$



Solving gives the two displayed numbers, with their roles exchanged when the starting refinement has Arf invariant one. Since translation runs through every refinement, the final counts are independent of the starting choice. □

14 Matrix holonomy and finite gluing

Let Γ be a connected finite graph. At every vertex v, place finite dimensional complex vector spaces V_v and W_v of the same dimension. For every oriented edge $e : u \to v$, let

$$A_e : V_u \longrightarrow V_v, \qquad B_e : W_u \longrightarrow W_v$$

be invertible. The reversed edge carries the inverse map.

$$\sum_{x}(-1)^{q(x)} = (-1)^{\mathrm{Arf}(q)}2^{r}$$

The alternating form alone does not determine the dyadic phase.

Figure 13. At residue characteristic two, the quadratic refinement and its Arf invariant carry phase information not contained in the alternating form.

Definition 14.1 (Path transport)**.** For an oriented path

$$\gamma = (v_0 \to v_1 \to \cdots \to v_m),$$

define

$$A_\gamma = A_{v_m v_{m-1}} \cdots A_{v_1 v_0}, \qquad B_\gamma = B_{v_m v_{m-1}} \cdots B_{v_1 v_0}.$$

For a loop based at r, these are the based holonomies.

Theorem 14.2 (Matrix holonomy criterion)**.** *Fix a root r and an isomorphism*

$$U_r : V_r \longrightarrow W_r.$$

The following conditions are equivalent.

(1) There are isomorphisms $U_v : V_v \to W_v$, with the declared U_r, such that

$$U_v A_e = B_e U_u$$

for every edge $e : u \to v$.

(2) For one fundamental cycle basis based at r,

$$U_r A_\gamma = B_\gamma U_r.$$

(3) The same identity holds for every based loop γ.

Proof. If the vertex maps exist, multiply the edge equations around a loop. Every intermediate vertex map cancels, giving condition three. Condition three implies condition two.

Conversely, choose a spanning tree. Starting from U_r, define U_v by transport along the unique tree path from r to v. The edge equations hold on every tree edge by construction. Every non tree edge closes one fundamental cycle. The edge equation on that edge is equivalent to the root holonomy identity for its fundamental cycle. Condition two therefore gives all remaining edge equations. □

Corollary 14.3 (Unbased gauge classification)**.** *There exists some family of vertex isomorphisms if and only if the two holonomy representations*

$$\pi_1(\Gamma, r) \longrightarrow \mathrm{GL}(V_r), \qquad \pi_1(\Gamma, r) \longrightarrow \mathrm{GL}(W_r)$$

are conjugate.

Proof. Apply theorem 14.2 and allow U_r to vary. □

Corollary 14.4 (Scalar and projective gluing)**.** *If every based loop acts by a scalar, finite gluing is equivalent to equality of the scalar holonomies on a fundamental cycle basis. The number of independent tests is*

$$\boxed{|E| - |V| + 1.}$$

Proof. A connected graph has a spanning tree with $|V| - 1$ edges. Every remaining edge gives one fundamental cycle. In the scalar case, conjugacy has no effect. □

Proposition 14.5 (Projective cocycle form)**.** *Suppose the edge maps are defined only up to scalar, in the setting where all based holonomies of both systems are scalar. Choose representatives. The ratio of the two scalar holonomies on each loop is unchanged by vertex rescaling. It defines a character of the first homology group when the scalar transport is abelian.*

Proof. A vertex rescaling appears once with positive exponent and once with negative exponent around a closed path, so it cancels. Multiplication of loops multiplies the scalar ratios. In the abelian case, the ratio factors through the abelianization of the fundamental group, which is the first homology group. □

Proposition 14.6 (Exact edge residual from cycle defect)**.** *Fix a spanning tree and construct the vertex maps by tree transport from U_r. Let $e : u \to v$ be a non tree edge. Let p_u and p_v be the tree paths from the root to u and v. Define the fundamental cycle defect*

$$D_e = U_r A_{p_v}^{-1} A_e A_{p_u} - B_{p_v}^{-1} B_e B_{p_u} U_r.$$

Then the edge residual is exactly

$$\boxed{U_v A_e - B_e U_u = B_{p_v} D_e A_{p_u}^{-1}.}$$

Proof. Substitute

$$U_u = B_{p_u} U_r A_{p_u}^{-1}, \qquad U_v = B_{p_v} U_r A_{p_v}^{-1}$$

into the left side and factor B_{p_v} on the left and $A_{p_u}^{-1}$ on the right. □

Corollary 14.7 (Quantitative finite gluing)**.** *With the notation of proposition 14.6,*

$$\|U_v A_e - B_e U_u\| \le \left\|B_{p_v}\right\| \|D_e\| \left\|A_{p_u}^{-1}\right\|.$$

Thus small fundamental cycle defects give small non tree edge residuals whenever the tree transports are uniformly conditioned.

Proof. Take operator norms in the exact identity. □

Remark 14.8. The theorem is an exact finite gluing result. It assumes that the packet spaces and edge transports have already been constructed on both sides.

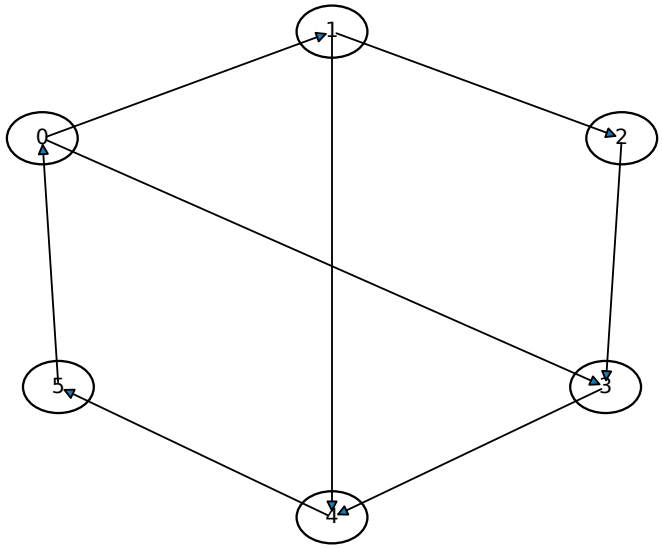


Figure 14. A spanning tree fixes the vertex gauges. The non tree edges test the remaining cycle holonomies.

15 Breakwise assembly

Wild inertia carries an upper ramification filtration. In favorable settings, a wild atom separates into finitely many break pieces. We state the finite algebra needed once such pieces are intrinsic.

Definition 15.1 (Orthogonal break decomposition)**.** An orthogonal break decomposition is a symplectic direct sum

$$V = \operatorname*{\perp}_{s \in S} V_s$$

that is preserved by the declared tame stabilizer. Each V_s is the finite symplectic packet assigned to one break.

Proposition 15.2 (Heisenberg tensor factorization)**.** *Fix compatible central characters. The irreducible Heisenberg representation of an orthogonal sum is the tensor product of the irreducible Heisenberg representations of its summands:*

$$\boxed{\omega_V \cong \bigotimes_{s \in S} \omega_{V_s}.}$$

Proof. The Heisenberg group of an orthogonal sum is the central product of the Heisenberg groups of the summands. The tensor product representation has the declared central character and has dimension

$$\prod_s \sqrt{|V_s|} = \sqrt{|V|}.$$

It is irreducible by the finite Stone von Neumann theorem, so it is the required representation. □

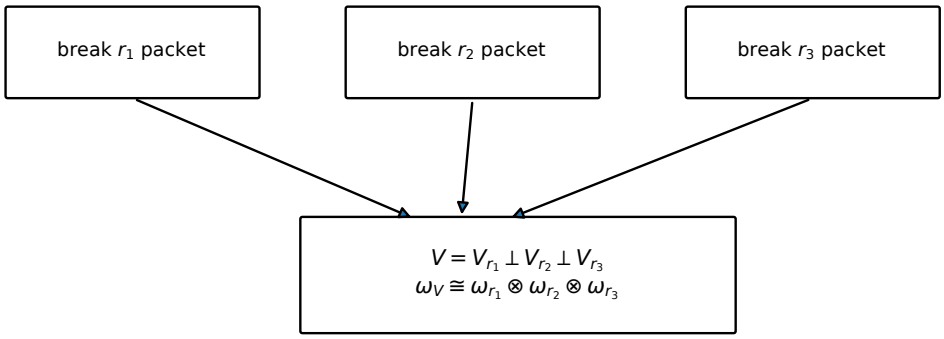

Figure 15. Orthogonal break packets produce tensor factors of the finite Heisenberg representation.

Corollary 15.3 (Breakwise phase product)**.** *In odd residue characteristic, let $g \in \mathrm{Sp}(V)$ preserve every break packet and suppose its restriction to $M = \mathrm{im}(g - I)$ is fixed point free. Put $g_s = g|_{V_s}$ and $M_s = \mathrm{im}(g_s - I)$. The moving restrictions are symplectic, and*

$$\boxed{\Phi_p(g|_M, M) = \prod_{s \in S} \Phi_p(g_s|_{M_s}, M_s).}$$

In residue characteristic two, the analogous normalized Gauss sign is the product of the signs determined by the breakwise quadratic refinements.

Proof. The invariant orthogonal decomposition gives $M = \perp_{s \in S} M_s$. Symplectic invariance gives $M^\perp = \ker(g - I)$. Fixed point freeness on M therefore makes the restricted form nondegenerate on M and on each M_s. Each restriction of $g_s - I$ to M_s is invertible, so proposition 12.4 applies to the moving spaces. A zero moving space contributes one. In characteristic two, apply corollary 13.6. □

Theorem 15.4 (Breakwise restricted bridge)**.** *Suppose every break has a restricted bridge datum, the symplectic isometries are compatible with the stabilizer action, and the scalar phases agree on a generating set of the stabilizer. Then the tensor product of the breakwise Heisenberg intertwiners gives a bridge for the full finite envelope. Any remaining gluing obstruction is exactly the matrix holonomy obstruction of theorem 14.2.*

Proof. Tensor the breakwise Heisenberg intertwiners from theorem 11.2. Phase agreement makes the tensor map equivariant on the chosen stabilizer generators. The breakwise direct sum and tensor factorization make the local comparisons compatible. If the packets are arranged over a transport graph, the only remaining condition is consistency of the local maps around cycles, which is exactly the holonomy criterion. □

16 Local factor tests and the remaining bridge

Local class field theory identifies one dimensional Weil characters with characters of $K^\times$ [27, 29]. The tame induction theorem extends this explicit picture to higher dimensional tame atoms. The local polynomial and conductor calculations in propositions 5.4 and 5.8 therefore give explicit finite

invariants for the declared tame packets. Finite Gauss sums give the residue field phase. The full local factor, however, also includes ramification depth, Haar measure normalization, the additive character conductor, and wild interaction data.

Proposition 16.1 (Finite tame comparison package)**.** *For a tame induced atom, the following data are determined by its packet coordinates:*

(1) the dimension and inertia orbit
(2) the Frobenius cycle polynomial
(3) the Artin conductor
(4) the local polynomial
(5) the tensor refinement into interaction packets
(6) the finite Gauss sum of each declared residue character, with unit-modulus phase normalization when that character is nontrivial.

Proof. The dimension and orbit follow from theorem 3.2. The cycle polynomial is proposition 4.4. For rank greater than one, the conductor is proposition 5.8. In rank one, the Swan conductor is zero, and the Artin conductor is zero for trivial inertia and one otherwise, by the formula $\mathrm{Art} = \dim V - \dim V^{I_K} + \mathrm{Sw}$. The local polynomial is proposition 5.4. Tensor refinement is theorem 5.1. The Gauss sum is its defining finite sum. For a nontrivial multiplicative character its unit phase is definition 6.2. For the trivial character and a nontrivial additive character ψ, the sum is $G(1, \psi) = -1$, because the sum of ψ over the whole field is zero. □

16.1 Arithmetic realization and the conditional comparison

Fix this chapter's reciprocity, additive-character, local-factor, and phase normalizations. Let $\mathcal{A}$ be the declared class of irreducible wild Weil atoms under consideration. For $\rho \in \mathcal{A}$, the supplied assembled finite datum d_ρ consists of the following inputs, historically denoted H1–H4:

(1) an intrinsic finite break decomposition on the Galois side;
(2) the declared equivariant symplectic bridges to the supplied breakwise type-side quotients;
(3) compatible odd or dyadic central-extension and phase data on every break, including every prescribed finite marking;
(4) a compatible transport system with vanishing matrix holonomy obstruction.

These are finite comparison inputs. Supplying separate breakwise target types does not itself supply one common arithmetic candidate. If a common candidate is already supplied, that is a stronger restricted hypothesis.

An *arithmetic realization witness* $\mathcal{R}(d_\rho, \pi)$ consists of actual arithmetic inducing data for an admissible supercuspidal π, together with explicit comparison and recovery maps carrying the prescribed assembled finite packet. The maps preserve its declared stabilizer action, all character values explicitly included in the supplied datum, central-extension and phase data, and compatible transports. Recovery returns that same π, with its fixed central character and noncompact completion. An enlarged actual inducing carrier is permitted. The whole packet is not required to be the original maximal-simple-type quotient. Any stronger native-marking or numerical-layer requirement is part of the declared datum and must be verified separately.

Conjecture 66 (Arithmetic packet realization)**.** For every $\rho \in \mathcal{A}$ with its supplied H1–H4 assembled finite datum d_ρ, there exists an actual admissible supercuspidal representation π of $\mathrm{GL}_{\dim \rho}(K)$ and an arithmetic realization witness $\mathcal{R}(d_\rho, \pi)$.

This is the realization problem isolated from historical Theorem 16.2 and original proof obligation 66 (row 95 of the historical all-records register). It asks for one witness for each admitted source, rather than for success of every proposed host or every noncompact completion. No proof of the unrestricted statement is claimed.

Proposition 16.3 (Comparison of one realized candidate)**.** *Let $\rho \in \mathcal{A}$, and let π be one actual admissible supercuspidal representation of $\mathrm{GL}_{\dim \rho}(K)$ with $\mathcal{R}(d_\rho, \pi)$. Suppose H5 holds for this same π: its required pair local factors equal those prescribed for ρ on the stipulated characterizing family of twists, with the fixed normalizations. Assume the stated local-factor characterization applies to that family and class. Then π is isomorphic to the representation assigned to ρ by the established local Langlands correspondence.*

Proof. H5 identifies the tested local factors for this actual candidate. The applicable local-factor characterization identifies its isomorphism class with the established correspondence [18]. The realization witness ensures that it is this same candidate which carries the prescribed assembled packet. No existence conclusion is inferred from the finite gluing conditions alone. □

Remark 16.4. H5 remains a conditional premise about the same fixed candidate. It is not a formal consequence of the finite symplectic bridge, conductor profiles, or a choice of noncompact root. This proposition adds no unconditional pair-factor obligation to the construction conjecture.

16.2 Exact open boundary

The following issues delimit the unrestricted program. The first four construct and normalize the finite inputs for broader source classes. Conjecture 66 asks for arithmetic realization once H1–H4 are supplied. The fifth is the independent route to replacing the retained conditional H5 input.

(1) Construct a choice free finite symplectic envelope from an arbitrary irreducible wild inertia atom, with its ramification filtration and tame stabilizer action.
(2) Prove a canonical equivariant symplectic isometry from that envelope to the type side quotient J^1_θ / H^1_θ.
(3) Recover the canonical beta extension phase in every break, including the required dyadic quadratic refinement.
(4) Prove matrix holonomy compatibility for the resulting packet transport system.
(5) Compare the full family of pair L, epsilon, and gamma factors without invoking the established correspondence.

The first item is a construction problem. The second is a comparison problem. The third is a normalization problem. The fourth is a descent problem. The fifth concerns proving the local factor premise needed for identification. Conjecture 66 does not assert this fifth step. None is replaced by a larger finite computation.

17 Examples and finite certificates

The examples in this section illustrate the exact finite formulas. They are not used as proofs of the general theorems.

Example 17.1 (A degree four tame orbit)**.** Over $\mathbb{F}_2$, the exponent orbit

$$1 \longmapsto 2 \longmapsto 4 \longmapsto 8 \longmapsto 1$$

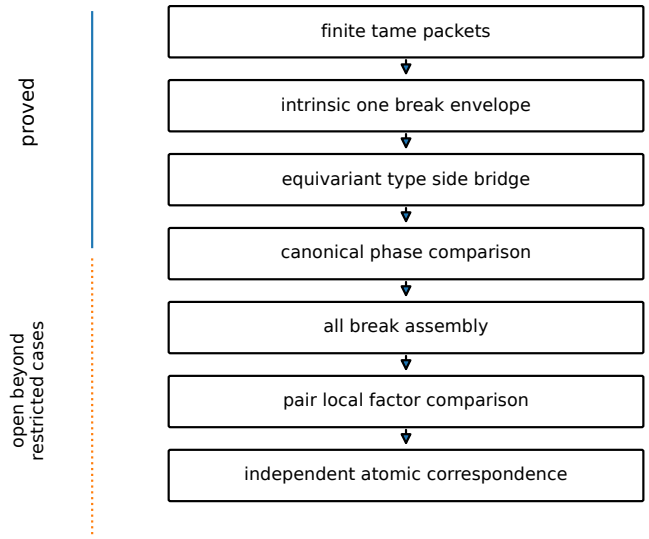

Figure 16. The proved finite layers and the remaining independent local correspondence steps.

has length four. It therefore gives a tame atom induced from the unramified extension of degree four. The Frobenius transfer has one four cycle, and the number of regular degree four orbits is three by proposition 3.6.

Example 17.2 (Tensor packets of lengths four and six)**.** For $n = 4$ and $m = 6$,

$$\gcd(4,6) = 2, \qquad \operatorname{lcm}(4,6) = 12.$$

The tensor product splits into two interaction packets of length twelve. Their total dimension is $2 \cdot 12 = 24$, equal to the product $4 \cdot 6$.

Example 17.3 (Rank one Heisenberg group)**.** Take $V = \mathbb{F}_3^2$. The Heisenberg group has order $3^3 = 27$, and its irreducible representation with a fixed nontrivial central character has dimension three. The trace vanishes on every noncentral element. Averaging the translation subgroup gives a rank one projector.

Example 17.4 (Nondegenerate twisted algebra)**.** Let $A = \mathbb{F}_p^2$ with its standard alternating form. A cocycle with that commutator form gives

$$\mathbb{C}^c[A] \cong M_p(\mathbb{C}).$$

The unique irreducible projective representation has dimension p.

Example 17.5 (Dyadic phase ambiguity)**.** On a symplectic plane over $\mathbb{F}_2$, choose refinements q_0 and q_1 with Arf invariants zero and one. Their polar forms are the same, while

$$\sum_x (-1)^{q_0(x)} = 2, \qquad \sum_x (-1)^{q_1(x)} = -2.$$

Thus the alternating packet alone cannot select the dyadic sign.

Example 17.6 (One cycle gluing obstruction)**.** Let a connected graph have one non tree edge. Tree transport determines every vertex map from one root map. The final edge equation holds exactly when the two holonomies around the unique fundamental cycle intertwine. Changing the scalar on that edge changes the cycle holonomy and produces a genuine obstruction.

18 Scope of the finite reconstruction

This chapter proves the following statements under their displayed hypotheses.

(1) Tame irreducible Weil atoms are transitive Frobenius packets induced from unramified extensions.
(2) Regular tame packets have the stated Möbius count.
(3) Finite cuspidal blocks have exact primitive central projectors.
(4) Tame tensor products satisfy the greatest common divisor and least common multiple packet formula.
(5) Tame local polynomials, conductors, and finite Gauss phases are explicit.
(6) Nondegenerate scalar projective commutators give full matrix twisted group algebras and unique finite Heisenberg representations.
(7) A declared one break Clifford datum has a choice independent radical free symplectic envelope.
(8) An equivariant symplectic isometry gives a Heisenberg bridge unique up to scalar.
(9) One generator phase removes the scalar discrepancy for a cyclic stabilizer.
(10) Odd finite Weil phases and dyadic Arf signs are multiplicative across orthogonal break packets.
(11) Matrix holonomy on a fundamental cycle basis is the exact finite gluing obstruction.

This chapter does not independently prove the local Langlands correspondence, simple character theory, the canonical beta extension, or universal wild companion existence. It does not construct the Galois to type symplectic isometry for an arbitrary wild atom. It does not compare all pair local factors in the wild case.

19 Restricted arithmetic realization theorems

The constructions provide actual arithmetic candidates and exact finite packet recovery in substantial restricted families. They do not establish conjecture 66 for every admitted source. Their detailed ordinary proofs are typeset in the appendices, and the original reviewed Markdown files accompany the volume. In these appendices F denotes the base local field, while $K = F[\beta]$ denotes a parameter field. These are local notation conventions. All references to "claim 66" in the retained notes mean the general endpoint now isolated as Conjecture 66.

19.1 The odd-prime trace-zero construction

Theorem 19.1 (Restricted odd-prime arithmetic realization)**.** *Let p be an odd prime, $F = \mathbb{F}_p((t))$, fix $d \geq 1$, and let*

$$0 < h_1 < \cdots < h_d, \qquad p \nmid h_i, \qquad q_i = (p+1)h_i, \qquad N = p^d.$$

There is an explicit maximal simple stratum in $M_N(F)$ with totally ramified full-degree parameter field, a literal defining sequence of degrees $p, p^2, \ldots, p^d$, and levels $n_j = p^{d-j}q_{d-j+1}$. Every native parameter and consecutive correction has trace zero over its recursive base field. The stratum admits a full simple character trivial on U_F^1. Its fixed canonical beta extension can be completed to an actual irreducible admissible supercuspidal π with any prescribed smooth central quasicharacter trivial on U_F^1, when its completion choices are free or already compatible.

Assume actually supplied labeled full-character extensions with whole two-dimensional symplectic quotients whose balanced complex-scalar central product has d planes, one vertex, and trivial stabilizer. Then the same π admits a full scalar-pushout realization of that packet and exact recovery of its unchanged inducing representation.

The prescribed central character must lie in the covered tame class. No literal embedding of the old matrix groups, canonical native marking, or prescribed numerical host-depth placement is inferred.

Proof. The explicit Artin–Schreier recursion and its normalized filtered lift construct the maximal parameter and literal defining sequence. See appendix B. Its trace transport identity makes every native trace zero, rather than relying on amplification by p. Native-rank full-character construction, full beta-determinant transfer, trace-zero correction, and maximal-field character extension give the scalar triviality and central completion. See appendix C. The actual leading symplectic layer has dimension $(p-1)p^{d-1} \geq 2d$ and survives every later approximation (appendix D). A labeled symplectic embedding gives a center-fixing full scalar-pushout isomorphism. Finite Stone–von Neumann decomposition separates the source factor from its orthogonal complement. Maximal-isotropic averaging on the complementary Heisenberg factor selects a one-dimensional representation line and hence a source-sized sector. The retained induction/idempotent recovery returns the same Λ and π, as proved in appendix A. □

For $p > 3$, a native minimal rank-p type quotient has dimension $p-1$, so it is not automatically a plane. The theorem requires genuinely supplied whole-plane data. Independence of source tensor factors is also an input. An arbitrary single-factor wild determinant need not be tame.

Under additional actual-inertia hypotheses, genuine scalar phases on the entire source carrier are realized by actual central matrices of a finite cover and descend to the stipulated operators. A direct matrix homomorphism from the stabilizer itself need not exist. The exact statement and descent proof are in appendix E.

19.2 The weighted dyadic construction and enlarged carriers

Theorem 19.2 (Restricted dyadic marked assembly realization)**.** *Let $F = \mathbb{F}_2((t))$, fix an additive character of conductor $t\mathcal{O}_F$, fix $d \geq 1$, and let $h_1 < \cdots < h_d$ be positive odd integers. Put $q_i = 3h_i$, $N = 2^d$, and $n_j = 2^{d-j}q_{d-j+1}$. The explicit recursive matrix generates a separable totally ramified degree-N maximal parameter field, normalizes the complete lattice chain, and has the literal defining sequence of degrees $2, 4, \ldots, 2^d$. It admits a full simple character trivial on U_F^1 and an actual supercuspidal completion with any prescribed central quasicharacter trivial on U_F^1, when the noncompact completion is free or already compatible.*

For actually supplied full marked whole-plane scalar-pushout data with one vertex, trivial stabilizer, and prescribed source central character trivial on U_F^1, an arithmetic assembly carrier exists at every length and recovers the same candidate: inside its original type for $d \geq 3$, and in explicit enlarged inducing carriers for $d = 1, 2$. Every supplied full character value and transported whole finite subgroup, lift, square, and phase marking is retained at the represented marking level. Any central-character kernel already factored out remains recorded separately. Scalar pushout does not recover its invisible elements. This does not identify the transported marking with an independently prescribed canonical native marking.

Proof. The Artin–Schreier filtered lift has native trace one. Consequently each native correction δ satisfies

$$v_F(\operatorname{tr}\delta) + s \geq 1 \quad (s = 1),$$

which makes its additive scalar correction trivial on U_F^1. The actual field and defining-sequence proof is appendix H. Full beta-determinant transfer and character extension at each new maximal native field prove the full-character claim, including the odd-critical endpoint $2(\lfloor r/2 \rfloor + 1) - r = 1$. See appendix I. The exact original quotient has dimension $2^d - 2$, which accommodates the required $2d$ source dimensions precisely for $d \geq 3$ (appendix J).

At rank two, with $q = 2m+1$, enlarge $J = U_K^1 U_A^{m+1}$ to $P = U_K^1 U_A^m$. The actual character ratio $\lambda = \theta^g/\theta$ for $g \notin J$ is nontrivial and sign-valued. With $H_0 = \ker\lambda$, the quotient is $P/H_0 \simeq \mathbb{F}_2^2$, and

$\mathrm{Ind}_J^P \theta$ is an irreducible two-dimensional Heisenberg carrier (appendix L). At rank four, the actual outer quadratic centralizer gives $P = JU_B^m$, $[P : J] = 2$, and $P/H_0 \simeq \mathbb{F}_2^4$, with carrier $\mathrm{Ind}_J^P \eta$ of dimension four (appendix M). The finite scalar center can be larger than μ_2. No literal extraspecial quotient is claimed.

At both ranks $K^\times$ normalizes P. Thus $\mathcal{N} = K^\times J$ is normal of index two in $\mathcal{M} = K^\times P$, and

$$\Sigma = \mathrm{Ind}_{\mathcal{N}}^{\mathcal{M}} \Lambda, \qquad \pi \simeq \mathrm{cInd}_{\mathcal{M}}^{\mathrm{GL}_N(F)} \Sigma.$$

Induction in stages preserves the full original Λ, its central character, and its noncompact root. See appendices N and O. The full marked scalar-pushout comparison applies to these actual enlarged pairs as well as to the original higher-rank types (appendix K). The full synthesis and scope are in appendix G. □

The original low-rank maximal-type capacity obstruction remains true. The new pair is a common arithmetic assembly carrier. It is not renamed as the original maximal-simple-character pair. For an independently fixed native quadratic marking, a preassigned embedding must satisfy $q_W(f(v)) = q_{\mathrm{src}}(v)$. At equal capacity, a free embedding requires equal Arf invariant. Spare capacity for $d \geq 4$ admits either source Arf type when the embedding is free. Retaining only the central $\{\pm 1\}$ would erase the distinction between whole marked finite extensions such as D_8 and Q_8.

19.3 Scope, numerical invariants, and evidence

For the same candidates the constructions give

	p odd	$p = 2$
$\dim_{\mathbb{F}_p}(J^1/H^1)$	$p^d - 1$	$2^d - 2$
$\mathrm{Swan}(\pi)$	$p^{d-1}(p+1)h_d$	$3 \cdot 2^{d-1} h_d$

and torsion number one. Here Swan denotes the Swan conductor, and a below denotes the ordinary pair conductor. An epsilon exponent for a specified additive character is a different quantity. The separate progress paper, Sections 22–24, reconciles these conventions and the actual-order hypotheses. Their self-pair conductor formulas are

$$a(\pi^\vee \times \pi) = p^{2d} - 1 + \sum_{i=1}^{d} (p^{2i} - p^{2i-2}) h_i \quad (p \text{ odd}),$$

$$a(\pi^\vee \times \pi) = N^2 - 1 + \sum_{i=1}^{d} 3 \cdot 4^{i-1} h_i \qquad (p = 2).$$

These identities do not prove H5, identify an endo-class, or construct a canonical source-to-host marking. At rank eight, the retained skipped-degree host has the same displayed numerical profiles as the full tower and a smaller Heisenberg quotient. The explicit construction, rather than numerical matching alone, supplies the arithmetic object.

The proofs use the stated Bushnell–Kutzko simple-type theorems [11] and the retained conductor inputs. Exact source locations and hypothesis checks are recorded in the component proofs and accompanying audits. The finite rank-nine and rank-eight runs check particular matrices, traces, normalized lifts, and filtration grades. They are bounded checks, not arbitrary-length proofs. No new Lean build of these arithmetic constructions is claimed.

Nontrivial prescribed symplectic stabilizer actions, independently fixed canonical native markings, arbitrary source/transport diagrams, and any required numerical layer placement remain outside the restricted results. The current totally ramified host cannot implement nontrivial prime-to-p symplectic actions by the stronger character-preserving inner-normalizer mechanism. This obstruction is stated

precisely in appendix F. That stronger mechanism is not silently imposed on the original conjecture. H5 remains conditional for the same fixed candidate.

The accompanying archive retains the mathematical reviews, computational evidence, and source records underlying the displayed scope.

Detailed ordinary proofs and construction records

The appendices give the selected construction proofs with their local notation, hypotheses and scope. The synthesis appendices combine the results. Other notes develop narrower lemmas, alternative routes and failed implications. The classical application of arithmetic induction in the leading-capacity argument is not an input to the direct constructor. Negative capacity results concern the original maximal-type carrier. Low-rank enlargement of the assembly carrier does not contradict them. These are ordinary mathematical proofs and do not prove Conjecture 66. Source notes are listed at the back.

A Odd-prime synthesis and complete scope

Source record: `Paper_XI_Base_Realization165.zip`.

This is a synthesis of the independently reviewed proofs in this continuation. The result is an ordinary mathematical proof, using the stated classical simple-type theorems. It is not a Lean certificate. Universal claim 66 remains open. Original H5 remains the original conditional premise about the same fixed candidate. No unconditional pair-factor comparison is asserted here.

A.1 1. The arithmetic construction now proved

Let p be odd, $F = \mathbb{F}_p((t))$, and

$$0 < h_1 < \cdots < h_d, \qquad p \nmid h_i, \qquad q_i = (p+1)h_i, \qquad N = p^d.$$

For every such tuple there is an explicit matrix $\beta \in M_N(F)$ whose field $K = F[\beta]$ is totally ramified of degree N, normalizes the complete lattice chain, and gives a maximal simple stratum. It has a literal defining sequence of degrees $p, p^2, \ldots, p^d$, with leading level n_1 and successive critical levels $n_2, \ldots, n_d$ given by

$$n_j = p^{d-j} q_{d-j+1} \quad (1 \le j \le d).$$

Every native parameter in the construction, every amplified approximation, and every consecutive correction has matrix trace zero over its base field.

For this actual stratum there exists a full simple character θ with $\theta|_{U_F^1} = 1$. Retaining its canonical beta extension, the residue character and noncompact extension can be selected so that the resulting irreducible admissible supercuspidal π has any prescribed smooth central quasicharacter ω trivial on U_F^1. These completion choices must be free or already compatible. Incompatible immutably supplied choices are not replaced.

The same candidate has

$$\begin{aligned} \operatorname{rank}(\pi) &= N, & t(\pi) &= 1, \\ \operatorname{Sw}(\pi) &= p^{d-1}(p+1)h_d, & \dim_{\mathbb{F}_p}(J^1/H^1) &= N-1, \\ \dim \eta &= p^{(N-1)/2}, & & \\ a(\pi^\vee \times \pi) &= p^{2d} - 1 + \sum_{i=1}^{d} (p^{2i} - p^{2i-2}) h_i. & & \end{aligned}$$

These numerical identities do not identify a Weil representation, an endo-class, or the pair epsilon factors required by H5.

A.1.1 Construction and proof

At a recursive base (L, t_L), introduce

$$E = L(\alpha), \qquad \alpha^p - \alpha = t_L^{-q_d}.$$

This is a separable totally ramified extension of degree p, with $v_E(\alpha) = -q_d$ and $\operatorname{Tr}_{E/L} \alpha = 0$. Choose $1 \le b < p$ with $q_d b \equiv -1 \pmod p$, set $a = (q_d b + 1)/p$, and put $z = t_L^a \alpha^b$. Then z is an explicit uniformizer. Write its Eisenstein polynomial as $f(X) = X^p + \cdots + a_0$.

Let P_0 extract the constant coefficient in the basis $1, z, \ldots, z^{p-1}$. The normalized corestriction $s = \kappa \operatorname{pr}$, where $\kappa = -f'(z)/z^{p-1}$, satisfies

$$u_0 = s(P_0) = a_0/z^p \in \mathcal{O}_E^\times, \qquad \operatorname{Lift}_E(C) = u_0^{-1} C P_0, \qquad s(\operatorname{Lift}_E(C)) = C.$$

The lift preserves the exact filtration valuation. Its crucial additional identity is

$$\mathrm{tr}_L(\mathrm{Lift}_E(C)) = \mathrm{Tr}_{E/L}\big(\kappa^{-1}\,\mathrm{tr}_E(C)\big).$$

Define

$$B(L, t_L; h_1, \dots, h_d) = \alpha I_{p^{d-1}} + \mathrm{Lift}_E\big(B(E, z; h_1, \dots, h_{d-1})\big),$$

with the degree-p multiplication matrix as the base case. Induction proves trace zero at every native rank. This is stronger than the automatic zero trace obtained by multiplying any matrix multiplicity by p in characteristic p.

For the inductive field step $d \geq 2$, put $n = p^{d-1}q_d$ and $R = p^{d-2}q_{d-1}$. The derived matrix is the recursively constructed maximal-field parameter, with $k_0 = -q_1$. The inequalities $n > pR > 2R$ imply $-2R > -n - q_1$. Bushnell–Kutzko Remark 2.2.7 therefore applies to the actual displayed matrix. It supplies its maximal field, normalization, and critical exponent. Valuation preservation and literal truncation of the recursion supply the whole defining sequence. The full details, quotient count, and conductor dependencies are in `tower/TRACE_ZERO_AS_TOWER166.md` and `tower/RECURSIVE_TOWER166.md`.

The full-character argument uses a specific order of operations. First construct a full character at native rank p^j, trivial on U_F^1. Transfer its full beta-determinant unit character to multiplicity p, using BK 3.6.13(ii) and 3.6.14. On a scalar $u \in U_F^1$, this gives $\theta_j(u^p) = 1$. Next add the actual trace-zero correction, using BK 3.3.18. It remains trivial on the scalar intersection of its domain. Finally extend at the next **maximal native parameter field**: the forced deep character and the trivial character of U_F^1 agree on their intersection, so they extend through a finite abelian unit quotient. BK 3.2.5 constructs the full simple character.

This procedure never substitutes an unjustified extension through a nonmaximal centralizer. It proves full-character compatibility, including shallow units, rather than merely cancellation of a leading trace. The residue factor fixes ω on $\mathbb{F}_p^\times$, and an N-th-root choice for the noncompact generator fixes $\omega(t)$. Every choice is recorded before H5. See `central/TRACE_ZERO_CHARACTER_INDUCTION166.md` for the complete induction.

A.2 2. The finite packet that this same candidate realizes

Assume the one-vertex scalar-pushout contract: there are d labeled, actually supplied full character extensions with whole symplectic quotients V_i of dimension two over $\mathbb{F}_p$. Their balanced $\mathbb{C}^\times$-central product has quotient $V_{\mathrm{src}} = \bigoplus_i V_i$ and Heisenberg carrier dimension $p^d = N$. Initially take the declared stabilizer $C = \{1\}$.

For $p = 3$, this applies directly to the retained cubic family with whole rank-three break-type quotients. For $p > 3$, it applies only when the supplied plane data genuinely satisfy the stated original bridge contract. A native minimal rank-p type quotient has dimension $p - 1$, so it must not automatically be called a plane.

The actual candidate from Section 1 has a nondegenerate leading subspace

$$S \subset J^1/H^1, \qquad \dim_{\mathbb{F}_p} S = (p-1)p^{d-1} \geq 2d.$$

Here S is the image of the concrete congruence subgroup at half the leading even level. BK's high-depth equality preserves this subgroup and its commutator pairing through every later approximation. See `capacity/LEADING_LAYER_CAPACITY166.md`, Section 1. This part of that note applies to the direct constructor and does not require its separate classical application of arithmetic induction.

Choose a labeled symplectic embedding $V_{\mathrm{src}} \to S$. For each original full character form

$$\mathcal{P}_i = (\mathbb{C}^\times \times J_i^1)/\{(\theta_i(h)^{-1}, h) : h \in H_i^1\}.$$

The balanced product and the corresponding host restriction have the same alternating commutator. The center-fixing extension isomorphism, obtained with matched Darboux lifts and complex roots, therefore preserves every supplied value $\theta_i(h)$, including the shallow values.

Write $W = V_{\mathrm{src}} \perp V_{\mathrm{src}}^{\perp}$. Finite Stone–von Neumann gives $\eta_W \simeq \eta_{\mathrm{src}} \otimes \eta_{\perp}$. Choose an isotropic eigenspace giving a line in the complementary factor. Its actual projector in the Heisenberg image algebra e has rank N. The retained induction/idempotent theorem recovers the **same** inducing representation Λ from $e\Lambda$, and then the same π by compact induction. No candidate is changed at recovery.

This attachment preserves the full source characters as scalar-pushout data. It does not identify the old matrix groups with literal subgroups of the new type, retain the old lower summand conjugacy classes, or place each source label at its old numerical host depth. Those stronger requirements have not been proved.

When the retained independent extraspecial tensor source has $d \geq 2$, its full determinant is trivial on wild inertia: each factor determinant has order dividing p, and tensor determinants raise it to p^{d-1}. Thus its central character belongs to the class in Section 1. For $d = 1$, wild triviality of the source determinant must be checked separately. Independence of the tensor factors is an input, not a consequence of distinct h_i.

A.3 3. A proved extension to genuine scalar inertia phases

There is also a positive result beyond $C = \{1\}$. Suppose the finite prime-to-p stabilizer acts trivially on the source scalar extension, and its prescribed honest operators on the **entire** rank-N Weil carrier are $\chi(c)I_N$, each lying in the actual inertia image. Assume the candidate's central character is the determinant of that same source under the fixed rank-one reciprocity convention.

Then a finite cover $\widetilde{C} \twoheadrightarrow C$ acts by actual central matrices in the unchanged candidate. Its represented operators descend to exactly χ on C. Hence the attachment and recovery above are equivariant for that action. A direct matrix homomorphism from C itself is not asserted and can fail.

Indeed, for residue cardinality q, let $B = \omega(\mathrm{Teich}(k^{\times}))$. The actual inertia hypothesis gives $\chi(C)^N \subset B$. Since N is a power of p and $\chi(C)$ has order prime to p, this implies $\chi(C) \subset B$. Choose k_0 inverse to N modulo $q-1$, and set

$$\delta(u) = \omega(\mathrm{Teich}(u))^{k_0}, \qquad \widetilde{C} = \{(c,u) : \chi(c) = \delta(u)\}.$$

The matrix $\mathrm{Teich}(u^{k_0})I_N$ acts by $\chi(c)$. The kernel acts trivially on the entire sector induction and ambient compact induction, because these matrices are central. This preserves the fixed Λ, its canonical beta-extension factor, and all completion choices. It does not assert that the canonical beta extension alone has scalar character χ.

The full theorem and the nonsplitting example are in `stabilizer/SCALAR_NATIVE_ATTACHMENT166.md`, with an independent review in `audit/SCALAR_NATIVE_REVIEW166.md`. An arbitrary abstract phase or a phase on a proper multiplicity space does not satisfy its hypotheses merely because it is scalar.

A.4 4. What was repaired, and what remains

The old fixed-field central argument genuinely failed. At $p = 3$, $(h_1, h_2) = (1, 5)$, its naturally transferred full character takes the value $\zeta_3 \neq 1$ on $1 + t^2$, although the desired wild center is trivial. A shallow character choice cannot repair a forced value. The two-stage changing-field repair is retained in `central/CENTRAL_REPAIR166.md`. The trace-zero tower above resolves this central issue uniformly in every length.

The construction does not use an inverse established correspondence or the classical arithmetic-induction/descent candidate to select π. It does use the named BK construction and type theorems, the retained type/formal-degree conductor formulas, and exact sector recovery. The capacity note separately retains an alternative consequence for a candidate supplied by the substantial classical arithmetic constructor. That is a different route and is not an input to Section 1.

The unresolved universal obligations are precise:

1. **Nontrivial prescribed symplectic stabilizer actions.** For this totally ramified full-degree host, the stronger inner-normalizer interpretation forces prime-to-p actions on the quotient to be trivial. It therefore cannot implement a genuinely nontrivial supplied symplectic action. The raw original contract does not automatically require that stronger interpretation. It still needs an actual valid arithmetic comparison, not relabeling of external operators.
2. **Arbitrary admissible source packets and transport diagrams.** The proved attachment has the whole-plane, one-vertex, finite scalar-pushout hypotheses above. It does not establish all source classes, arbitrary graphs, or prescribed numerical layer placement.
3. **The dyadic construction with all markings.** A separate field-level recursion and some capacity statements exist at $p = 2$. The odd-prime trace-zero/full-character theorem here does not settle that case.

Original H5 stays exactly where it was: if supplied for this fixed candidate and the stipulated tests, the retained conditional endpoint applies. No claim that the displayed profiles imply H5, or that one of the noncompact root choices must satisfy H5, is made. The unresolved construction issues above are not renamed epsilon-factor obligations.

A.5 5. Evidence and reproducibility

The arbitrary-length theorem is proved symbolically and independently reviewed. The exact $p = 3, d = 2, (h_1, h_2) = (1, 2)$ computation in `tower/as_rank9check/` verifies the displayed matrix, trace identities, corestriction, and levels. It is a finite check, not the universal proof. The separate rank-27 run in `tower/run_rank27/` checks the earlier non-trace-zero recursion and must not be described as an AS central completion example. No Lean build was run.

`STATUS166.json` records the closed and open obligations. The component audits identify the exact reviewed files and hashes. The dependency file pins prior checkpoints and the authorized primary-source copy without redistributing that publication.

B The trace-zero Artin–Schreier tower

B.1 Exact statement

Let p be odd, F=F_p((t)), and 0<h_1<…<h_d with p not dividing any h_i. Put q_i=(p+1)h_i. The constructor below gives an actual matrix B_d over F of size p^d with exactly the field, simplicity, approximation-level, odd-prime quotient, and conductor conclusions of `RECURSIVE_TOWER166.md`. In addition, its matrix trace is exactly zero. Every native shorter constructor and every amplified arithmetic approximation also has matrix trace zero. Therefore every difference between consecutive arithmetic approximations has matrix trace zero.

The trace statement is an identity over the current coefficient field, not merely a congruence, a field trace inferred from characteristic zero, or a division by the matrix size. All coefficient fields have characteristic p, so division by p^j would be invalid.

B.2 1. An explicit separable minimal extension with a traceless parameter

At an arbitrary recursive step let L have residue field F_p and uniformizer t_L. Given q>0 prime to p, set

```
E=L(alpha),  alpha^p-alpha=t_L^(-q).
```

The right side is not an Artin–Schreier coboundary in L: the negative valuation of x^p-x, if x has negative valuation, is divisible by p. Thus the polynomial is irreducible of degree p. The extension is separable, and the valuation equation forces ramification index p and

```
v_E(alpha)=-q.
```

It is therefore totally ramified and alpha is minimal over L. For odd p its field trace is

```
Tr_(E/L)(alpha)=sum_(c in F_p)(alpha+c)=0.
```

Choose the unique b in {1,…,p-1} with qb congruent to -1 modulo p, put a=(qb+1)/p, and define

```
z=t_L^a alpha^b.
```

Then v_E(z)=pa-qb=1, so z is a uniformizer and E=L(z). Its monic minimal polynomial $f(X) = X^p + a_{p-1}X^{p-1} + \cdots + a_0$ is Eisenstein. It is an explicit polynomial: compute the product over the p conjugates

```
f(X)=product_(c in F_p) (X-t_L^a(alpha+c)^b)
```

and reduce coefficients using $\alpha^p - \alpha = t_L^{-q}$. The invariant coefficients belong to L. This is a finite algebraic instruction, with no choice of an unknown extension or matrix.

B.3 2. Normalized corestriction and an explicit filtered right inverse

Use the basis 1,z,…,z^(p-1) of E over L. If T_ij is its coefficient matrix unit and pr is the trace corestriction, then

```
pr(T_ij)=z^i z_j^*,
z_j^*=sum_(k=j+1)^p a_k z^(k-j-1) / f'(z),  a_p=1.
```

Set

```
kappa=-f'(z)/z^(p-1),  s=kappa pr.
```

The displayed dual-basis formula gives

```
s(T_ij)=-z^(i-j) + terms of strictly larger E-valuation.
```

Indeed v_E(a_k)>=p for 1<=k<p, so the contribution indexed by a_k has valuation at least k greater than the first contribution. Applying s entrywise on E^m gives a B-bimodule corestriction from End_L(E^m) to B=End_E(E^m). With the complete interleaved period-pm L-chain and period-m E-chain, it preserves grades and satisfies $s(P^r) = Q^r$.

Let P0 extract the constant coefficient on every E-coordinate. The constant dual coefficient satisfies

```
z_0^*=-a_0/(z f'(z)),
u_0=s(P0)=kappa z_0^*=a_0/z^p in O_E^times.
```

For any C in M_m(E), define the actual L-linear matrix

```
Lift_E(C)=u_0^(-1) C P0.
```

Then

```
s(Lift_E(C))=C.
```

This lift preserves the exact filtration valuation. To see this, first multiply C by the unit u_0^(-1), which does not change its valuation in the E-chain. Expand each entry in the basis 1,z,…,z^(p-1). The only nonzero columns of Lift are its constant-coefficient columns. The L-grade of a coefficient c_i z^i E_uv is

```
pm*v_L(c_i)+mi+u-v,
```

equal to its E-grade, and distinct i have valuations distinct modulo p. Thus the minimum cannot cancel. This also proves the stated surjectivity $s(P^r) = Q^r$ without a compactness assumption or an assumption that a lift exists.

B.4 3. Exact trace identity

For y in E, extraction of its constant coefficient is

```
coeff_0(y)=Tr_(E/L)(z_0^* y).
```

The ordinary L-matrix trace of the rank-one operator yP0 is coeff_0(y). Consequently, for every C in M_m(E),

```
tr_L(Lift_E(C))
   =Tr_(E/L)(z_0^* u_0^(-1) tr_E(C))
   =Tr_(E/L)(kappa^(-1) tr_E(C)).            (T)
```

Here tr_E(C) is the ordinary m-by-m matrix trace over E. In particular, if tr_E(C)=0, then the lift has ordinary L-matrix trace zero exactly.

B.5 4. The recursive actual matrix

Define B(L,t_L;h_1,…,h_d) by induction. For d=1 use the multiplication matrix of the alpha from Section 1 with q=q_1. For d>=2 use Section 1 with q=q_d, put m=p^(d-1), recursively construct

```
C=B(E,z;h_1,...,h_(d-1)),
```

and set

```
B(L,t_L;h_1,...,h_d)=alpha I_m+Lift_E(C).      (ASR)
```

Everything in (ASR) is explicit in finite field operations and the displayed degree-p polynomial extensions. It differs from the old conjugacy-preserving two-summand construction. Preserving old lower summand conjugacy classes is not claimed.

Inductively tr_E(C)=0. Equation (T) and the Artin–Schreier trace give

```
tr_L(B)=m Tr_(E/L)(alpha)+tr_L(Lift_E(C))=0.
```

For the induction base the trace is Tr_(E/L)(alpha)=0. Thus this argument proves tracelessness in the current base field for every native rank, not merely tracelessness after an amplification whose size is divisible by p.

B.6 5. Actual fields and profiles

Set gamma=alpha I_m and b=Lift_E(C). The minimal outer stratum has

```
n=p^(d-1)q_d,  k_0(gamma)=-n.
```

The inner actual maximal field supplied by induction has

```
R=p^(d-2)q_(d-1),  v(C)=-R,  k_0(C)=-q_1.
```

We have s(b)=C, v(b)=-R, and n>pR>2R because p is odd and the h_i increase. Hence

```
-2R > -n-q_1 = k_0(gamma)+k_0(C).
```

BK Remark 2.2.7 applies to this pure derived maximal field. It gives the field generated by the actual displayed gamma+b, with degree and ramification p^d, residue degree one, normalization of the complete chain, and k_0=-q_1. Its valuation remains -n. Thus [A,n,0,B] is simple.

This repeats the precise argument of `RECURSIVE_TOWER166.md` with a new outer minimal extension and normalized right inverse. No step of that argument required the old polynomial e^p+t e+t.

B.7 6. Native approximations, amplification, and traceless corrections

For the full rank p^d matrix put, for 1<=j<=d,

```
B^[j]=B(F,t;h_(d-j+1),...,h_d) tensor I_(p^(d-j)).
```

These are literal truncations of (ASR). At the outer level the same largest q_d selects the same Artin–Schreier extension and uniformizer in all truncations. At the next level the same q_(d-1) does the same, and so on. Thus no hidden change of bases or incompatible parameter fields enters the truncations. Lift_E commutes with amplification by an identity because P0 acts separately on each coordinate.

Every native shorter B has trace zero by Section 4. Its amplification therefore has trace zero. In particular

```
tr_F(B^[j])=0,
tr_F(B^[j+1]-B^[j])=0.                          (Z)
```

The same is true at native rank p^(j+1): the correction between B(F,t;h_(d-j),…,h_d) and the identity-p amplification of B(F,t;h_(d-j+1),…,h_d) has trace zero. This native assertion is the one relevant when constructing characters before each transfer.

The field degrees and critical levels of $B^{[j]}$ are exactly

```
degree p^j,  n_j=p^(d-j)q_(d-j+1).
```

Valuation preservation by every Lift gives

```
v_A(B^[j+1]-B^[j])=-n_(j+1).
```

Thus the approximation and defining-sequence proof of the first note applies unchanged. The odd-prime J/H dimensions, grade-index formula, Swan conductor and self-pair conductor depend on these same levels and centralizer degrees, so all their formulas carry over unchanged.

B.8 7. Precisely what the trace supplies

For any displayed correction delta and any scalar u in L^times for which its additive correction character is defined,

```
psi_delta(u I)=psi_L((u-1)tr_L(delta))=1.
```

This proves triviality of the actual additive correction on the scalar subgroup of its domain. It does not, by itself, construct a simple character with prescribed values on larger scalar groups. Compatible extension, transfer, and intersection arguments for the full simple character are separate obligations.

The note also does not identify the constructed candidates with any Weil source, choose them by inverse LLC, realize arbitrary stabilizer operators, or prove same-candidate H5. Its new output is an explicit arithmetic defining sequence whose trace vanishes at every native and amplified stage, suitable as input to that separate character argument.

B.9 Primary dependency

Bushnell–Kutzko, The admissible dual of GL(N) via compact open subgroups, Remark 2.2.7 (printed p. 55), with the defining-sequence and ring recursion already pinned in `RECURSIVE_TOWER166.md`. Retained source SHA256: `d69db0827256707a34cd2562af68b9de11fc889ab3f43535ec47b620d58ca9c8`. The trace-dual and Artin–Schreier calculations above are given in full.

C Native-rank full characters and tame central completion

Source record: Paper_XI_Base_Realization165. Arithmetic input: `attachment166/tower/TRACE_ZERO_AS_TOWER166.md`, together with its `RECURSIVE_TOWER166.md` defining-sequence proof. Input hashes are recorded in `TRACE_ZERO_CHARACTER_PINS166.json`.

Evidence: ordinary proof using the explicitly constructed arithmetic parameters and the named Bushnell–Kutzko character and transfer theorems. No arithmetic-induction/descent constructor or inverse correspondence is used. No Lean verification is claimed.

C.1 1. Statement

Let p be odd, F=F_p((t)), and

```
0<h_1<...<h_d,       p not dividing any h_i,
q_i=(p+1)h_i,        N=p^d.
```

Let beta_d be the actual trace-zero Artin–Schreier matrix constructor in the named tower note. There exists an actual full simple character theta for its maximal simple stratum such that

```
theta restricted to U_F^1 is the trivial character.            (1)
```

Every step constructing theta is specified below: a finite abelian character extension, the standard simple-character transfer, or the explicit additive correction from the displayed defining sequence. The field, order, and parameter are the actual tower ones, not an unspecified arithmetic realization.

The actual canonical beta extension can then be completed to a maximal extended type and supercuspidal pi with any prescribed smooth central quasicharacter omega_F trivial on U_F^1. Its rank, Swan conductor, torsion number and self-pair conductor remain those proved for the same tower. The residue and noncompact extension choices must be free or already compatible with omega_F.

For p=3, this gives full scalar-pushout attachment and same-candidate sector recovery for any number d of the supplied cubic source planes, with declared stabilizer C={1} and the one-vertex contract. All original full source character values are retained in the attachment. A general nontrivial stabilizer, transport diagram, or H5 conclusion is not part of this statement.

C.2 2. The exact arithmetic inputs

For 1<=j<=d, put

```
b_j=B(F,t;h_(d-j+1),...,h_d) in M_(p^j)(F),
```

where B is the trace-zero constructor. The tower proof gives:

1. K_j=F[b_j] is a totally ramified maximal field of degree p^j, normalizing the native complete period-p^j chain A_j.
2. For $1 \leq j < d$, in rank p^(j+1), gamma_j=b_j tensor I_p is a simple approximation to b_(j+1), at the critical level r_j=q_(d-j)>0 of b_(j+1). They are equivalent as strata at that level.
3. For $1 \leq j < d$, delta_j=b_(j+1)-gamma_j has grade -r_j and F-matrix trace zero.
4. At native rank p, b_1 is multiplication by alpha in the explicit Artin–Schreier field
   `E=F(alpha),       alpha^p-alpha=t^(-q_d).`
   Its actual field trace is zero, since p is odd.

For completeness, the tower's exact trace identity is

```
tr_L Lift_E(C)=Tr_(E/L)(kappa^(-1) tr_E(C)),
```

where s=kappa*pr is its normalized trace corestriction and Lift_E(C)=s(P0)^(-1) C P0. The recursive inner matrix has trace zero, so this proves zero trace at every native rank. It is not merely the automatic zero obtained by amplifying any matrix p times in characteristic p. The literal compatibility of the truncations is proved in Section 6 of the tower note.

C.3 3. A finite character extension fact

Let K/F be a finite totally ramified local extension. Suppose chi is a smooth character of U_K^a, and chi is trivial on U_K^a intersect U_F^1. Then chi extends to a smooth character of U_K^1 trivial on U_F^1.

Indeed, on U_K^a U_F^1 define chi_0(ku)=chi(k). Agreement on the intersection makes this a character. Choose M>=a such that chi is trivial on U_K^M. The character chi_0 descends to a subgroup of the finite abelian group U_K^1/U_K^M. It extends to that whole group by successively adjoining generators and selecting complex roots. Pulling it back proves the assertion. This also describes an actual finite procedure for making the extension choices.

This fact will be used only when the parameter field is maximal in the current native matrix rank. Direct use in a nonmaximal centralizer would require checking its determinant image and would not follow from the scalar intersection alone.

C.4 4. Base character at native rank p

Let E=K_1, and let n_1=q_d be the native level of alpha. Since n_1 is even, set a=n_1/2+1. On U_E^a the forced character of field units is

```
phi(v)=psi_F(Tr_(E/F)(alpha(v-1))).
```

It is trivial on U_E^a intersect U_F^1 because Tr_(E/F)(alpha)=0. Section 3 gives a full character chi_E of U_E^1 extending phi and trivial on U_F^1. No normalization of the additive character is needed for this implication: the trace is exactly zero.

For the native minimal stratum, $H^1 = U_E^1$ U_(A_1)^(a). Define theta_1 by chi_E on U_E^1 and by psi_alpha on U_(A_1)^a. They agree on the intersection, so BK 3.2.1 supplies the actual full simple character. It satisfies theta_1 | U_F^1=1.

C.5 5. Transfer the full field character before adding the next layer

Suppose theta_j has been constructed on the native rank-p^j stratum of b_j, with theta_j | U_F^1=1. Its restriction to U_(K_j)^1 is the full beta-determinant character chi_j, since its native centralizer is K_j itself.

Use the standard simple-character transfer to the multiplicity-p realization gamma_j=b_j tensor I_p in rank p^(j+1). Denote the transferred full character by Theta_j. The exact primary result is BK 3.6.13(ii), with existence in Theorem 3.6.14: transfer preserves the full beta-determinant character on U_(K_j)^1. Consequently its restriction to the centralizer order is chi_j composed with det_(K_j).

For every literal scalar u in U_F^1 this gives

```
Theta_j(u I)=chi_j(u^p)=theta_j(u^p)=1.            (2)
```

The determinant exponent p is essential. We do not replace (2) by an unsupported pullback along a scalar matrix embedding. This transfer also deals with nonminimal b_j: beta-determinant preservation is the general theorem, not just the minimal-character formula.

C.6 6. Add the actual correction and extend at maximal rank

Let r=r_j=q_(d-j), m=floor(r/2)=r/2, beta=b_(j+1), gamma=gamma_j, and delta=beta-gamma. The actual defining sequence gives

```
D=H^(m+1)(beta)=H^(m+1)(gamma).
```

By BK 3.3.18, the character

```
vartheta=Theta_j restricted to D times psi_delta
```

is an actual simple character at level m for beta. For every scalar u in D intersect U_F^1, equation (2) and the exact trace identity give

```
vartheta(u)=Theta_j(u)
               psi_F((u-1)tr_F(delta))=1.        (3)
```

The new parameter field K=K_(j+1) is maximal and totally ramified, and the native chain has K-period one. Thus

```
U_K^1 intersect D=U_K^(m+1),
U_F^1 intersect D=U_F^ceil((m+1)/p^(j+1)).
```

In particular (3) supplies the exact compatibility condition for extending vartheta | U_K^(m+1) while imposing triviality on all U_F^1. Apply Section 3 to obtain such a character chi_K of U_K^1.

BK 3.2.5, including its explicit extension formula, now constructs

```
theta_(j+1)(kd)=chi_K(k) vartheta(d),
k in U_K^1, d in D.
```

The proposition supplies normalization of vartheta by the field units, well-definedness, and the full simple-character condition. This theta_(j+1) has the claimed trivial wild center. Induction proves (1) at the actual final rank p^d.

The proof deliberately performs every arbitrary character extension at maximal native rank. Extending directly along amplified intermediate centralizers M_(p^(d-j))(K_j) would introduce determinant-image compatibility conditions. Merely knowing that their ambient matrix trace is zero would not discharge those conditions. Transfer first, followed by maximal-rank extension, removes that ambiguity rigorously.

C.7 7. Complete this same type with the prescribed tame center

Keep the actual canonical beta extension kappa of the resulting theta. The final K/F is totally ramified of degree N, with residue rank one. The compact type group satisfies

```
J/J^1 = k_K^times = F_p^times.
```

On U_F^1 the beta extension acts by theta, hence trivially. For a prescribed omega_F trivial on U_F^1, choose the residue character

```
sigma=omega_F|F_p^times divided by omega_kappa|F_p^times.
```

Its inflation gives lambda=kappa tensor sigma with the right center on O_F^times. Complete lambda to an actual extension Lambda_0 on the inducing group K^times J using the retained maximal-type completion theorem. If its center is omega_0, choose s in C^times with

```
s^N=omega_F(t)/omega_0(t).
```

Multiply Lambda_0 by the character of K^times J trivial on J and taking a K-uniformizer to s. The quotient (K^times J)/J is Z, and t has image N. This proves exact agreement of the resulting central character with omega_F on all F^times. Canonical kappa is unchanged.

The resulting pi=c-Ind Lambda is irreducible, admissible and supercuspidal. All these choices are made before H5. If a residue character or noncompact extension has been immutably supplied, it must already satisfy this compatibility. An incompatible datum is not silently replaced.

By the exact same parameter and defining-sequence calculations,

```
rank(pi)=N=p^d,
torsion(pi)=1,
Swan(pi)=p^(d-1)(p+1)h_d,
a(pi^vee x pi)=p^(2d)-1
                + sum_i (p^(2i)-p^(2i-2))h_i.
```

No determinant twist changes the depth. These are the proved arithmetic tower profile formulas, not a proof of H5.

C.8 8. Full packet attachment in arbitrary cubic length

For p=3, retain d original supplied full characters theta_i and their actual character groups H_i^1 normal in J_i^1, with whole symplectic quotients V_i that are the d labeled planes. Assume the declared stabilizer is C={1} and the diagram is one vertex. The source balanced scalar extension has quotient V_src of dimension 2d and Heisenberg carrier dimension 3^d, the original rank.

The actual final host has total quotient dimension N-1. Its leading nondegenerate symplectic layer has dimension

```
(p-1)p^(d-1)=2*3^(d-1) >= 2d.
```

This follows either from the explicit defining-sequence quotient calculation or the independently proved leading-layer lemma. Choose a labeled symplectic embedding of the supplied V_src in that layer. Write W=V_src perpendicular-sum V_perp. Choose a maximal isotropic subspace L in V_perp. Its associated eigenspace in the actual Heisenberg carrier has dimension 3^d, and L-perp/L is V_src.

Form the actual reduced scalar extension using the full host character and its extension to the inverse image of L. Form each original full pushout

```
P_i=(C^times x J_i^1)/
          {(theta_i(h)^(-1),h): h in H_i^1}.
```

The center-fixing symplectic-extension isomorphism, constructed by matched Darboux lifts and complex roots, maps their balanced product to that actual reduced scalar extension. In particular each original h in H_i^1 maps to the scalar theta_i(h). Every prescribed shallow and deep source character value is retained. Source character attachment does not claim that the original field units are the same literal scalar matrices in the new host.

Finite Stone–von Neumann supplies the full carrier intertwiner. The retained sector induction and recovery idempotent then recover this same Lambda and this same pi from the source-sized sector. The canonical beta extension, residue factor, central character, and noncompact scalar are those actually selected in Section 7. No source-independent alternate candidate is substituted in recovery.

For the retained independent tensor family with d>=2, each factor's wild determinant has order dividing p, because the abelianization of its extraspecial order-p^3 image is elementary abelian. The tensor determinant raises each factor determinant to p^(d-1), so the full source determinant is trivial on wild inertia. Thus the source's prescribed central quasicharacter lies in the class covered by Section 7. At d=1, matching this central conclusion requires the source determinant itself to be trivial on wild inertia. It is not inferred merely by taking a tensor power of length one.

For p>3, the same arithmetic host and character theorem hold, and the same attachment works for any actually supplied valid packet whose whole quotient and markings meet the stated symplectic

contract. A proposed source plane is not automatically a whole rank-p type quotient: that latter quotient has dimension p-1. No admission of all such plane sources into original H2 is inferred.

C.9 9. Boundary and primary-source check

This provides the previously missing full-character and actual wild-center construction for the explicit odd-prime arithmetic tower in every prime-power rank. The proof uses no classical automorphic-induction/descent candidate. It retains the supplied finite characters through the declared scalar-pushout attachments.

It does not preserve old summand matrix conjugacy classes, produce a prescribed nontrivial stabilizer action, preserve arbitrary numerical depth labels, handle arbitrary transport graphs, settle the dyadic case, or prove original same-candidate H5. It therefore does not close unrestricted claim 66.

The retained primary BK text, SHA256 `d69db0827256707a34cd2562af68b9de11fc889ab3f43535ec47b620d58ca9c8`, was directly checked at:

- Definition 3.2.1 and Proposition 3.2.5, printed pp. 98–100: minimal character condition and explicit full-character extension.
- Corollary 3.3.18, printed pp. 112–113: the actual additive correction takes the approximation character to the next simple character.
- Condition 3.6.13(ii) and Theorem 3.6.14, printed pp. 136–137: transfer preserves the full beta-determinant character, including at m0=0.

The actual field and defining-sequence assertions are the separately proved and independently reviewed trace-zero tower inputs, with BK 2.2.7 and the retained simple-stratum theorems. No newly downloaded source or new novelty claim is involved.

D The surviving leading symplectic layer

Status: ordinary proof from the retained Bushnell–Kutzko theorems and, for the source-defined candidate, the substantial published Bushnell–Henniart arithmetic induction/descent constructor. No Lean build or bounded computation is used. The accompanying audit files identify the scope of the internal review.

D.1 The useful simplification

Full critical-profile rigidity is unnecessary for the trivial-stabilizer finite attachment contract. An even leading level produces a symplectic subspace that survives every later simple approximation. For the independent rank-p Heisenberg tensor sources, this single subspace already has enough dimension to hold every source plane, however many there are.

The argument below concerns the actual type in the source-defined arithmetic candidate. It does not identify that type with a separately guessed binder parameter.

D.2 1. Leading-layer theorem

Let F have residue field k of cardinality q and residue characteristic p. Let pi be an actual irreducible supercuspidal representation of GL_n(F) with torsion number one, where n=p^r. Suppose

```
a(pi)=n+N,     N>0 even,     v_p(N)=r-1.
```

Then an actual maximal simple type in pi, with Heisenberg quotient $W = J^1/H^1$, contains a nondegenerate symplectic F_p-subspace S of dimension

```
[k:F_p] (p-1)p^(r-1).
```

For k=F_p this is exactly (p−1)p^(r−1). The subspace is the image of the concrete congruence group U^(N/2)(A) in J^1/H^1. It is present regardless of the later critical exponents, their parities, or the number of intermediate approximation fields.

D.2.1 1.1. Actual parameter field and leading level

By BK maximal-type existence, pi contains a maximal simple type. Its positive level follows from a(pi)>n. Write its stratum as [A,N_A,0,beta], with parameter field K=F[beta]. BK 6.2.5 gives

```
t(pi)=n/e(K/F).
```

Thus e(K/F)=n. Since [K:F] divides n, K/F is totally ramified of degree n and has residue degree one. The principal-order assertion after BK 6.2.5 gives e(A)=n. Accordingly A is the complete principal hereditary order. The established conductor formula

```
a(pi)=n+n N_A/e(A)
```

now implies N_A=N. This is the same source-checked formula used in Block165, originating in BH1999 Section 6.1 Lemma 2 and retained in `PRINCIPAL_ORDER_CONDUCTOR161.md`.

Put P=rad(A), $U^a(A) = 1 + P^a$ for a>=1, and m=N/2.

D.2.2 1.2. The terminal minimal approximation has degree p

Apply the defining-sequence construction BK 2.4.1–2 to beta. Write gamma for its terminal minimal approximation. Every transition has a critical level c<N, and gamma has the same A-level N as beta. All approximation residue degrees divide f(K/F)=1, and all approximation ramification degrees divide n. Therefore E=F[gamma] is totally ramified of degree d dividing n.

The scalar case is impossible: a scalar of F has A-valuation divisible by n, whereas v_p(N)=r−1. Thus gamma is noncentral and minimal in the ordinary field sense. Its field valuation is

```
−v_E(gamma)=Nd/n.
```

Minimality, by BK 1.4.14–15, requires gcd(Nd/n,d)=1. Since d is a p-power and v_p(N)=r−1, integrality first gives p|d, while coprimality forces d=p. Hence E/F is totally ramified of degree p.

Set B=End_E(F^n), B_order=A∩B, and Q=rad(B_order). The same complete lattice chain has period n/p over E. Each P-grade has k-dimension n and each Q-grade has k-dimension n/p. In particular,

```
dim_k P^m/(Q^m+P^(m+1))=n−n/p.
```

No assertion that E is literally a subfield of the final field K is needed. It is the actual minimal approximation field in the defining sequence.

D.2.3 1.3. The high subgroup survives every approximation

The minimal definitions BK 3.1.7–8 give

```
J_order(gamma)=B_order+P^m,
H_order(gamma)=B_order+P^(m+1).
```

At a nonminimal transition beta_i→beta_(i+1), with critical level c_i<N, the recursive J-order definition uses the threshold ceil(c_i/2). Since ceil(c_i/2)<=m, the inclusion P^m⊂J_order(beta_(i+1)) implies P^m⊂J_order(beta_i). Starting at gamma, induction proves

```
U^m(A)⊂J^1(beta).
```

For H, BK 3.1.9(ii) states that $H^a(\beta_i) = H^a(\beta_{i+1})$ as soon as

```
a>=floor(c_i/2)+1.
```

Every c_i is at most 2m−1, so this threshold is at most m. Consequently

```
H^m(beta)=H^m(gamma).
```

Here H^m means $H^1 \cap U^m(A)$. Therefore the image S of U^m(A) in W is canonically

```
S = U^m(A)/H^m(beta)
  = U^m(A)/H^m(gamma)
  ≅ P^m/(Q^m+P^(m+1)).
```

The last group identification uses m>=1, so multiplication is additive modulo P^(m+1). Thus |S|=q^(n−n/p).

D.2.4 1.4. Its actual commutator form is nondegenerate

Choose the actual simple character theta contained in the type of pi. By the standard deep-restriction property of simple characters, theta restricts to psi_beta on U^(m+1)(A). This follows directly from BK 3.2.1–4 by induction along the defining sequence.

For u,v in U^m(A), their group commutator is in $U^{2m}(A) = U^N(A)$, which lies in U^(m+1)(A). The terminal approximation satisfies

```
beta−gamma∈P^(1−N),
```

because every critical level in the sequence is less than N. Hence

```
(beta−gamma)([u,v]−1)∈P.
```

With the standard level-one additive character psi_A=psi_F∘tr_A/F, psi_A is trivial on P. We therefore have the exact equality

```
theta([u,v]) = psi_beta([u,v]) = psi_gamma([u,v]).
```

The right side is the Heisenberg commutator pairing for the minimal simple stratum of gamma. Its quotient $J^1(\gamma)/H^1(\gamma)$ is precisely $U^m(A)/H^m(\gamma)$, because $J^1(\gamma) = U^1(B_{\mathrm{order}})U^m(A)$, with $U^1(B_{\mathrm{order}}) \subset H^1(\gamma)$. BK's nondegeneracy theorem for simple-character commutators therefore says that the form on S is nondegenerate.

For general k, this is a nondegenerate alternating F_p-form of dimension $[k : \mathbb{F}_p](n - n/p)$. For $k = \mathbb{F}_p$, it has dimension $n - n/p$. This proves the theorem.

The argument uses no self-pair conductor and no determination of the later critical levels. Those invariants remain useful for finer arithmetic identification, but they are not needed for this finite-sector capacity claim.

D.3 2. Arbitrary-length odd-prime source family

Fix an odd prime p and F=F_p((t)). Let the complete marked Weil source rho be an independent tensor product of r rank-p wild Heisenberg factors at distinct positive levels

```
0<h_1<...<h_r,     p does not divide h_i.
```

Here independence means the stipulated balanced-central-product description of the wild image is valid, and rho|P_F is irreducible. We do not infer independence from the inequalities alone. Suppose the retained Tsushima source calculation supplies the usual highest slope

```
slope(rho)=(p+1)h_r/p.
```

Then rank(rho)=n=p^r and

```
Swan(rho)=N=(p+1)p^(r−1)h_r.
```

Let Pi_BH(rho) be the published source-defined arithmetic induction/descent candidate, with its full prescribed central character, as audited in Block165. The construction is applied to the complete actual rho, including its scalar normalization. Its codomain is the torsion-one supercuspidal class, and its standard epsilon-function property gives a(Pi_BH(rho))=n+N. These are uses of the substantial classical constructor, not consequences of finite Heisenberg algebra alone and not a selection of an inverse LLC image.

For odd p, N is even and v_p(N)=r−1. The leading-layer theorem therefore puts a symplectic space of dimension

```
D=(p−1)p^(r−1)
```

inside the actual Heisenberg quotient of a type in this same Pi_BH(rho).

The source packet is the orthogonal sum of r planes, so its symplectic dimension is 2r. The elementary inequality

```
(p−1)p^(r−1)>=2r
```

holds for every odd p and r>=1: it suffices that 3^(r−1)>=r, which follows by induction. Thus the actual candidate's leading symplectic layer alone can receive the entire source packet.

D.3.1 2.1. Full characters and recovery for declared C={1}

Work under the same finite scalar-pushout contract as `SAME_CANDIDATE_ATTACHMENT165.md`: declared stabilizer C={1}, one vertex, and full source character extensions retained, with no requirement of literal old matrix-group inclusion or equality of old numerical depths with host depths.

Let P_src be the balanced C×-central product of the r supplied full source character extensions. Its quotient V_src has dimension 2r over F_p and its central-character-one Heisenberg representation has dimension p^r=n. Choose a symplectic embedding V_src→S⊂W.

The C×-pushout of the actual type character, restricted to this subspace, has the same alternating commutator as P_src. The retained extension theorem supplies a center-fixing isomorphism from P_src to that restriction. Consequently every source h∈H_i^1 is carried to the scalar theta_i(h), preserving the full character value. No shallow source values are discarded.

Let V be the image and write W=V⊥V_perp. Stone–von Neumann gives

```
eta_W ≅ eta_src⊗eta_perp.
```

Choose a line in eta_perp and the corresponding rank-n projector e in the actual finite Heisenberg image algebra. Then e eta_W≅eta_src. Applying the retained Block159 induction/idempotent theorem to the unchanged actual extended type Lambda in Pi_BH(rho) recovers Lambda and then this exact Pi_BH(rho). All source normalization and the actual noncompact scalar remain fixed.

This proves same-candidate finite attachment for arbitrary r in this C={1} odd-prime family. Original H5, when supplied for this same candidate, remains exactly the original conditional comparison premise. We do not prove it here.

D.3.2 2.2. First new rank: GL_27

For p=3,r=3, the source has rank 27 and V_src has dimension 6. Put h=h_3 with 3∤h. The actual candidate has

```
N=36h,       m=18h,
dim_F3 S=27−9=18.
```

Thus its high layer contains the entire three-plane source packet. At least a 3^9-dimensional Heisenberg contribution is present, while the required source sector has dimension 27=3^3. The six surplus symplectic pairs can be projected onto a line in their representation, together with any additional lower layers. This proves the required capacity and sector realization for the new rank 27 family without solving its two possible lower critical levels.

In particular, for (h_1,h_2,h_3)=(1,2,4), N=144 and the same high subspace has dimension 18. These numbers are a specialization of the universal proof, not a numerical experiment.

D.4 3. Why trying to force every critical level was unnecessary

At rank 27, a hypothetical complete degree pattern 27→9→3 has leading level N=36h_3 and lower critical levels a<b<N. The standard full-profile conductor count would give

```
Swan(End rho)=18N+6b+2a.
```

Comparing with the stipulated source formula 8(h_1+9h_2+81h_3) only gives

```
a+3b=4h_1+36h_2.
```

That single linear relation does not determine both a and b, and by itself does not force each parity. Nor does it establish that all three degrees occur rather than skipping degree 9. This observation is only a warning about the insufficient equations. It is not presented as an arithmetic counterexample or as existence of every numerical profile satisfying the equation.

The leading-layer theorem bypasses these unresolved profile choices. It supplies a fixed nondegenerate high subspace in every actual candidate with the two required invariants.

D.5 4. Dyadic capacity boundary

The leading-layer theorem itself is valid at p=2. If an actual torsion-one candidate of rank 2^r has

```
N=3·2^(r−1)h,     h odd,     r>=2,
```

then its high subspace has dimension 2^(r−1) over F_2. This alone is at least 2r for r>=4, with equality at r=4. It does not supply enough capacity by itself for r=2 or 3. For r=1, N is odd and this theorem does not apply.

This is a capacity statement only. Applying it to a dyadic source requires the actual source family, its arithmetic candidate and whatever quadratic/phase markings the original contract requires. No universal dyadic attachment theorem is claimed from dimension alone.

D.6 5. Boundaries that remain

1. The full character attachment here is through center-fixing scalar-pushout maps. Literal embeddings of prescribed old arithmetic matrix groups are not proved.
2. No nontrivial prescribed stabilizer action is attached. Capacity does not imply equivariant placement.
3. All planes may be placed in the leading host layer. Preservation of supplied numerical ramification depths, or a specified map into individual host depth layers, would be an additional requirement and is not claimed.
4. General packet transport graphs are not handled here. The statement is for C={1} and one vertex.
5. The arithmetic induction/descent theorem is an explicit major external input. This is a new capacity/attachment consequence for its actual output, not a new elementary reconstruction of that classical constructor.
6. H5 remains conditional and refers to that unchanged actual candidate. No additional pair-factor premise is introduced.
7. No Lean verification is claimed.

D.7 6. Primary locators and retained dependencies

The authorized primary BK text was read at these exact results: 1.4.14–15 (minimality), 2.4.1–2 (defining sequence and degree divisibility), 3.1.7–9 (recursive orders and high-depth equality), 3.2.1–4 (deep restriction of simple characters), 3.4.1 (nondegenerate Heisenberg commutator), and 6.2.5 with the following paragraph (torsion number and principal period).

The standard conductor and published arithmetic-constructor properties are reused from the source-pinned Block165 audit and Block161 conductor proof. The finite scalar-pushout and sector-recovery arguments are exactly those retained and restated in `SAME_CANDIDATE_ATTACHMENT165.md`. No entire copyrighted source is copied into this continuation.

E Actual scalar inertia phases and finite-cover descent

Evidence: ordinary proof using rank-one reciprocity, the given central character, and elementary finite group arguments. The result constructs actual central matrix operators through a finite cover and proves their descent. It does not construct a new arithmetic candidate or alter a canonical beta extension.

E.1 1. Exact statement

Let F be a nonarchimedean local field with residue field k of cardinality q and residue characteristic p. Put Q=q-1 and n=p^r, allowing r=0. Let rho:W_F -> GL_n(C) be a smooth Weil representation with finite inertia image. Use the fixed reciprocity convention identifying its determinant with a character omega:F× -> C×.

Let C be a finite group of order prime to p, and suppose its prescribed operators on the **full source carrier** are

```
Omega_src(c)=chi(c)I_n,
```

where chi is a character and each Omega_src(c) belongs to the actual matrix image rho(I_F). A finite cyclic scalar tame image is the intended example. This hypothesis refers to actual source operators, not freely chosen phases on an unrelated multiplicity-space factor.

Let Pi be any already constructed irreducible smooth GL_n(F) representation with central character omega. Suppose it has its supplied actual inducing representation Lambda on N, with F× contained in N, and an attached finite sector E=eLambda realizing the prescribed source Heisenberg packet. Assume the prescribed C action on the source scalar extension is trivial, and that the honest scalar phase on the packet is the same chi above.

Theorem. There is a finite group C_tilde surjecting onto C and a genuine homomorphism

```
g:C_tilde -> F× I_n contained in N
```

whose action on Lambda and on Pi descends to the prescribed honest C action chi(c)I. Every finite sector is stable under this action. Any center-preserving Heisenberg attachment and its intertwiner are C-equivariant. The retained recovery maps from sector induction recover the same Lambda and Pi equivariantly. All actual inducing data, including the fixed canonical beta extension, remain unchanged.

The arithmetic action is supplied by actual central matrices, with an explicit finite-cover descent. The theorem does not assert that C itself embeds as a matrix subgroup. Such an embedding can fail even for a genuine scalar tame source, as Section 4 shows.

E.2 2. Construction and proof

Let D=k×, and let Teich:D -> O_F× be the canonical multiplicative lift. For p=2 this is still the prime-to-p root-of-unity subgroup. When q=2, D is trivial and the argument below forces chi trivial as well.

Local reciprocity identifies the determinant image of inertia with

```
det rho(I_F)=omega(O_F×).
```

The unit group decomposes as

```
O_F× = Teich(D) times U_F¹.
```

The smooth character image omega(U_F¹) is a finite p-group, while omega(Teich(D)) has order prime to p. Therefore the prime-to-p elements of omega(O_F×) are exactly omega(Teich(D)).

For every c in C, the hypothesis on the actual source implies

```
chi(c)^n=det(Omega_src(c)) in det rho(I_F).
```

This value has order prime to p, and hence lies in omega(Teich(D)). Since n is a p-power and chi(C) has order prime to p, the map z -> z^n permutes chi(C). Consequently

```
chi(C) is contained in omega(Teich(D)).                (1)
```

In particular every source phase has order dividing Q. This conclusion does not require selecting a splitting of the tame quotient or choosing Frobenius representatives.

Choose an integer k_0 with n k_0 congruent to 1 modulo Q. When Q=1 take k_0=1. Define

```
delta(u)=omega(Teich(u))^(k_0),       u in D.
```

Because exponentiation by k_0 is an automorphism on every group of roots of unity of order dividing Q, delta(D)=omega(Teich(D)). Define the finite fiber product

```
C_tilde={(c,u) in C times D : chi(c)=delta(u)}.          (2)
```

It is a subgroup, and projection pr:C_tilde -> C is surjective by (1). Define the actual central matrix homomorphism

```
g(c,u)=Teich(u^(k_0)) I_n.                              (3)
```

Its action on Lambda and Pi is the scalar from the central character

```
Lambda(g(c,u))=omega(Teich(u^(k_0)))I
              =delta(u)I=chi(c)I.                      (4)
```

If (1,u) belongs to ker pr, (4) is the identity. Hence the represented action factors uniquely through C. It is exactly the prescribed source action. Although selecting a particular matrix representative for c may require a choice of u, the represented operator is independent of that choice. Changing k_0 by a multiple of Q leaves (3) unchanged.

All matrices (3) are central. Their conjugation on actual groups, characters, and scalar pushouts is therefore the identity, and their Lambda operators are scalar. Thus they preserve every e and every sector E. The source extension action is also the identity by hypothesis, so any attachment of those scalar extensions is equivariant. Both honest carrier actions are chi(c)I, so every Heisenberg intertwiner intertwines C without a new phase choice.

For the recovery step, put P={a in N:Lambda(a)eLambda(a)^(-1)=e}. Then F× is contained in P. The retained maps

```
Phi:Ind_P^N E -> Lambda,
j:Lambda -> Ind_P^N E
```

are N-equivariant. They therefore commute with all actual matrices (3), and ker pr also acts trivially on Ind_P^N E: its matrices are central elements of P acting trivially on E, hence trivially on every induced translate. Thus the equality descends through pr to C. The recovering idempotent, and then compact induction to GL_n(F), preserve this equivariance. They recover the same fixed Lambda and Pi. QED.

E.3 3. What this closes and what it does not

For a source packet whose marked tensor carrier is the entire rank-n source, this proves the stabilizer step whenever its genuine tame operators are scalar and an actual host with the correct central character and full-character attachment is already present. There is no remaining scalar-phase equation to solve in that situation: the determinant and central character supply it.

If only the source symplectic C action is known to be trivial, the preceding `STABILIZER_CONTRACT166.md` proves triviality of its full scalar-extension action for prime-to-p C. Schur then gives a scalar packet character. To apply the present theorem one must still identify that character with the action of actual inertia on the full source. That identification holds when the supplied honest packet carrier is the whole source carrier. It is not automatic for a proper multiplicity-space factor, whose omitted factor can contribute to the determinant.

For several factors the total packet character is the product of the supplied factor characters. The theorem matches that product on the whole attached packet. It does not represent independent factor actions by distinct central matrices unless those additional marked actions are separately specified and verified.

The result uses the fixed full inducing representation Lambda. If Lambda | J=kappa_can tensor sigma, then kappa_can and sigma are both unchanged. Equation (4) concerns Lambda, and does not assert that kappa_can alone has the same scalar character. A contract prescribing an action specifically on the canonical beta extension requires that distinction to remain explicit.

No nontrivial source symplectic action is realized here. No new base candidate, new H5 comparison, dyadic quadratic refinement, or general rank theorem is claimed. Existing quadratic refinements are preserved because the actual central conjugation action is the identity.

E.4 4. Why a direct map C into residue units is too strong

Take q=5, n=5^r, and let omega on k×=F5× be the quadratic character. Let C=C2 and let chi be its nontrivial character. Such scalar tame behavior is obtained by twisting a tame-trivial rank-5^r source by the quadratic tame character, whenever such a source is supplied. The retained odd-prime two-factor family supplies rank 25 examples.

A group homomorphism a:C2 -> F5× must send its generator to 1 or -1. Both have quadratic character 1. Consequently

```
omega(a(c)) = chi(c)^n
```

is impossible at the nontrivial c, since n is odd. The proposed direct section is not forced by genuine scalar tame source data. Reciprocity supplies a quotient of residue units. That quotient need not split.

The construction above still works. Here k_0=1 modulo 4, C_tilde is the cyclic group of order 4, and its central matrices act by the quadratic character. The kernel of C_tilde -> C2 acts trivially on the fixed candidate, so the actual operator action descends correctly. This example explains why finite-cover descent is necessary rather than a cosmetic reformulation.

E.5 Dependencies and review status

External input: rank-one local class field theory with the fixed normalization for $\omega = \det \rho$, the supplied candidate's central-character identity, and sector recovery. The finite-cover construction and descent are proved above without local Langlands candidate selection. No Lean certificate is claimed.

F The precise stabilizer-action contract and normalizer obstruction

Evidence: direct audit of the original statement, a new elementary reduction, and an explicit actual-source/actual-type H1–H2 witness. No Lean closure, class-wide arithmetic realization, or H5 witness is claimed.

Primary audit verdict: incomplete, with the smallest missing implication being the identification of the declared finite action with the action intended on a newly constructed common arithmetic candidate. The original text does not define that identification by a common matrix normalizer.

F.1 1. Exact contract, and what is already an input

The controlling text is `closure_attempt162/inputs/original_reading.txt`:

- Proposition 9.8, starting line 4834: a finite group acting by automorphisms of the one-break Clifford datum acts symplectically on its intrinsic envelope.
- Definition 11.1, lines 4911–4923: a bridge supplies an equivariant isometry to an actual type quotient for a finite cyclic stabilizer C, with common central character and additional dyadic lift data.
- Proposition 11.3 and Theorem 11.5: once the two honest cyclic actions are chosen, their discrepancy is a character, killed by equality of phases at the generator.
- Theorem 15.4 and Theorem 16.2: breakwise comparisons and transports are supplied and tensored. They do not construct a common arithmetic host from separate actual type targets.

Thus H2 and H3 already settle the finite action comparison **on each supplied break target**. They do not leave a second free stabilizer action to invent on that same target. Their transport into a new common arithmetic type is another assertion. Neither a map C into its matrix normalizer nor arbitrary transported operators are identified with that assertion by the original text.

The cyclic group in Definition 11.1 is not explicitly required there to have order prime to p. The reduction below assumes that order condition. It applies to the declared tame prime-to-p case, and cannot silently be applied to an arbitrary finite-order Frobenius operator.

F.2 2. Full scalar-extension rigidity for a native tame action

Let an actual maximal simple type in GL_n(F) have a totally ramified parameter field K/F of degree n=p^r and residue matrix rank one. Let

$$W=J^1/H^1,\quad P=(C\times J^1)/\{(\theta(h)^{-1},h):h\in H^1\},$$

and let eta be its irreducible Heisenberg representation. Let C be finite of order prime to p. Suppose the C action on P fixes the scalar center and is genuinely induced by character-preserving matrix normalizers of this type. It is enough that it is an honest action whose action on W comes from those normalizers. Then:

1. C acts trivially on W.
2. C acts trivially on the full scalar extension P.
3. Every honest C action Omega on eta implementing this action is Omega(c)=chi(c)I for one character chi of C.

Proof. The retained normalizer theorem in Block162 gives

$$N=K\times J^1,\qquad N/(F\times J^1)=\mathbb{Z}/n\mathbb{Z}.$$

The action on W factors through this cyclic p-group, so a homomorphic image of the prime-to-p group C is trivial.

For any central extension P of the elementary abelian p-group W by C×, the kernel of

```
Aut_(C×)(P) -> Aut(W)
```

is naturally Hom(W,C×). Indeed, an automorphism phi fixing the quotient and the center has phi(x)=a(x_bar)x. The scalar a is independent of the lift x and multiplication shows that a is a character. Conversely every such character defines an automorphism. Since W has exponent p, this kernel is a finite elementary abelian p-group. The action of C lies in this kernel and therefore is trivial. Finally an implementing operator commutes with the irreducible P action, so is scalar by Schur. Honesty makes its scalar a character. QED.

This strengthens the earlier W-level obstruction: passing to the full scalar pushout cannot hide a nontrivial native prime-to-p action above an identity quotient action.

F.3 3. Exact attachment criterion in this native setting

Suppose a marked source scalar extension P_src has a symplectic embedding into W, and an actual finite sector of eta realizes that extension. Fix its center-preserving attachment and a Heisenberg intertwiner T. If the host has the native tame action of Section 2, the attachment intertwines the full honest C actions if and only if

```
the source action on P_src is trivial, and
chi_src = chi_host.
```

Necessity follows from equivariance and Section 2. For sufficiency, trivial extension actions make both honest carrier actions scalar by Schur, and equal characters commute through every Heisenberg intertwiner. Any sector is stable under the scalar host action.

If the source C action on its symplectic quotient is trivial, its action on the full scalar extension is already trivial by the Hom-kernel argument. For several break factors, the source character is the product of their characters. Thus the criterion is a single equality of scalar characters, rather than a further system of symplectic placement equations.

This applies to the original C={1} fixture immediately. For nontrivial C, H3 equates source and **supplied break-target** phases. It does not equate their product with a separately built common host's phase without a dictionary. We do not change a fixed canonical beta extension to enforce this equality.

F.4 4. H2 and matching carrier dimensions do not force trivial C

Here is an actual H1–H2 witness under the literal original allowance of separate type targets. It is not a claimed H5-admitted input, and does not assert equal ambient matrix ranks for source and break target.

Take F=Fp((t)), p odd. The retained primary source by Tsushima, Definition 3.1, Lemmas 2.6, 2.8, 3.9, 3.12, 3.14 and Corollary 3.15, with R(X)=X^p and m=1, constructs a genuine rank-p Weil representation irreducible on wild inertia. Its wild image is extraspecial of order p^3. The source envelope is a symplectic plane, and its actual tame image C=mu_(p+1) acts by multiplication on the roots of $X^{(p^2)}+X$. This action is nontrivial and has order p+1. The source's finite Heisenberg carrier has dimension p.

For the actual type target, take the unramified quadratic extension E/F and the maximal order A=End_OF(OE). Let beta=t^(-2)a, where a is a unit generating the residue extension. This is a minimal simple stratum of even level two. The standard minimal simple-character formulas give

```
J¹=U_A¹,  H¹=U_E¹ U_A²,
W_theta=End_Fp(Fp²)/Fp²,     dim_Fp W_theta=2,
dim eta_theta=p.
```

These are actual groups of a simple character, not an abstract replacement. The type residue units act by conjugation. Write sigma(x)=x^p and decompose

```
End_Fp(Fp²)=Fp² direct-sum Fp² sigma.
```

On the quotient represented by b sigma, conjugation by u in Fp²× is

```
b -> u^(1-p)b.
```

Its image is the norm-one torus, of order p+1. Consequently the actual projective residue action of Fp²×/Fp× on the two-dimensional quotient is nontrivial. It has the same symplectic C-module as the source: identify the cyclic groups using the displayed ratio map. The two invariant alternating forms differ by a nonzero Fp scalar, and multiplication by lambda in Fp²× rescales an alternating form by Norm(lambda). Surjectivity of the norm gives an equivariant symplectic isometry.

This supplies the actual source, actual type quotient, matching degree-p Heisenberg carriers, and nontrivial equivariant H2 action. For p=3, C has order 4 and the action is an irreducible rotation of the F3 plane.

The target here is in GL_2(F), while the source has rank p. This is permitted by the literal breakwise definitions, which contain no relation between the individual type targets' ambient ranks. Block161 already recorded that exact omission. If a stricter intended contract requires every break target in a specified GL_(p^r)(F), this example does not settle that stricter question. We have not supplied H5 for a common candidate or certified fixed canonical beta-extension phases for this example. It refutes only the proposed inference that actual H2 plus equality of finite carrier dimensions forces C trivial.

F.5 5. Result for the next construction attempt

There are three distinct cases:

Given contract	Exact remaining issue
Original C={1} fixture	No stabilizer issue remains.
Native prime-to-p C action in a degree-p^r totally ramified host	Source extension action must be trivial. Then compare one scalar character.
Nontrivial source symplectic C action under the original finite contract	A dictionary for the arithmetic action on a common host is needed. Requiring an inner normalizer makes this impossible for the preceding host. Transporting external operators alone was already done in Block 161.

Thus "solve arbitrary nontrivial stabilizer attachment by adjusting the current totally ramified binder" is not a viable native-inner target. That is a precise failure of that stronger construction route, not a refutation of 16.2.

F.6 Evidence and self-review

Dependencies: original Sections 9–11,15–16; Block162's source-backed normalizer theorem; Block165's base realization contract and same-candidate attachment; the retained published Tsushima text; the retained minimal-stratum group formulas. The new Hom-kernel lemma and attachment criterion are ordinary elementary proofs. The witness uses the displayed arithmetic constructor inputs, not a

numerical experiment. No independent review of this new note is claimed in this file, and no new Lean compilation was attempted.

Self-review explicitly checked: the prime-to-p qualification, honest action versus projective implementers, center-fixed scalar extension automorphisms, separate target rank versus original rank, and the absence of an H5 witness.

G Dyadic synthesis and assembly scope for all lengths

The odd-prime construction used here is pinned in `TARGET167.md`. Evidence: ordinary mathematical proof and independent component reviews. No Lean verification or universal claim 66 closure is asserted.

G.1 1. Combined arithmetic theorem

Let $F = \mathbb{F}_2((t))$, fix an additive character ψ_F of conductor $t\mathcal{O}_F$, and take increasing odd positive integers $h_1 < \cdots < h_d$. Put

$$q_i = 3h_i, \qquad N = 2^d, \qquad n_j = 2^{d-j} q_{d-j+1}.$$

There is an explicit $\beta \in M_N(F)$ generating a separable totally ramified degree-N field that normalizes the complete lattice chain. It gives a maximal simple stratum with leading level n_1, final critical exponent $-q_1$, and successive approximation-field degrees $2, 4, \ldots, 2^d$, with critical levels $n_2, \ldots, n_d$.

The actual stratum admits a full simple character θ trivial on U_F^1. Its canonical beta extension can be completed to an actual irreducible admissible supercuspidal π of $\mathrm{GL}_N(F)$ with any prescribed smooth central quasicharacter ω trivial on U_F^1, provided the noncompact completion is free or already compatible. Over this residue field, such ω is unramified.

For this same constructed candidate,

$$t(\pi) = 1, \qquad \mathrm{Sw}(\pi) = 3\,2^{d-1} h_d,$$
$$\dim_{\mathbb{F}_2} W = N - 2, \qquad \dim \eta = 2^{N/2-1}, \qquad W = J^1/H^1,$$
$$a(\pi^\vee \times \pi) = N^2 - 1 + \sum_{i=1}^{d} 3\,4^{i-1} h_i.$$

Matching these profiles does not identify the source, its endo-class, or the pair factors in original H5.

G.2 2. The explicit construction and its depth invariant

At a recursive coefficient field L of characteristic two, with residue field $\mathbb{F}_2$ and uniformizer t_L, put

$$E = L(\alpha), \qquad \alpha^2 - \alpha = t_L^{-q}, \qquad a = (q+1)/2, \qquad z = t_L^a \alpha.$$

The extension is separable and totally ramified of degree two, and z is a uniformizer and

$$z^2 + t_L^a z + t_L = 0, \qquad \mathrm{Tr}_{E/L}(\alpha) = 1.$$

For constant-coefficient projection P_0 in the basis $1, z$, the normalized trace corestriction and exact filtered right inverse are

$$\kappa = \alpha^{-1}, \qquad s = \kappa\,\mathrm{pr}, \qquad s(P_0) = t_L/z^2, \qquad \mathrm{Lift}_E(C) = (z^2/t_L) C P_0.$$

They satisfy $s(\mathrm{Lift}_E(C)) = C$, preserve the exact filtration valuation, and give the identity

$$\mathrm{tr}_L\,\mathrm{Lift}_E(C) = \mathrm{Tr}_{E/L}\big(\alpha\,\mathrm{tr}_E\,C\big).$$

The actual recursive matrix is

$$B(L, t_L; h_1, \ldots, h_d) = \alpha I_{2^{d-1}} + \mathrm{Lift}_E\big(B(E, z; h_1, \ldots, h_{d-1})\big),$$

with multiplication by α as the rank-two base case.

Every native constructor has trace one. At every next native rank, the preceding parameter amplified by two has trace zero, so the native correction also has trace one. At full ambient rank, the earlier amplified approximations instead have trace zero and the final one has trace one. These are different

statements. No amplified trace is used as a substitute for the native trace needed in character construction.

At an inductive field step $d \geq 2$, set $n = 2^{d-1}q_d$, $R = 2^{d-2}q_{d-1}$. Then $n > 2R$ and $-2R > -n - q_1$. BK Remark 2.2.7 gives the maximal field generated by the actual displayed matrix. Literal truncation and the filtered lift give the defining sequence. Nonzero native trace also proves separability: the irreducible characteristic polynomial has a nonzero coefficient of X^{N-1}, so its derivative is nonzero. See `tower/DYADIC_AS_TOWER167.md` for all field and filtration details.

The replacement for trace zero is the depth inequality

$$\boxed{v_F(\operatorname{tr}\delta) + s \geq 1.}$$

It makes the additive correction trivial on scalar U_F^s, because $(u-1)\operatorname{tr}\delta \in t\mathcal{O}_F$. Our native corrections have trace one, so the inequality holds at $s = 1$. This is the exact source-to-target transfer of the weighted-visibility principle. The Euler coefficient theorem is motivation, not an input to the arithmetic proof. In characteristic two, the weights are uniformizer depths, rather than integer powers of two in the coefficient field.

G.3 3. Full characters, including the odd critical endpoint

At the minimal rank-two base, extend the forced character on $U_E^{(q+1)/2}$ to U_E^1, imposing triviality on U_F^1. The prescriptions agree on their intersection because the parameter trace is one and $\psi_F(u-1) = 1$. This is an actual finite abelian character extension and gives the full minimal simple character.

For a later native step, first transfer the full beta-determinant unit character to multiplicity two. BK 3.6.13(ii) and 3.6.14 give, on scalar units,

$$\Theta_j(uI) = \theta_j(u^2) = 1.$$

For odd critical level r, use $m = \lfloor r/2 \rfloor$ and $D = H^{m+1}(\beta) = H^{m+1}(\gamma)$. The endpoint is valid because $2(m+1) - r = 1$: the cross term for the additive character lies in the radical on which the matrix additive character is trivial. BK 3.3.18 supplies $\vartheta = \Theta_j|_D\, \psi_{\beta-\gamma}$. Integral trace makes it trivial on $D \cap U_F^1$.

The next parameter field is maximal. Extend the forced character on its deep units together with the trivial character of U_F^1, then apply BK 3.2.5 to obtain the next full character. All new extensions occur at maximal native rank. No unverified determinant-image extension in a nonmaximal centralizer is used.

For the final totally ramified field, $J/J^1 = \mathbb{F}_2^\times = 1$, so $J = J^1$ and the canonical beta extension is η. Extend to $K^\times J$, and choose the noncompact scalar to match $\omega(t)$. The needed N-th root exists in $\mathbb{C}^\times$. The compact type stays fixed. All choices precede H5. See `central/DYADIC_FULL_CHARACTER167.md` for the complete proof.

G.4 4. Exact packet capacity and marked attachment

The dyadic floors cannot be replaced by the odd-prime dimension formula. At stage j, the centralizer grade has dimension 2^{d-j}. Its contribution to J^1/H^1 is

$$\left(2^{d-j+1} - 2^{d-j}\right)\mathbf{1}_{n_j \text{ even}}.$$

Every n_j for $j < d$ is even, whereas $n_d = q_1$ is odd and contributes zero. The sum is exactly $N-2$. BK nondegeneracy makes this a symplectic space. A whole source packet of d planes fits if and only if $N - 2 \geq 2d$, equivalently $d \geq 3$.

Ambient rank	Host quotient dimension	Host Heisenberg carrier	Required source carrier	Outcome
2	0	1	2	Insufficient
4	2	2	4	Insufficient
8	6	8	8	Exact capacity
16	14	128	16	Spare capacity

Now assume $d \geq 3$, the one-vertex contract, declared $C = \{1\}$, and actually supplied full character extensions with labeled whole-plane quotients. Retain their complete dyadic finite central-extension markings, including their specified central embeddings, lifts, square values, refinements and phases. Any central-character kernel already factored out must be recorded. A scalar pushout cannot recover invisible kernel elements.

Under the scalar-pushout realization contract, with no independently fixed conflicting host marking, choose a labeled symplectic embedding into W. Matching commutators gives a center-fixing isomorphism between the source $\mathbb{C}^\times$ extension and the corresponding host restriction. **Retain the image of the whole marked finite subgroup and every lift.** For this isomorphism F_0,

$$F_0(a)^2 = F_0(a^2).$$

Thus its square bits, refinement and Gauss sign survive, along with all supplied full character values. They are not inferred from the unmarked pushout. Stone–von Neumann gives the source factor inside η. A complementary line gives an actual rank-N image-algebra projector. The retained induction/recovery idempotent recovers the same Λ and the same π.

This gives an actual represented marked finite subgroup in the scalar extension of the actual type. It permits complex scalars times type operators, as the declared contract does. It does not assert literal inclusion of old matrix groups, numerical depth placement, or identification with a separately fixed canonical native finite subgroup.

If a genuine host-native quadratic refinement and its finite μ_2-central extension are independently supplied, quadratic embedding has a sharper condition. With otherwise free embeddings, at rank eight the equal-dimensional source and host must have equal Arf invariants. For $d \geq 4$, the host has at least one spare symplectic plane, so either source Arf type embeds. If the original embedding is preassigned, it must instead satisfy the pointwise equation $q_W(f(v)) = q_{\mathrm{src}}(v)$. These conclusions require the actual host marking as input. Dimension does not manufacture it.

The full finite proofs are in `markings/DYADIC_MARKINGS167.md`. In particular, the D8 and Q8 unmarked complex pushouts coincide while their whole marked finite μ_2-central extensions differ. Merely recording the central $\{\pm 1\}$ subgroup would lose that distinction.

G.5 5. Failed repairs and boundaries

The rank-two and rank-four carrier failures cannot be repaired by changing the maximal simple parameter while keeping the specified Swan exponent and torsion number. At rank two, odd Swan forces a minimal odd-level stratum and $J^1 = H^1$. At rank four, Swan $6h_2$ with h_2 odd forces the degree pattern $4 \to 2$. The maximal quadratic derived field forces an odd lower critical level. Every such maximal-type carrier has dimension two, below the required four. Scalar twists preserve this capacity.

This is an obstruction to the whole-source sector inside that maximal-type carrier. It is not a counterexample to the original theorem or a proof that a different arithmetic carrier in the same representation cannot work. Section 7 constructs such carriers and proves their exact recovery.

At rank eight, numerical profiles alone also fail to determine capacity. `capacity/DYADIC_CAPACITY167.md`, Section 6, constructs an actual skipped-degree $8 \to 2$ host with the same Swan, torsion and self-pair conductor but quotient dimension four rather than six. Our successful result uses the explicit full tower, rather than inferring its profile from invariants.

Thus the completed dyadic scope is:

- Actual fields, full characters and central completion in every rank 2^d.
- Full marked scalar-pushout packet realization for the stated family when $d \geq 3$, with $C = 1$, one vertex, and transported markings retained.
- A conditional quadratic embedding into an independently supplied native marked host, with the exact Arf or pointwise condition above.

Section 7 constructs different actual arithmetic carriers at the two low ranks and recovers the same candidate from them. The maximal-type capacity failure above remains true. Original H5 stays the original same-candidate conditional premise. These conductor identities and noncompact root choices do not prove it.

G.6 6. Evidence

The arbitrary-length field and full-character arguments are ordinary proofs. The exact rank-eight run for $h = (1, 3, 5)$ checks actual matrix identities, normalized lifts, leading and adjacent-correction grades $-60, -18, -3$, native traces one and ambient traces $0, 0, 1$. It outputs a matrix with 25 nonzero Laurent polynomial entries. The corresponding critical exponents are proved symbolically. The run does not prove simplicity, full-character existence, or universal marked realization. Those conclusions use the separate proofs and their stated scope. No Lean build was run.

The base synthesis before the low-rank continuation is preserved in `history/PROOF167_BEFORE_ENLARGEMENT.md`, together with its review. Its previously open enlarged-carrier route is executed next.

G.7 7. The low-rank repair: enlarge the actual inducing carrier

The maximal-type carrier is not the only arithmetic carrier available in the constructed representation. The following constructions keep the original β, θ, Λ and π fixed.

G.7.1 Rank two

Write the odd minimal level as $q = 2m + 1$, with $m \geq 1$, and let $J = H^1 = J^1 = U_K^1 U_A^{m+1}$. Define

$$P = U_K^1 U_A^m.$$

This is an actual compact open group, with $J \triangleleft P$, $[P : J] = 2$ and $P \cap (K^\times J) = J$. For $g \in P \setminus J$, the actual intertwining theorem makes $\lambda = \theta^g/\theta$ nontrivial. The commutator $[P, J] \subset U_A^{m+1}$ lies in the forced domain of the additive character, so λ has values $\{\pm 1\}$. Put $H_0 = \ker \lambda$. Then

$$P/H_0 \simeq \mathbb{F}_2^2, \qquad E = \mathrm{Ind}_J^P \theta \text{ is irreducible of dimension 2.}$$

The actual represented generators are a diagonal sign and an off-diagonal matrix that anticommute. Thus their commutator form is nondegenerate, and $\theta|_{H_0}$ is the full character of an actual new arithmetic Heisenberg pair. No abstract operators create that group action.

The identity compact-induction double coset realizes E inside the same π, as functions supported on $(K^\times J)P$. The complete group and recovery proof is `lowrank/RANK2_ENLARGED_CARRIER167.md`.

G.7.2 Rank four

Use the actual rank-four outer approximation field E_0/F of degree two and its centralizer $B = \mathrm{End}_{E_0}(F^4)$. The odd lower critical level is $r = 3h_1 = 2m+1$. The half leading level is $a = 3h_2 > r$. Define

$$P = J\,U_B^m,$$

where $J = J^1$ is the actual compact type group. The filtered centralizer estimate for the actual final field, without assuming $E_0 \subset K$, proves that P is a compact group with J normal of index two. For a concrete new coset representative u, $\lambda = \theta^u/\theta$ on the actual $H = H^1$ is nontrivial with values $\{\pm 1\}$. Put $H_0 = \ker\lambda \subset H$. The calculation proves

$$P/H_0 \simeq \mathbb{F}_2^4, \qquad E = \mathrm{Ind}_J^P \eta \text{ is irreducible of dimension 4.}$$

The new represented commutators are scalar, its quotient has exponent two, and nondegeneracy follows from its exact scalar preimage and irreducibility. The finite scalar center may be larger than μ_2. A literal extraspecial quotient is not asserted. The full character values are retained by the actual finite Heisenberg extension. Again E occurs inside the same π through the identity double coset. See `lowrank/RANK4_ENLARGED_CARRIER167.md`.

G.7.3 Exact recovery, with the noncompact normalization retained

At both low ranks, $K^\times$ normalizes the new P. In rank two this follows directly from normalization of A and its radical. In rank four, a K-uniformizer is approximated by the derived chain shift R times a unit of B, with relative error in P_A^{n-r}. Its conjugation error on U_B^m lies in $U_A^{n-r+m} \subset J$, which proves normalization. The exact argument is `lowrank/RANK4_INDUCTION_BY_STAGES167.md`.

Consequently $\mathcal{M} = K^\times P$ is an actual open group compact modulo the center, $\mathcal{N} = K^\times J$ is normal of index two in $\mathcal{M}$, and

$$\Sigma = \mathrm{Ind}_{\mathcal{N}}^{\mathcal{M}} \Lambda, \qquad \Sigma|_P \simeq E, \qquad \boxed{\pi \simeq \mathfrak{c}\mathrm{Ind}_{\mathcal{M}}^G \Sigma.}$$

Restriction to P is irreducible, so Σ is irreducible. Induction in stages proves the last equality for the original Λ, including its fixed central character and noncompact root. This is an actual enlarged inducing representation. It changes neither the candidate nor its original canonical beta-extension data.

There is also a recovery from compact data explicitly recording that root. With $A_0 = \Lambda(\varpi_K)$ and $X = \mathfrak{c}\mathrm{Ind}_J^G \eta$, define $(Tf)(g) = A_0^{-1} f(\varpi_K g)$. Then $X/(T-1)X \simeq \pi$. After imposing the fixed central character, $\mathcal{N}/(F^\times J)$ is cyclic of order N, and the finite average $N^{-1}\sum_{i=0}^{N-1} T^i$ selects this same extension. These operators act on complex representation spaces, so their scalar division by N is valid. This is a different recovery from the Block159 projector onto a sector of η. The exact kernel and finite projector are proved in `lowrank/ENLARGED_CARRIER_CONTRACT167.md`.

G.7.4 What the low-rank repair admits

Apply the marked scalar-pushout theorem of Section 4 to the **actual new** pair (H_0, P) and its carrier E. It has exactly the capacity of the whole source at each low rank. All full source character values and the transported whole finite subgroup, lifts, squares and phase markings can be attached and retained. The displayed Σ and induction in stages recover the same candidate.

The old H2 break targets remain their supplied actual simple-character quotients. The enlarged pair is their common arithmetic assembly carrier. It is not renamed as the original maximal-simple H^1, J^1 pair. If a stronger reading requires the whole packet itself to be the quotient of a maximal simple character in the same candidate, the earlier dimension obstruction still applies. Likewise, agreement

with an independently fixed native quadratic marking must be checked separately. The contract note proves this distinction explicitly.

G.8 8. Final scope and next construction question

The weighted dyadic mechanism now gives actual arithmetic fields, full characters and tame central completion in every rank 2^d of the stated increasing odd-break family. Under the one-vertex, $C = 1$, full marked scalar-pushout **assembly** contract, the packet carrier can be realized at every length: inside the original type for $d \geq 3$, and in the explicit enlarged inducing carrier at $d = 1, 2$. The source's prescribed central character must belong to the covered tame class. In particular no arbitrary single-factor wild determinant is assumed to be trivial.

Remaining universal obligations are construction/comparison of independently prescribed canonical native markings, nontrivial symplectic stabilizer actions, general source/transport diagrams and any required numerical layer placement. Original H5 remains conditional for this same fixed candidate. No equality of profiles or choice among noncompact roots is promoted to H5.

The next concrete target is equivariance of the arithmetic attachment for a nontrivial prescribed symplectic action. Another matrix search inside the old low-rank maximal-type carrier would repeat its already proved obstruction. `STATUS167.json` and `ROUTES167.md` record the achieved scopes and open routes.

H The explicit dyadic arithmetic tower

No character, quotient-dimension, source attachment, pair-factor, or universal Chapter XI closure is asserted here.

H.1 1. Statement

Let F=F_2((t)), let 0<h_1<…<h_d be odd positive integers, and set

```
q_i=3h_i,  N=2^d.
```

The explicit recursion below constructs B_d in M_N(F) such that

```
F[B_d] is a totally ramified maximal field normalizing
   the complete period-N lattice chain,
v_A(B_d)=-2^(d-1)q_d,
k_0(B_d,A)=-q_1,
tr_F(B_d)=1.
```

There are explicit native constructors of ranks 2^j for the largest j exponents. Their identity-amplifications give the actual defining sequence with field degrees 2,4,…,2^d and critical levels

```
n_j=2^(d-j)q_(d-j+1),  1<=j<=d.
```

Every parameter in this ambient defining sequence has the same leading level n_1. The quantities n_2,…,n_d are its successive critical approximation levels, not new leading levels of the ambient matrices.

Every native constructor has trace 1. Every correction from an identity-2 amplification of the preceding native constructor to the next native constructor also has trace 1. In full ambient rank 2^d, the earlier amplified approximations instead have trace 0, because their multiplicities are even. This distinction is essential.

H.2 2. The minimal degree-two building block

Let L be a complete discretely valued field of characteristic 2 with residue field F_2, and choose a uniformizer t_L. For odd q>0 put a=(q+1)/2 and define

```
E=L(alpha),  alpha^2-alpha=t_L^(-q),
z=t_L^a alpha.
```

The Artin–Schreier polynomial is irreducible: an element x^2-x of negative L-valuation has even negative valuation. Its derivative is 1, and the valuation equation forces ramification index 2. Thus E/L is separable and totally ramified, v_E(alpha)=-q, and alpha is minimal.

The element z has E-valuation 2a-q=1 and satisfies

```
f(z)=z^2+t_L^a z+t_L=0.
```

Thus 1,z is a uniformizer power basis, and

```
alpha=z/t_L^a,  Tr_(E/L)(alpha)=1.
```

H.3 3. An explicit normalized corestriction and lift

On E use the coefficient basis 1,z. Its trace-dual elements are

```
z_0^*=(z+t_L^a)/t_L^a,
z_1^*=1/t_L^a.
```

Let pr(T_ij)=z^i z_j^* be the trace corestriction. Put

```
kappa=t_L^a/z=alpha^(-1),
s=kappa pr,
u_0=s(P0)=t_L/z^2.
```

Here P0 is constant-coefficient projection, applied separately to each coordinate when acting on E^m. The identity for u_0 follows from f(z)=0. It is a unit: v_E(t_L)=v_E(z^2)=2. More explicitly,

```
s(T_i0)=z^i(1+t_L^a/z),
s(T_i1)=z^(i-1).
```

Since v_E(t_L^a/z)=2a-1=q>0, these preserve the expected leading grades. On End_L(E^m), take the complete interleaved chain in the basis w_(mi+b)=z^i v_b. Its centralizer is M_m(E) with its complete E-chain. The formulas give s(P^r) contained in Q^r for all integers r.

For C in M_m(E), define the explicit L-linear operator

```
Lift_E(C)=u_0^(-1) C P0=(z^2/t_L) C P0.
```

B-bimodularity gives s(Lift_E(C))=C. The lift preserves exact valuation: u_0^(-1) is an E-unit, and expansion in 1,z gives coefficient valuations distinct modulo 2. Each coefficient entry has the same grade in the interleaved L-chain and the E-chain. In particular $s(P^r) = Q^r$.

H.4 4. Exact trace transport

For every C in M_m(E), ordinary matrix traces satisfy

```
tr_L(Lift_E(C))
   =Tr_(E/L)(z_0^* u_0^(-1) tr_E(C))
   =Tr_(E/L)(kappa^(-1) tr_E(C))
   =Tr_(E/L)(alpha tr_E(C)).                (T2)
```

The first equality follows by taking the L-trace of each rank-one operator yP0, which is the constant coefficient of y. This coefficient is Tr_(E/L)(z_0^* y).

Thus the trace of a lift is 1 whenever the inner ordinary E-matrix trace is 1. It is not asserted that arbitrary trace values are unchanged.

H.5 5. Recursive actual matrices and fields

Define B(L,t_L;h_1,…,h_d) as follows. For d=1 use the multiplication matrix of alpha from Section 2 with q=q_1. For d>=2 apply Section 2 with q=q_d, set m=2^(d-1), recursively construct

```
C=B(E,z;h_1,...,h_(d-1)),
```

and put

```
B(L,t_L;h_1,...,h_d)=alpha I_m+(z^2/t_L) C P0.       (D2)
```

This is a finite algebraic recipe. It uses specified separable quadratic extensions and no unknown support, genericity choice, or correspondence inverse.

The degree and simplicity proof is by induction. The base alpha is minimal and generates E. At a later step let gamma=alpha I_m and b=Lift_E(C). The outer minimal stratum has

```
n=2^(d-1)q_d,  k_0(gamma,A)=-n.
```

The inner induction hypothesis gives an actual maximal field E[C] normalizing the complete E-chain with

```
R=2^(d-2)q_(d-1),  v(C)=-R,  k_0(C)=-q_1.
```

Because h_d>h_(d-1), we have n>2R. Therefore

```
-2R > -n-q_1 = k_0(gamma,A)+k_0(C).
```

The derived stratum with parameter s(b)=C is pure, and its field is maximal. Bushnell–Kutzko Remark 2.2.7 consequently gives the field generated by the actual gamma+b, not merely an equivalent replacement. It has ramification and degree 2^d, residue degree one, normalizes the complete chain, and has k_0=max(-n,-q_1)=-q_1. Since v(b)>v(gamma), its level is n and [A,n,0,gamma+b] is simple.

The derived model E[C] is not identified with L[gamma+b]. In particular no literal embedding of E into the latter field is claimed.

H.6 6. Trace 1 at every native stage

The base matrix has trace Tr_(E/L)(alpha)=1. Inductively tr_E(C)=1, so (T2) gives tr_L(Lift_E(C))=1. For d>=2 the L-trace of alpha I_m is

```
m Tr_(E/L)(alpha)=0,
```

because m is even. Hence tr_L(B)=1 at every native rank.

For any j>=1, let A_j denote the native rank-2^j constructor using a fixed list of the largest j exponents. The next native rank-2^(j+1) constructor A_(j+1) uses the same largest exponents and adds the next smaller one. With their compatible interleaved bases, put

```
Delta_(j+1)=A_(j+1)-A_j tensor I_2.
```

Then

```
tr(Delta_(j+1))=1-2*1=1                    in characteristic 2.
```

This native trace identity is stronger and more relevant than a claim obtained merely by amplifying to a rank divisible by two.

H.7 7. Full arithmetic defining sequence

For the final rank 2^d define

```
B^[j]=B(F,t;h_(d-j+1),...,h_d) tensor I_(2^(d-j)).
```

All truncations use the same top q_d to select the first extension and uniformizer, the same next q_(d-1) to select the next extension, and so on. The coefficient projection and lift commute with amplification. Thus these are literal truncations of (D2).

Their parameter fields have degree 2^j, and their critical levels in the ambient complete chain are n_j=2^(d-j)q_(d-j+1). Valuation-preserving lifts give

```
v_A(B^[j+1]-B^[j])=-n_(j+1).
```

Later differences have strictly greater valuation, since n_j>2n_(j+1). This proves that the displayed parameters form an actual defining sequence of simple approximations.

Their ambient traces are

```
tr_F(B^[j])=0 for j<d,  tr_F(B^[d])=1.
```

Consequently ambient corrections before the last step have trace 0, and the last correction has trace 1. Every one of these trace values is integral. On a scalar principal unit u, the additive correction character has value psi_F((u-1)tr(delta)). This is 1 for an additive character trivial on the maximal ideal. No assertion about full simple character extension follows here without its separate intersection and transfer argument.

H.8 8. Concrete rank-eight instance and limits

For h=(1,3,5), the construction gives actual approximation-field degrees 2,4,8 and critical levels 60,18,3. The supplementary exact program constructs its Laurent polynomial matrices, verifies the normalized lift identities, and checks the native/ambient trace distinctions and matrix grades. It does not prove field existence or simplicity by bounded computation: those are consequences of Section 5.

The odd-prime Heisenberg quotient and conductor counting from Block166 cannot simply be copied: q_1 is odd here. This note makes no dyadic quotient, full-character, stabilizer, phase, source-attachment, or H5 claim. It also changes lower parameter conjugacy classes, as in the corresponding odd-prime Artin–Schreier construction.

H.9 Dependencies and provenance

Primary theorem: Bushnell–Kutzko, The admissible dual of GL(N) via compact open subgroups, Remark 2.2.7 (printed p. 55), together with the amplification normalization and defining-sequence conventions already checked in Block166.

Retained primary source text SHA256: `d69db0827256707a34cd2562af68b9de11fc889ab3f43535ec47b620d58ca9c8`.

Block166 inputs are pinned separately in `INPUT_PINS167.json` and are not modified by this continuation. The Artin–Schreier, trace-dual, and trace calculations needed specifically for p=2 are proved above.

I Dyadic full characters and the odd critical endpoint

Source record: Paper_XI_Dyadic167. Dependency: Paper_XI_Attachment166.

Evidence: ordinary mathematical proof using the actual Artin–Schreier matrix tower and the retained Bushnell–Kutzko character and transfer theorems. No Lean verification is claimed. This note proves no dyadic quotient-capacity, quadratic-phase, packet-attachment, or H5 result.

I.1 1. Exact theorem

Let F=F_2((t)), let psi_F be an additive character of conductor t O_F (trivial there and nontrivial on O_F), and let

```
0<h_1<...<h_d,       each h_i odd,
q_i=3h_i,           N=2^d.
```

Use the dyadic Artin–Schreier recursion specified in Section 2. It gives the actual maximal simple parameter beta_d with its native arithmetic defining sequence. There is an actual full simple character theta of its maximal simple stratum such that

```
theta restricted to U_F^1 is trivial.                    (1)
```

The construction retains the actual canonical beta extension and can be completed with any prescribed central quasicharacter omega_F trivial on U_F^1. Because $k_F^\times = \mathbb{F}_2^\times$ is trivial, such an omega_F is unramified. Thus this covers every tamely ramified central quasicharacter for this particular residue field.

The corresponding compact induction is an actual irreducible admissible supercuspidal of rank N, by the retained maximal-simple-type theorem. No claim is made here about its Heisenberg quotient size or about realization of a supplied dyadic finite packet.

The trace-zero argument from Block 166 does not apply verbatim: at p=2 the primitive Artin–Schreier parameter has trace one. The correct invariant is **integral trace**, not necessarily zero trace. Since psi_F kills t O_F, integral correction trace is sufficient on scalar principal units. The recursion below preserves the stronger exact value one.

I.2 2. Actual dyadic recursion and exact native traces

At a recursive step let L be a characteristic-two local field with residue field F_2, uniformizer t_L, and a positive odd q. Define

```
E=L(alpha),       alpha^2-alpha=t_L^(-q).
```

The right side is not an Artin–Schreier coboundary: a negative valuation of x^2-x is even, whereas -q is odd. The degree-two polynomial is therefore irreducible and separable. Its valuation equation gives total ramification and v_E(alpha)=-q. Put

```
a=(q+1)/2,       z=t_L^a alpha.
```

Then z is an actual uniformizer and its Eisenstein polynomial is

```
f(Z)=Z^2+t_L^a Z+t_L.                                    (2)
```

Its two conjugate alpha values are alpha and alpha+1, so

```
Tr_(E/L)(alpha)=1.                                       (3)
```

Use the coefficient basis 1,z, the trace corestriction pr, and the same normalized corestriction convention as in Block 166:

```
kappa=-f'(z)/z = t_L^a/z = alpha^(-1),
s=kappa pr.
```

Minus and plus agree in characteristic two. If P0 extracts the constant coefficient on every E-coordinate, then

```
u_0=s(P0)=t_L/z^2 is a unit,
Lift_E(C)=u_0^(-1) C P0,
s(Lift_E(C))=C.
```

The trace-dual calculation in Block 166 gives, as an identity of L-matrix traces for every matrix C over E,

```
tr_L Lift_E(C)
   =Tr_(E/L)(kappa^(-1) tr_E(C))
   =Tr_(E/L)(alpha tr_E(C)).                                  (4)
```

The lift preserves the complete-chain filtration valuation, by expansion in 1,z. Thus it is the actual filtered right inverse used in the field constructor, not an arbitrary inverse on vector spaces.

Define B(L,t_L;h_1,…,h_s) recursively. At s=1 use the L-matrix of multiplication by alpha with q=q_1. At s>=2 use (2) with q=q_s, m=2^(s-1), and

```
C=B(E,z;h_1,...,h_(s-1)),
B(L,t_L;h_1,...,h_s)=alpha I_m+Lift_E(C).                     (5)
```

The base trace is one by (3). If tr_E(C)=1, then (4) gives lift trace one. Since m is even, the trace of alpha I_m as an L-matrix is m Tr_(E/L)(alpha)=0. Consequently

```
tr_L B(L,t_L;h_1,...,h_s)=1                                   (6)
```

for every native recursion, by induction. There is no division by the rank and no confusion between a native trace and its amplified trace.

The actual field proof from Block 166 applies with this degree-two extension and normalized lift. At a nontrivial step its hypotheses are n=2^(s-1)q_s, R=2^(s-2)q_(s-1), s(Lift(C))=C, and

```
n>2R,
-2R>-n-q_1.
```

The first strict inequality follows from h_s>h_(s-1). These are the conditions used in BK Remark 2.2.7. The displayed beta itself generates the totally ramified degree-2^s field normalizing the complete chain, and its final critical exponent is -q_1. This statement does not identify the final field with its auxiliary derived field.

For the final length d write the native shorter matrices as

```
b_j=B(F,t;h_(d-j+1),...,h_d),       1<=j<=d.
```

They are the compatible native truncations of (5), because the outer extension, uniformizer, and lift depend on the same retained largest h at each stage. For $1 \leq j < d$, in rank 2^(j+1), put

```
gamma_j=b_j tensor I_2,
delta_j=b_(j+1)-gamma_j.
```

The defining-sequence calculation of Block 166 gives gamma_j as a simple approximation at the critical level r_j=q_(d-j) of b_(j+1), and delta_j has grade -r_j. Equation (6) gives the exact scalar identity

```
tr_F(gamma_j)=0,
tr_F(delta_j)=1.                                              (7)
```

Thus for every scalar u in U_F^1 on which its additive correction is defined,

```
psi_(delta_j)(u I)=psi_F((u-1)tr_F(delta_j))
                  =psi_F(u-1)=1.                              (8)
```

It is (8), not a false trace-zero assertion, that drives the full character construction.

I.3 3. The odd-critical-level rounding

The critical levels r=q_i are odd. Write r=2s+1, and set

```
m=floor(r/2)=s,        m+1=(r+1)/2.
```

The relevant BK statements use the floor, with no assumption that r or the residue characteristic is odd or even:

- BK 3.1.9(ii) identifies H^k(beta) and H^k(gamma) for k>=floor(r/2)+1.
- BK 3.3.18 gives the correction bijection at floor(r/2)<=m<=r-1.
- BK 3.2.5 extends the resulting character at floor(r/2) to a full character, its fibers being the indicated determinant characters.

At our exact endpoint m=s, the correction character is legitimate. For x,y in the radical power P^(s+1),

```
delta*x*y belongs to P^(2(s+1)-r)=P^1.
```

The level-one additive matrix character is trivial on P^1, so the multiplicative cross term contributes one. Therefore psi_delta is a character on U^(s+1), and hence on the recursive subgroup used below. This checks the borderline odd-level rounding directly. Replacing m by r/2 as if it were an integer would be incorrect.

The same check applies at the native minimal base level q, which is odd: its forced additive character begins at floor(q/2)+1=(q+1)/2, and 2*(q+1)/2-q=1.

I.4 4. Finite character extension at maximal rank

We reuse the elementary extension procedure with its compatibility condition explicit. If K/F is a finite totally ramified field, and chi is a smooth character of U_K^a trivial on U_K^a intersect U_F^1, define a character on U_K^a U_F^1 by

```
chi_0(ku)=chi(k).
```

It is well defined by the intersection condition. Choose M>=a with chi|U_K^M=1. Then chi_0 is a character of a subgroup of the finite abelian group U_K^1/U_K^M. Extend it by adjoining generators and choosing the required complex roots, and pull it back. The resulting chi_K extends chi and is trivial on U_F^1.

All freely chosen character extensions below take place at maximal native rank, where the centralizer is K itself. We do not apply this scalar-intersection argument directly inside a nonmaximal matrix centralizer, which would require a separate determinant-image check.

I.5 5. Base full character with trace one

At native rank two, let E=F[alpha], with q=q_d and a=floor(q/2)+1. The forced character on U_E^a is

```
phi(v)=psi_F(Tr_(E/F)(alpha(v-1))).
```

For scalar u in U_E^a intersect U_F^1, equation (3) gives

```
phi(u)=psi_F((u-1)Tr_(E/F)(alpha))=psi_F(u-1)=1.
```

Section 4 constructs chi_E on U_E^1 extending phi and trivial on U_F^1. Define theta_1 on $H^1 = U_E^1$ U_(A_1)^a by chi_E on the first factor and psi_alpha on the second. The restrictions agree on the intersection. BK 3.2.1 gives the actual full simple character, with theta_1 | U_F^1=1.

This uses the true trace value one and only the stated conductor condition on psi_F. It does not require an artificial zero-trace primitive parameter in a quadratic extension.

I.6 6. Native-rank induction via full beta-determinant transfer

Assume theta_j is a full simple character for native b_j in rank 2^j, with theta_j | U_F^1=1. Let K_j=F[b_j]. Since K_j is maximal, the character chi_j=theta_j | U_(K_j)^1 is its full beta-determinant character.

Transfer theta_j to the multiplicity-two realization gamma_j=b_j tensor I_2 in rank 2^(j+1), using BK 3.6.14. Denote the full transferred character by Theta_j. BK 3.6.13(ii) preserves the entire beta-determinant character on U_(K_j)^1 at level m0=0. Hence for every literal scalar u in U_F^1,

```
Theta_j(u I)=chi_j(det_(K_j)(u I_2))
           =chi_j(u^2)=theta_j(u^2)=1.                    (9)
```

This statement includes nonminimal b_j. The determinant exponent two is essential and has not been suppressed.

Now set beta=b_(j+1), gamma=gamma_j, delta=delta_j, r=r_j, m=floor(r/2), and

```
D=H^(m+1)(beta)=H^(m+1)(gamma).
```

The equality and endpoint m were verified in Section 3. BK 3.3.18 constructs the actual recursive simple character

```
vartheta=(Theta_j restricted to D)*psi_delta.
```

For u in D intersect U_F^1, equations (8) and (9) prove

```
vartheta(u)=1.                                            (10)
```

The new field K=F[beta] is maximal and totally ramified in native rank 2^(j+1). Its chain has K-period one, so

```
D intersect U_K^1=U_K^(m+1),
D intersect U_F^1=U_F^ceil((m+1)/2^(j+1)).
```

Thus (10) is exactly the compatibility required by Section 4. Extend vartheta | U_K^(m+1) to chi_K on U_K^1 trivial on U_F^1. BK 3.2.5 constructs the full simple character by

```
theta_(j+1)(kd)=chi_K(k)*vartheta(d),
k in U_K^1, d in D.
```

That proposition supplies normalization and well-definedness. Its proof is an argument extending characters and imposes no exclusion of residue characteristic two. The new theta_(j+1) is trivial on U_F^1. Induction proves (1) in every native rank 2^d.

More generally the character argument needs only integral base field trace and integral traces for the native corrections. The dyadic tower establishes their exact value one, while the odd-prime tower of Block 166 establishes zero.

I.7 7. Canonical beta extension and prescribed tame center

Let K/F be the final totally ramified degree-N parameter field and let eta be the Heisenberg representation for the constructed theta. The compact type group is

```
J=O_K^times J^1.
```

Here $\mathcal{O}_K^\times = U_K^1$ because the residue field is F_2. Since U_K^1 is contained in J^1, we have

```
J=J^1,       J/J^1=F_2^times={1}.                    (11)
```

Thus the actual canonical beta extension on J equals eta. There is no residue-character choice and no change of that extension. It acts trivially on the central U_F^1 by (1). Equation (11) does not identify any externally prescribed dyadic quadratic phases.

Let omega_F be any smooth quasicharacter trivial on U_F^1. Since $\mathcal{O}_F^\times = U_F^1$, it is determined by its value omega_F(t). The actual maximal type extends to K^times J. Concretely, (K^times J)/J is infinite cyclic, generated by a K-uniformizer. An intertwiner for its conjugation action on eta gives an extension Lambda_0. Denote its central character by omega_0.

Choose a complex scalar s with

```
s^N=omega_F(t)/omega_0(t).
```

Multiply Lambda_0 by the character of K^times J trivial on J and taking the K-uniformizer to s. Because t has valuation N in K, this changes its scalar by s^N and gives the requested central quasicharacter on all F^times. The value at every element of J, including the canonical beta extension, is unchanged. This does not assume that a chosen K-uniformizer raised to N equals t.

The retained maximal-simple-type theorem now gives the actual irreducible admissible supercuspidal pi=c-Ind_(K^times J)^GL_N(F) Lambda. The noncompact scalar is fixed before any H5 comparison. An incompatible immutably prescribed extension is not overwritten. As in Block 166, its value must be free or already compatible.

I.8 8. What this closes and what it does not

This closes the full-character and actual tame-central-character construction for the explicit dyadic arithmetic tower. The failure of trace zero at p=2 is repaired by the correct integral trace invariant. Both the odd-level floor and the multiplicity-two determinant transfer are accounted for explicitly.

This note does not compute J^1/H^1 or prove that it contains a particular dyadic source packet. It does not establish a quadratic refinement, canonical phase matching, nontrivial stabilizer action, general transport graph, source admission, or H5. In particular, an actual supercuspidal host with the required central character is not asserted to be a completed realization of the original dyadic packet without those separate proofs.

I.9 9. Exact source checks and input pins

The following final Block 166 files were read and reused without editing:

- `attachment166/central/TRACE_ZERO_CHARACTER_INDUCTION166.md` SHA256 `99cb6e80c419e0bf7325e2b2b3fbaba1391903448a3b6a0c4cd9f3944ed406a1`.
- `attachment166/tower/TRACE_ZERO_AS_TOWER166.md` SHA256 `49a18fb733f0209b3e38118f5132839a060961edd0bdc0211e1f7b441a4e5653`.
- `attachment166/tower/RECURSIVE_TOWER166.md` SHA256 `6f39a077df18eb03f9fab2b6e426529dbe14cf4f7e1cfce95ddb0fcd187d7b33`.
- `attachment166/audit/TOWER_CENTRAL_REVIEW166.md` SHA256 `4bc71dd050ddb321a253105c8a4ee7a86185af255532d5605caa7a9de383e26b`.

Primary retained source: Bushnell–Kutzko, *The admissible dual of GL(N) via compact open subgroups*, text SHA256 `d69db0827256707a34cd2562af68b9de11fc889ab3f43535ec47b620d58ca9c8`. The current dyadic check reread Definitions 3.1.7–8 and Proposition 3.1.9(ii) (printed pp. 90–91), Definition 3.2.1 and Proposition 3.2.5 (printed pp. 98–100), and Corollary 3.3.18 (printed pp. 112–113). Their level

thresholds are floor(r/2)+1 or floor(r/2), as used above, and their statements do not exclude p=2. The transfer's preservation of the full beta-determinant character is BK 3.6.13(ii), with existence Theorem 3.6.14 (printed pp. 136–137), already directly checked in Block 166 and reread for this application.

The character-extension and correction proofs use neither division by two nor an odd-order averaging argument. The exact dyadic trace calculation and the borderline correction-character check are given in Sections 2–3. No new publication lookup, external arithmetic-induction/descent constructor, or inverse LLC is used.

J Exact dyadic capacity and numerical-profile obstruction

Status: ordinary proof from the supplied actual defining sequence and the retained primary Bushnell–Kutzko results. No Lean or numerical computation is used. This note calculates the quotient of an actual simple type. It does not prove universal H5 or identify an explicitly constructed host with the source-defined arithmetic candidate.

J.1 1. Exact hypotheses and result

Let F=F_2((t)). Fix d>=1 and increasing positive odd integers

```
h_1<...<h_d,        q_i=3h_i,        n=2^d.
```

Suppose the actual arithmetic constructor supplies a full-degree totally ramified parameter beta on the complete period-n chain, with actual approximating fields of degrees

```
2,4,...,2^d
```

and ambient critical levels

```
nu_j=2^(d-j) q_(d-j+1),        1<=j<=d.
```

These are the supplied dyadic specialization of the recursive tower's field/profile conclusions. The calculation applies equally to the original polynomial tower of Block166 and to an Artin–Schreier variant once that variant's field/profile conclusions are established. No trace-zero assertion is needed here.

The exact actual Heisenberg quotient is

```
dim_F2(J^1/H^1)=2^d-2,
dim eta=2^((2^d-2)/2).
```

Consequently its symplectic dimension is at least the 2d dimensions of the whole d-plane source packet exactly when d>=3. In rank 8, d=3, the quotient has dimension 6 and eta has dimension 8: the source carrier fits exactly, with no complementary Heisenberg factor needed.

d	Ambient rank	Actual quotient dimension	eta dimension	Source carrier dimension	Capacity
1	2	0	1	2	Fails
2	4	2	2	4	Fails
3	8	6	8	8	Exact
4	16	14	128	16	Sufficient
general	2^d	2^d−2	$2^{2^{d-1}-1}$	2^d	Sufficient iff d>=3

This improves the sufficient threshold obtained from the leading layer alone d>=4 to the exact threshold obtained from the whole profile d>=3. It also exposes a genuine low-rank limitation of this proposed whole-carrier realization.

J.2 2. Floors and ceilings in the actual BK orders

Write P=rad(A), and let B_j be the A-centralizer of the degree-2^j approximation. Its complete-chain grade has F_2-dimension

```
b_j=2^(d-j),        b_0=n.
```

Put

```
a_j=ceil(nu_j/2),       t_j=floor(nu_j/2)+1.
```

The exact BK definitions, 3.1.7–8, use a_j as the J cutoff and t_j as the H cutoff. Thus a_j=t_j for an odd critical level, while t_j=a_j+1 for an even critical level.

The increasing h_i give

```
nu_j>2 nu_(j+1),       1<=j<d.
```

This strict separation is useful: the centralizer approximation estimate from BK 3.1.5 puts each newly introduced centralizer into the preceding one modulo a term above the preceding half-level. In the notation of these stages, the relevant error level is nu_j−nu_(j+1)>nu_j/2. Therefore the successive grade dimensions are b_j. There is no unproved assumption that the approximation fields are literally nested inside the final field.

Applying the ring recursion gives the J-grade staircase:

- below a_d the grade dimension is b_d=1;
- on a_(j+1)<=k<a_j it is b_j;
- from a_1 upward it is b_0=n.

The H staircase uses the corresponding t_j. Hence the exact contribution of transition j to J^1/H^1 is

```
(b_(j−1)−b_j) · 1_(nu_j even).
```

One can also obtain this by subtracting the exact logarithmic indices of H and J in 1+P. It is an equality of the group index $|J^1/H^1|$, not a guess from the visible leading matrix support. BK 3.4.1 makes the resulting commutator pairing nondegenerate.

For j<d the level nu_j has a factor of 2 and is even. The final level nu_d=q_1 is odd. Therefore

```
dim_F2 J^1/H^1
  =sum_(j=1)^(d−1) (2^(d−j+1)−2^(d−j))
  =2^d−2.
```

The omitted final increment would have dimension 1. It cannot be treated as a symplectic plane or silently restored: at that odd level the two defining lattice cutoffs are exactly equal. Its disappearance is also consistent with the even dimension required of a nondegenerate alternating space.

The source packet requires dimension 2d. At d=1,2, 2^d−2<2d. At d=3 equality holds. If the inequality holds for d>=3, then

```
2^(d+1)−2−2(d+1) = (2^d−2−2d)+(2^d−2)>0,
```

so it continues to hold for every larger d. This proves the exact threshold.

J.3 3. Conductors still match despite the lost final contribution

This section reuses the same retained formal-degree and self-pair conductor identities already audited in Blocks 161 and 165. It is not needed to prove the dimension formula, but shows why numerical conductor checks do not expose the low-rank capacity failure.

Put Delta_j=b_(j−1)−b_j. The exact grade count gives

```
I=log_2[(1+P):J^1]
  =sum_j Delta_j ceil(nu_j/2)−(n−1).
```

For this profile only the final level is odd and Delta_d=1. Therefore

```
2I=sum_j Delta_j nu_j+1−2(n−1).
```

The Heisenberg dimension exponent is D/2, where D=n−2. The retained formal-degree identity for a full-degree, totally ramified, torsion-one maximal type gives

```
a(Pi^vee×Pi)=n^2−1+(n−1)+2I+D.
```

Substitution yields exact cancellation of the odd-cutoff correction:

```
a(Pi^vee×Pi)=n^2−1+sum_j Delta_j nu_j
          =2^(2d)−1+sum_(i=1)^d 3·4^(i−1) h_i.
```

The ordinary conductor is n+nu_1, so Swan(Pi)=2^(d−1)·3h_d, and the torsion number is one. These are the usual three numerical invariants of the stipulated independent dyadic Heisenberg tensor source.

Thus all three numerical invariants can match while eta is too small for the whole source carrier at ranks 2 and 4. This is a capacity failure, not a conductor mismatch. It does not by itself refute any original H1–H5 statement.

J.4 4. Rank 2 failure is forced by Swan and torsion alone

Let Pi be any actual supercuspidal representation of GL2(F) with torsion number one and odd Swan exponent N=3h_1. BK 6.2.5 forces its maximal parameter field K/F to be totally ramified of degree 2 and its hereditary order to have complete period 2. The ordinary conductor formula then fixes its native level as N.

Every parameter beta of a maximal simple type in Pi has v_K(beta)=−N, which is odd. Since the residue extension is trivial, BK 1.4.14–15 say beta is minimal over F. The two order definitions are therefore

```
J_order=O_K+P^ceil(N/2),
H_order=O_K+P^(floor(N/2)+1).
```

The exponents coincide because N is odd. Hence $J^1 = H^1$, eta is one-dimensional, and no two-dimensional symplectic source plane can embed into this quotient.

This proves failure for every maximal simple type of every candidate with these two invariants. It is stronger than failure of one explicit matrix formula. It remains a statement about attachment inside the actual maximal-simple-type Heisenberg carrier, not a proof that no other arithmetic realization relation could work.

J.5 5. Rank 4 failure is also forced by Swan and torsion

Let Pi be any actual supercuspidal representation of GL4(F) with torsion number one and Swan exponent N=6h_2, where h_2 is odd. Its maximal parameter field is totally ramified of degree 4, its order has period 4, and its native level is N.

Here v_2(N)=1. The defining-sequence/minimality argument of Block166 forces the terminal minimal approximation field E/F to have degree 2. There is no possible intermediate degree between 2 and 4. The scalar terminal case is excluded by 4 not dividing N, and a minimal full-degree 4 parameter is excluded because gcd(N,4)=2. Thus the actual degree pattern is forced to be 4→2.

Write c=−k_0(beta,A), so 1<=c<N. Select the critical approximation furnished by the construction in BK 2.4.1 and the remark preceding 2.4.7. Because the original field is maximal, this approximation can be selected with a simple maximal derived stratum in B=End_E(F^4)≅M2(E). Equivalently one can replace its derived stratum by an equivalent simple representative and use BK 2.2.2–3. The derived field has degree 2 and ramification index 2 over E. A simple stratum [B_order,c,c−1,alpha] is minimal. Since the complete B-chain has period 2 and the derived field is totally ramified, BK 1.4.14 forces

```
gcd(c,2)=1.
```

Therefore c is odd. It cannot be made even while preserving this degree pattern and a genuine maximal derived field.

Let j=(c+1)/2. The actual orders are

```
J_order=O_K+Q^j+P^(N/2),
H_order=O_K+Q^j+P^(N/2+1).
```

The final low transition contributes nothing, while the high transition has dimension 4−2=2. Thus every such Pi has

```
dim_F2 J^1/H^1=2,       dim eta=2.
```

The desired two-plane source carrier has dimension 4, so it cannot be a sector of this eta. Requiring the self-pair conductor additionally fixes c=3h_1 through

```
a(Pi^vee×Pi)=15+2N+c,
```

but is unnecessary for the capacity failure.

J.6 6. Rank 8: the three invariants do not force the good profile

The full 2→4→8 tower has quotient dimension 6 and enough capacity. Nevertheless Swan, torsion number and self-pair conductor alone do not force that degree pattern. Here is an actual skipped-degree arithmetic construction with the same three numerical invariants and a smaller quotient.

Fix increasing odd h_1<h_2<h_3 and put

```
q=3h_3,       N=4q=12h_3,       c=h_1+4h_2.
```

Then c is odd and 0<c<N. Indeed c<5h_3, so even 2c<N.

Construct the separable totally ramified quadratic extension

```
E=F(alpha),       alpha^2+alpha=t^(-q).
```

Put a=(q+1)/2 and z=t^a alpha. Then z is a uniformizer and

```
z^2+t^a z+t=0.
```

The element alpha has E-valuation −q and is minimal over F. On E^4, gamma=alpha I_4 is minimal of ambient level N in the complete period-eight order A.

Now construct the separable Eisenstein quartic extension over E

```
L=E(e),       e^4+z e+z=0,
```

and let C be multiplication by e^(−c) on L as a four-dimensional E-space. Since c is odd, e^(−c) is minimal, generates L/E, and defines a simple maximal derived stratum [B_order,c,c−1,C].

Let P0 extract the coefficient of 1 on each E-coordinate in the basis 1,z. The normalized outer corestriction from the Artin–Schreier right-inverse calculation has

```
s(P0)=t/z^2.
```

Consequently the explicit F-linear lift

```
b=(z^2/t) C P0
```

satisfies s(b)=C and has valuation −c. Define the actual rank-eight matrix

```
beta=alpha I_4+(z^2/t) C P0.
```

BK 2.2.3 applies because gamma is simple at level c<N and the derived stratum is simple maximal. It proves that F[beta]/F is totally ramified of degree 8, normalizes the complete chain, has leading level N, and has critical exponent −c. Its defining degree pattern is 8↠2, skipping degree 4.

Since N is even and c is odd, the actual Heisenberg quotient has dimension

```
(8−4)·1+(4−1)·0=4,
```

so eta has dimension 4. Yet its invariants are

```
Swan=N=12h_3,
torsion=1,
a(Pi^vee×Pi)=63+4N+3c
            =63+48h_3+12h_2+3h_1,
```

exactly the same as the full three-stage profile. Any maximal simple character and its standard type completion give an actual supercuspidal Pi with these values. The required full three-plane source carrier would have dimension 8, larger than this eta.

This is an arithmetic counterexample to the proposed implication from those three numerical invariants to adequate rank-eight Heisenberg capacity. It is not an H5 counterexample, does not identify the skipped host with the source-defined classical candidate, and does not claim that it preserves the supplied full source characters.

J.7 7. Which repairs have actually been tested

J.7.1 Replacing the displayed type or parameter at fixed Swan and torsion

At ranks 2 and 4 this fails by Sections 4–5 for every maximal simple type satisfying those invariants. A new matrix search or a different critical coefficient cannot manufacture the missing quotient dimensions.

At rank 8 the full tower supplies the good profile, but the three invariants alone do not force it inside a separately selected candidate. Section 6 proves the failure of that proposed inference with an explicit actual host. A finer endo-class or ramification comparison would be needed for that same-candidate assertion.

J.7.2 Skipping approximation degrees or changing critical parity

At rank 2 there is no degree to skip. At rank 4 the level excludes both a scalar minimal approximation and a full-degree minimal approximation. The remaining quadratic derived step has odd critical exponent by minimality. Thus neither skipping nor declaring that exponent even is a valid repair at fixed invariants.

At rank 8 a degree skip is genuinely possible, but it decreases capacity in the explicit example above.

J.7.3 Scalar twists, shallow or deep

A scalar twist of the existing actual inducing representation does not increase its dimension. The exact Block164 pushout transport identifies the same quotient J/H and leaves its commutator pairing unchanged. Thus it cannot turn an insufficient eta into a whole source carrier.

For an actual parameter, replacing beta by beta+aI with a∈F leaves its field, centralizer and commutator map unchanged. A shallow scalar addition does not change the leading level. A dominating scalar addition can change that level, but it contributes no new noncentral Heisenberg directions: in the defining sequence the added scalar stage has equal H and J orders. This agrees with

the exact representation-level twist transport. Enlarging a displayed numerical level is therefore not a capacity repair.

This paragraph does not assert that every arbitrary scalar character twist is represented by one globally specified additive parameter. The already proved group/representation transport suffices for its negative capacity conclusion.

J.7.4 Adding residue multiplicity or increasing ambient rank

The torsion-one condition forces a full-degree totally ramified parameter field and residue multiplicity one. A host with an unramified or residual multiplicity factor does not preserve that invariant. Increasing the ambient rank changes the required source rank. Neither maneuver closes the current fixed-rank construction.

J.7.5 Using a larger arithmetic carrier inside the same representation

A larger compact subgroup representation, a genuinely different arithmetic quotient, or an induction-stage carrier might have enough dimension. Such an enlargement is not ruled out here. It would need an actual finite Heisenberg action carrying the prescribed full source data and a proved recovery in the unchanged candidate. Artificially adding vector-space copies or transporting abstract operators to an induced space does not provide that arithmetic attachment or prove its kernel compatibility. No such repair is constructed in this note.

J.8 8. Quadratic refinements and marked centers

For d>=3, the dimension result gives a symplectic embedding of the source quotient into the actual host quotient. With C trivial, a C×-central pushout can then be matched by its alternating commutator, and Stone–von Neumann supplies the corresponding source sector. This is the same finite scalar-pushout attachment contract used previously.

At p=2, that statement must not be promoted to an identification of arbitrary preselected native quadratic refinements. The C× pushout permits rescaling lifts by i and can identify the pushouts of the dihedral and quaternion extraspecial planes, even though their native square functions differ. A chosen source embedding can preserve that source's full finite central extension and its character values. It does not thereby identify a separately marked target mu_2 extension or its Arf invariant.

In particular, symplectic-isotropic reduction respects a prescribed quadratic form only when the reduced subspace is totally singular for that form. The retained `DYADIC_AND_WEAK_ATTACHMENT159.md` gives the exact quadratic/Arf obstruction. Additional source or target marked centers, chosen lifts, quadratic refinements and nontrivial stabilizer actions therefore require their own comparison. They are neither erased from the task nor supplied by a dimension inequality.

J.9 9. Scope and source provenance

The strongest proved conclusion is exact capacity for the specified actual full defining profile, together with invariant low-rank failures and an explicit rank-eight counterexample to numerical profile forcing. No universal impossibility for original Theorem 16.2 is asserted. In particular this note supplies no complete original H1–H5 counterexample and does not decide whether that endpoint requires this precise whole-maximal-type-carrier realization.

K Whole finite extensions and dyadic marking criteria

Evidence: direct reading of the original dyadic contract and ordinary finite group proofs. This note does not prove a dyadic arithmetic field construction, its simple-character existence, nontrivial stabilizer attachment, H5, or a Lean closure. It identifies exactly what a supplied actual host and sector must preserve, and proves the marked finite attachment step for C={1}.

K.1 1. The original datum includes more than the alternating form

The original text `closure_attempt162/inputs/original_reading.txt` states in Definition 11.1, starting line 4911, that at p=2 a restricted bridge additionally supplies compatible quadratic refinements and an isomorphism of the resulting Heisenberg central extensions lifting the given symplectic isometry. Sections 13.1–13.9 define the refinements and their Arf/Gauss signs.

The retained visual appendix is particularly explicit, at lines 6892–6947: with center {I,-I} fixed, squares of lifts carry the quadratic bit. Multiplying a lift by i changes the particular finite central-extension realization. The appendix says that allowing complex scalar rescaling **without recording this distinction** erases data that the bridge is required to retain.

The finite record must therefore retain at least:

- the labeled symplectic quotient and its pairing;
- the supplied quadratic refinement q;
- the specified finite central extension, its central embedding/character, and any marked lifts or specified extension isomorphism;
- the resulting normalized Gauss sign, and all declared phase operators;
- the complete original character values retained by the scalar pushout.

The last item alone does not retain the preceding finite-subgroup/lift marking unless that marking is explicitly carried along. The raw text does not require literal embeddings of the old arithmetic matrix groups into a new type. Nor does it define a unique quadratic refinement extracted automatically from an unmarked C× scalar extension of every arithmetic type.

K.2 2. General criterion for finite central extensions

Let V be an elementary abelian 2-group with ordered basis v_1,…,v_m. Let E_s and E_t be central extensions of V by the same abelian group Z. Fix the identity on Z and a quotient isomorphism f. Choose lifts a_i of v_i in E_s and b_i of f(v_i) in E_t. Write

```
a_i²=s_i,  b_i²=t_i,  [a_i,a_j]=c_ij, [b_i,b_j]=d_ij.
```

Every element has a unique normal form

```
z a_1^(epsilon_1) ... a_m^(epsilon_m), epsilon_i in {0,1},
```

and analogously on the target. The multiplication is completely determined by the displayed squares and commutators.

Criterion. A center-fixing isomorphism lifting f exists precisely when

```
c_ij=d_ij for every i,j,
s_i/t_i belongs to Z² for every i.                    (1)
```

Indeed, every such isomorphism must take a_i to lambda_i b_i for some lambda_i in Z, forcing lambda_i²=s_i/t_i. Conversely these equations make the assignment a_i -> lambda_i b_i preserve all relations, and the normal forms prove it is bijective.

If the **particular lifts** a_i and b_i must correspond exactly, the condition is s_i=t_i, with lambda_i=1. If a full chosen section is marked, rather than only generating lifts, its multiplication coefficients must also correspond:

```
a(v)a(w)=c_s(v,w)a(v+w),
b(fv)b(fw)=c_t(fv,fw)b(f(v+w)),
```

and exact section preservation requires c_s(v,w)=c_t(fv,fw) for every pair. Transporting the complete section under an existing group isomorphism retains these identities automatically. Preserving just its squares need not retain an additional independently specified section.

K.2.1 2.1. Fixed two-element center

For $Z=\{+1,-1\}$, $Z^2=\{1\}$. The lift square is independent of the lift within its fiber and defines

```
a(v)²=(-1)^(q_s(v)).
```

The identity $(ab)^2=a^2b^2[b,a]$ gives the quadratic refinement law. Criterion (1) becomes the exact requirement

```
q_t(f(v))=q_s(v) for every v.                    (2)
```

For an unspecified symplectic isomorphism between equal-dimensional nondegenerate spaces, such an f exists exactly when their Arf invariants agree. For a preassigned f, equality of Arf invariants alone is insufficient: (2) must hold for that f.

K.2.2 2.2. Four-element and complex centers

For Z=mu_4, multiplication of a lift by i changes its square by -1. The unmarked extension criterion preserves square classes modulo Z^2=mu_2. In particular, squares +1 and -1 do not distinguish unmarked mu_4 extensions. A separately marked finite mu_2-central extension subgroup (such as the full D8 or Q8), or prescribed lifts, still distinguishes them.

For Z=C× every square ratio has a square root. Thus matching commutators is sufficient for an unmarked center-fixing extension isomorphism. This fact does not delete a marked finite subgroup from the objects being compared.

K.3 3. Exact D8/Q8 check

In dimension two over C put

```
X=[[0,1],[1,0]],       Z=[[1,0],[0,-1]].
```

Then $X^2=Z^2=I$, XZ=-ZX, and [X,Z]=-I. The group generated by X and Z has order 8 and is D8. Its refinement on $V=F2^2$ is

```
q_D(x,y)=xy,       Arf(q_D)=0,
```

with square table (+1,+1,+1,-1) at (0,e,f,e+f), and Gauss sum +2.

The generators iX,iZ also anticommute, but each squares to -I and their product also squares to -I. They generate Q8, with

```
q_Q(x,y)=xy+x+y,   Arf(q_Q)=1,
```

square table (+1,-1,-1,-1), and Gauss sum -2.

Both C× pushouts identify with the same ambient matrix group

```
P={z X^a Z^b : z in C×, a,b in {0,1}}.
```

Nevertheless the marked subgroups

```
H_D=<X,Z>,          H_Q=<iX,iZ>
```

are different. No isomorphism fixing the two-element center can map H_D onto H_Q: it would preserve q and hence the Arf invariant, which differs. There is also no center-fixing automorphism of P carrying the marked H_D onto H_Q. Their unmarked pushouts are isomorphic, but the marked objects (P,H_D) and (P,H_Q) are not.

Conversely a Q8 source embeds perfectly into the same P by sending its generators to iX and iZ. This preserves every source square and its negative Gauss sign. It does not identify those generators with the independently marked D8 lifts X,Z. This is the distinction needed for the arithmetic sector.

K.4 4. Marked scalar-pushout attachment with C={1}

Assume an actual type, its full character theta, and its Heisenberg quotient W have already been constructed. Let P_W be its actual C× scalar pushout, acting on its actual Heisenberg representation eta_W. Let V_src be a finite nondegenerate symplectic F2-space of dimension 2s, with its complete supplied dyadic marked extension data. For several breaks use their labeled orthogonal sum, balanced central product, and supplied product refinement.

Assume the following precise finite contract:

1. The source full-character pushout P_src has quotient V_src and the same represented scalar center as P_W.
2. The supplied finite central extensions and their marked lifts are retained as subgroups/elements of P_src, or as already specified maps into P_src. Any central character kernel already factored out must be recorded. A scalar pushout cannot recover invisible elements of that kernel.
3. The host has enough symplectic capacity, dim W>=2s, and the new attachment into this host has no independently fixed conflicting quadratic marking.
4. The declared stabilizer is C={1}, and the graph has one vertex.

Then a complete marked attachment exists in the **same actual candidate**.

Proof. Choose a symplectic embedding f:V_src -> W and let V be its image. The restriction P_V of P_W and P_src have the same commutator. Criterion (1) with center C× produces an isomorphism

```
F:P_src -> P_V
```

fixing every scalar and lifting f. Carry every supplied finite subgroup H_src to the actual subgroup F(H_src) of P_V, and every marked lift a to F(a). This operation does not erase square data:

```
F(a)²=F(a²),        [F(a),F(b)]=F([a,b]).              (3)
```

Since F fixes the scalar center, a²=(-1)^q(v) implies F(a)²=(-1)^q(v). The transported refinement is therefore exactly q, not a new choice with the same polar form. All marked section products, specified extension maps, and finite group relations are preserved by the same F. Consequently the Arf invariant and normalized Gauss sign are unchanged.

Every original h in a full character domain still maps to theta_i(h), because F fixes the entire scalar center. Thus the dyadic marking is retained together with the full original character values.

Write W=V perpendicular-sum U. Finite Stone–von Neumann gives

```
eta_W isomorphic to eta_src tensor eta_U.
```

Choose a line in eta_U and its projector e. It lies in the actual Heisenberg image algebra, and the marked source subgroup acts on e eta_W by precisely its supplied irreducible Heisenberg representation. Its lift squares remain the operators in (3). The existing sector recovery theorem then

recovers the unchanged inducing representation Lambda, and the same arithmetic candidate. There is no C-equivariance equation to solve because C={1}. QED.

This realizes an actual finite marked subgroup in the scalar extension of the actual type, with actual represented operators that are complex scalars times type operators. It does not assert that every marked source element is the image of an unscaled element of the old or new arithmetic matrix group. That stronger requirement of a literal embedding is absent from the present contract.

It also does not assert that the newly marked subgroup equals a separately specified canonical native subgroup of the host. The marked subgroup is part of the result and must be retained in the artifact. Omitting it and recording only the unmarked P_W would reproduce the loss displayed by D8/Q8.

K.5 5. If the host refinement is independently fixed

Suppose instead that the actual host arrives with a particular nonsingular quadratic refinement q_W and its actual finite mu_2 central extension H_W. An attachment into that marked extension requires a quadratic isometric embedding, not merely a symplectic embedding. There is a sharp capacity test.

Theorem. Let dim V_src=2s and dim W=2R. With embeddings otherwise free, a quadratic isometric embedding

```
(V_src,q_src) -> (W,q_W)
```

exists if and only if R>=s and, in the equal-capacity case R=s,

```
Arf(q_src)=Arf(q_W).                                    (4)
```

If R>s, either source Arf type embeds.

Proof. Necessity of dimension is immediate. An equal-dimensional embedding is an isometry, forcing (4). If R>s, choose a nondegenerate quadratic space U of dimension 2(R-s) with

```
Arf(q_U)=Arf(q_W)+Arf(q_src).
```

Both Arf types exist in every positive even dimension, by original Proposition 13.7. The orthogonal sum V_src perpendicular-sum U then has the same dimension and Arf invariant as W. Original Standard Fact 13.4 gives an isometry to W. Restriction to V_src gives the desired embedding. QED.

After this embedding is chosen, the preimage of its image in H_W has exactly q_src. The criterion for a fixed two-element center in Section 2 gives the extension isomorphism. Generating lifts with the specified squares can be matched. Additional fully prescribed section elements still require their exact product relations, as described in Section 2.

Thus **one spare symplectic plane absorbs the Arf mismatch**, without changing the host's own refinement. This conclusion remains conditional on the host's actual marked refinement/finite extension being supplied or constructed. It does not manufacture a canonical arithmetic quadratic datum from its dimension.

For a preassigned embedding f, the missing equation is instead

```
q_W(f(v))=q_src(v) for all v.                            (5)
```

Its discrepancy q_W composed with f minus q_src is a linear functional. Strict capacity allows a different quadratic embedding when it is free. It does not authorize replacing a fixed original map, fixed depth placement, or fixed transport marking.

K.6 6. Exact outcome for the dyadic construction

Under the retained one-vertex, C={1}, full scalar-pushout realization contract, an actual host with sufficient symplectic capacity does support every supplied finite dyadic marking, provided the

transported finite subgroup, lifts, refinement, and phase are explicitly kept. The proof is Section 4, rather than an assertion that commutators determine the dyadic sign.

If a particular host-native quadratic extension is fixed in advance, use Section 5. Strict capacity suffices for its quadratic embedding. Equal capacity requires the Arf equation, and a preassigned embedding requires (5). If only the type quotient is known and a specifically canonical host quadratic datum is requested, constructing and comparing that datum remains an arithmetic obligation. The scalar-pushout proof must not silently claim to have done it.

No part of this note handles nontrivial prescribed C actions. In that case quadratic embedding, full extension action, lift markings, and chosen honest phase operators must all be equivariant. Dimension and Arf equality alone do not settle those equations.

K.7 Evidence and author self-review

Read directly: original Definition 11.1, Sections 13 and 15, and visual appendix pages V–22/V–23 in the retained raw file; final Block166 `PROOF166.md`, Section 2, and `LEADING_LAYER_CAPACITY166.md`, Sections 2.1 and 4. The extension criterion and D8/Q8 calculation are complete finite proofs. The quadratic embedding theorem uses the Arf classification already explicitly supplied by the original paper. The sector conclusion reuses the retained exact recovery theorem and does not assert new arithmetic existence.

Self-review checked that complex lift rescaling is never treated as an automorphism changing squares within a fixed marked extension, that the marked subgroup remains in the output, that preassigned maps differ from freely chosen embeddings, and that fixed native refinements require their own actual input. No independent review of this note or new Lean execution is claimed here.

L The actual enlarged rank-two inducing carrier

Status: ordinary proof. The construction below supplies an actual arithmetic finite Heisenberg pair and exact recovery of an already fixed representation. It does not change the previously audited zero-dimensional BK quotient at rank two. No Lean verification or H5 comparison is claimed.

L.1 1. Exact setting and result

Let F=F_2((t)) and G=GL2(F). Let [A,q,0,beta] be a minimal simple stratum with K=F[beta] totally ramified of degree 2 and A its complete period-two hereditary order. Assume

```
q=2m+1>=3,        m>=1.
```

Write R=rad(A), $U_A^a = 1 + R^a$ for a>=1, and $U_K^q = 1 + \mathfrak{p}_K^q$. Let theta be a full simple character. Since q is odd and the residue field is F2, the actual maximal simple type group and character groups coincide:

```
J=J^1=H^1=U_K^1 U_A^(m+1).
```

Fix the full actual extension Lambda of theta to

```
N=K×J,
```

and the already fixed irreducible supercuspidal candidate

```
Pi=c-Ind_N^G Lambda.
```

Lambda is one-dimensional here. Its value on a uniformizer of K, including the noncompact scalar normalization, is part of the fixed data.

Define the larger compact open arithmetic subgroup

```
P=U_K^1 U_A^m.
```

Then the following statements hold.

1. J is normal of index 2 in P, and P∩N=J.
2. E=Ind_J^P theta is an actual irreducible two-dimensional P-representation.
3. There is an explicitly defined normal subgroup H_new⊂J of index 2 such that P/H_new≅F2² and theta_new=theta|H_new has nondegenerate commutator pairing on that quotient. E is its Heisenberg representation.
4. E embeds into the restriction of the same Pi, as the subspace of inducing functions supported on NP.
5. With X=c-Ind_J^G theta, a uniformizer varpi_K and s=Lambda(varpi_K), there is an exact quotient
   ```
   Pi ≅ X/(T−s)X,
   (Tf)(g)=f(varpi_K g).
   ```
   Induction in stages identifies X with c-Ind_P^G E. This gives an exact same-candidate recovery using the retained noncompact scalar, not merely a nonzero cyclic-generation assertion.

The new Heisenberg pair is an actual pair of compact subgroups of GL2(F), but is not asserted to be the BK H^1/J^1 pair of a maximal simple type. Whether the original H2 realization relation allows this enlargement is a separate obligation.

L.2 2. The compact enlargement is a group, with normal subgroup of index two

K× normalizes A and every power of its radical, so U_K^1 normalizes U_A^m. Therefore P is a subgroup and is compact open. It is contained in U_A^1 because m>=1 and $U_K^1 \subset U_A^1$.

The standard radical calculation gives

```
[U_A^a,U_A^b]⊂U_A^(a+b),        a,b>=1.
```

Indeed, for x∈R^a and y∈R^b, the difference (1+x)(1+y)−(1+y)(1+x) is in R^(a+b), and multiplication by unit inverses preserves that ideal.

Consequently

```
[U_A^m,U_K^1]⊂U_A^(m+1),
[U_A^m,U_A^(m+1)]⊂U_A^(2m+1)⊂U_A^(m+1).
```

These facts, and normalization by U_K^1, show that J is normal in P. They also show

```
[P,J]⊂U_A^(m+1).                                    (1)
```

To calculate the index, use

```
U_A^m∩J=U_K^m U_A^(m+1).
```

For if ku∈U_A^m with k∈U_K^1 and u∈U_A^(m+1), then $k \in K^\times \cap U_A^m = U_K^m$. The reverse inclusion is immediate. The complete period-two A-grade R^m / R^{m+1} has F2-dimension 2, and its field grade $\mathfrak{p}_K^m / \mathfrak{p}_K^{m+1}$ has dimension 1. Thus

```
[P:J]=[U_A^m:U_K^m U_A^(m+1)]=2.                    (2)
```

Finally, if kj∈P with k∈K× and j∈J, then $k \in Pj^{-1} \subset U_A^1$. Hence k∈U_K^1 and kj∈J. Therefore

```
P∩N=J.                                              (3)
```

These arguments use the actual group intersections. They do not replace P or J by a vector space surrogate.

L.3 3. Irreducibility and the conjugate-character ratio

For the minimal simple character, the primary BK intertwining theorem gives

```
I_G(theta)=J K×J=N.
```

Here K× normalizes J and theta. In particular, for g∈P\J, (3) says g does not intertwine theta. Because J is normal in P, this means that the two characters

```
theta,
theta^g(j)=theta(gjg^−1)
```

are distinct. The index-two induction E=Ind_J^P theta is therefore irreducible. This also follows directly from the two distinct J-weight lines, which are interchanged by g.

Define the actual character of J

```
lambda(j)=theta^g(j)/theta(j).
```

It is nontrivial. By (1),

```
lambda(j)=theta(gjg^−1j^−1),
```

and the argument of theta lies in U_A^(m+1). The full simple character has exact restriction

```
theta(1+x)=psi_F(tr_F(beta x)),       x∈R^(m+1).
```

Since F has characteristic 2, its additive characters take values in {1,−1}. Consequently

```
lambda(J)={1,−1}.                                    (4)
```

No assertion about shallow values of theta is used here. Theta may have a larger finite image on J. Only its ratio with its actual conjugate is proved to have order 2.

As g²∈J, conjugation by g² fixes the character theta. Thus $\lambda^g = \lambda^{-1} = \lambda$. It follows that

```
H_new=ker(lambda)
```

is normal in P. It has index 2 in J and index 4 in P.

L.4 4. The actual finite Heisenberg pair

Use the function model of E with f(jp)=theta(j)f(p) and right translation by P. Coordinates are f(1),f(g). Then for j∈J,

```
E(j)=diag(theta(j),theta^g(j))
    =theta(j) diag(1,lambda(j)),
```

while

```
E(g)=[[0,1],[theta(g²),0]].                          (5)
```

Therefore E(g)²=theta(g²)I. Choose j_0∈J with lambda(j_0)=−1, and put

```
Z=theta(j_0)^−1 E(j_0)=diag(1,−1),
X=E(g).
```

The exact matrix identity is

```
XZX^−1=−Z.                                           (6)
```

The projective image of J has order 2, generated by Z, while X is off-diagonal and contributes an independent projective involution. Thus the projective image of P is exactly C2×C2, with nontrivial commutator (6). Its projective kernel is precisely H_new. In particular

```
P/H_new≅F2².
```

On H_new, E is the scalar theta_new=theta|H_new. This character is P-invariant: conjugation by J fixes theta and conjugation by g changes theta by lambda, which is trivial on H_new. The resulting alternating form

```
(pH_new,p'H_new)↦theta_new([p,p'])
```

is nondegenerate, since its two displayed generators have commutator −1. Therefore (H_new,P,theta_new) is an actual arithmetic finite Heisenberg pair, and its actual irreducible carrier E has dimension 2.

All representations here have finite image on the compact group P: theta has open kernel, the induction has finite dimension, and an open normal core of that kernel acts trivially. Thus no issue with an infinite projective image is being suppressed.

This proof does not require rescaling the actual matrix g inside GL2(F). Its represented square theta(g²) can be an arbitrary retained scalar. Rescaling X is only allowed later in a C× pushout if that is the attachment contract.

L.5 5. Explicit embedding into the same fixed candidate

Realize Pi as functions F:G→C with

```
F(nx)=Lambda(n)F(x),
```

compact support modulo N, and right translation by G. For f∈E define i(f) by

```
i(f)(np)=Lambda(n)f(p),       n∈N, p∈P,
```

and zero off NP. This is well-defined because N∩P=J and Lambda|J=theta. The set NP is a finite union of N-cosets, by [P:J]=2, so the support is compact modulo N. The map i is P-equivariant and injective.

Its image is exactly the two-dimensional P-stable subspace of Pi consisting of inducing functions supported on NP. Thus the enlarged carrier is already inside the given Pi. No new candidate is chosen, and all noncompact values of Lambda remain fixed.

Since Pi is irreducible and i(E) is nonzero, its G-span is Pi. More precisely, there is the canonical G-equivariant quotient

```
Q_E:c-Ind_P^G E→Pi,
Q_E(F)=sum_(Px∈P\G) Pi(x^−1)i(F(x)).                (7)
```

The sum is finite and independent of representatives. If x is replaced by px, then F(px)=E(p)F(x) and P-equivariance of i cancels the additional Pi(p^−1). Formula (7) is nonzero and hence onto. The next section identifies its kernel exactly.

L.6 6. Exact recovery by the noncompact Hecke eigenvalue

Let X=c-Ind_J^G theta, in the same left-covariant/right-translation convention. Induction in stages gives an explicit isomorphism

```
c-Ind_P^G E → X,
F ↦ [x↦F(x)(1)].                                   (8)
```

The inverse sends f∈X to the E-valued function F(x)(p)=f(px). Both covariance statements follow directly from the definitions, and the finite index [P:J] ensures the support conditions agree.

Fix a uniformizer varpi=varpi_K. Because K× normalizes theta, the operator

```
(Tf)(x)=f(varpi x)                                 (9)
```

is a well-defined invertible G-equivariant operator on X. Put s=Lambda(varpi), which is nonzero. Since k_K=F2 and J contains U_K^1,

```
N/J≅K×/U_K^1≅Z,
```

with generator varpi. Define

```
Q:X→Pi,
(Qf)(x)=sum_(ell∈Z) s^(−ell) f(varpi^ell x).       (10)
```

For each x the sum is finite, since f has compact support modulo the open subgroup J. Equation (10) satisfies

```
(Qf)(varpi x)=s(Qf)(x),
(Qf)(jx)=theta(j)(Qf)(x),      j∈J,
```

and therefore the required N-covariance. Its support is compact modulo N. It commutes with G-right translation and satisfies

```
QT=sQ.                                             (11)
```

It is onto: a function in Pi has finite support modulo N, and on each occupied N-coset its value can be lifted to a function supported on one J-coset. Extend those finitely many choices using theta.

To compute the kernel, decompose X as the algebraic direct sum of its subspaces supported on the left N-cosets in G. Each such summand is the space of finitely supported sequences on N/J≅Z, with the fixed theta covariance. The operator T is a bilateral shift. On that summand, (10) is evaluation of

its Laurent polynomial at the nonzero scalar s, up to the harmless convention of replacing the Laurent variable by its inverse. The kernel is therefore the principal ideal generated by T−s. The elementary identity

```
ker(C[z,z^−1]→C, z↦s)=(z−s)
```

proves, summand by summand, that

```
ker Q=(T−s)X.
```

All vectors occupy finitely many such summands, so no completion or closure is needed. Thus

```
Pi ≅ X/(T−s)X ≅ (c-Ind_P^G E)/(T−s)(c-Ind_P^G E),    (12)
```

where T is transported through (8).

Under (8), formula (10) agrees with (7): on the standard copy of E supported on P, it gives exactly i, and G-equivariance then gives equality everywhere. Thus (12) identifies the kernel of the canonical recovery map, not merely the kernel of an unrelated surjection.

The same description can be phrased as evaluation of the type Hecke algebra at the character determined by Lambda. Its intertwining support is N, each supported intertwining space is one-dimensional, and the retained extension Lambda normalizes the Laurent generator. The explicit formulas above avoid any ambiguity about convolution orientation.

The scalar s is essential. E alone, being compact data, does not determine it. Changing s can change the unramified normalization of the candidate. The construction retains the original Lambda and s, so it recovers the exact original Pi rather than an unspecified member of its inertial class.

L.7 7. Full scalar-pushout attachment and remaining marking obligations

Form the C× pushout of the actual pair (H_new,P,theta_new). It is a Heisenberg extension of the actual symplectic plane P/H_new. Any supplied source plane with the same chosen alternating form has a center-preserving pushout isomorphism into it. Every source full-character value is then preserved in the center, as in the retained full-character attachment theorem. Stone–von Neumann identifies its source carrier with the actual two-dimensional E.

Together with the embedding i and exact quotient (12), this provides an actual arithmetic carrier and recovery inside the same fixed candidate. It closes the carrier-capacity failure of the old rank-two eta by changing the compact arithmetic pair, not by increasing the old eta or discarding its dimension calculation.

At p=2, a C× pushout does not automatically identify a separately marked native mu_2 extension or quadratic refinement. The source finite central extension can be retained through its chosen embedding, while a required comparison with the target's preselected square function remains an additional question. No arbitrary native Arf invariant is asserted here.

Nontrivial stabilizer operators, transport graphs, and original H2's requirement that a target be a particular BK type-side quotient are likewise separate. In particular, the theorem proves that the new pair is an actual arithmetic finite Heisenberg pair, but does not rename it as the unchanged maximal-simple-type pair. No new hypothesis is silently added to original Theorem 16.2.

L.8 8. Scope, smallest boundary, and sources

The inequality q>=3 matters. If q=1, then m=0 and the displayed enlargement is not the group used above. Over residue field F2 the complete Iwahori unit group equals U_A^1, and a naive level-zero replacement does not give the asserted index-two enlargement. No q=1 claim is made. The source levels q=3h with positive odd h satisfy the required q>=3.

The proof uses the actual one-dimensional Lambda because the maximal parameter field has full degree and residue field F2. It does not apply the same scalar argument automatically to a higher-rank inducing representation.

Primary BK passages: 3.1.7–8 (odd minimal H/J equality); 3.2.1–2 (deep restriction and K× normalization); 3.3.2 and 5.1.1/5.1.8 (intertwining); and 6.2.1–5 (the fixed maximal-type extension and compact induction). The subgroup, matrix, Mackey-support, and Laurent-evaluation calculations are proved explicitly above. No external correspondence theorem is used in this enlargement.

```

The previously reviewed negative statement concerned eta of the original BK J^1/H^1. That quotient remains zero. The new positive statement concerns a different, explicitly constructed arithmetic pair inside the same ambient representation, with exact recovery that preserves the noncompact normalization.

M The actual enlarged rank-four inducing carrier

M.1 Result and boundary

For the actual rank-four Artin–Schreier candidate of Block167, one can enlarge the compact group J1 to an actual compact subgroup P with

```
J1 normal in P,  [P:J1]=2,
E=Ind_(J1)^P(eta) irreducible of dimension 4.
```

The representation E occurs inside the restriction of the same actual supercuspidal candidate pi. There is an explicit normal subgroup H0 of P with [P:H0]=16 such that P/H0 is elementary abelian and the commutator form supplied by the actual character on H0 is nondegenerate. Thus the carrier has an actual four-dimensional binary symplectic quotient. No abstract transfer of matrix operators is used to create this action.

The finite image of P has scalar center theta(H0), which can be larger than {+1,-1}. It is literally an extraspecial group if this scalar center has order two. That additional assertion is not assumed or proved here. The construction supplies an actual finite Heisenberg central extension with nondegenerate projective quotient F_2^4. Matching an independently prescribed quadratic phase is also a separate assertion.

M.2 1. Actual arithmetic groups and notation

Let F=F_2((t)), and take the audited rank-four constructor with odd 0<h_1<h_2. Write

```
q_i=3h_i,  n=2q_2,  a=n/2=q_2,
r=q_1=2m+1,  m=(r-1)/2>=1.
```

We have a>r, so n>2r. Let A be the complete period-four hereditary order, with radical P_A. Let gamma be the actual degree-two outer minimal approximation, E=F[gamma], B=End_E(F^4)=M_2(E), B0=A cap B, and Q=rad(B0). The actual final parameter is beta=gamma+delta, and

```
s(delta)=c,
```

where c is the minimal degree-two Artin–Schreier parameter over E, of B0-level r. The final field K=F[beta] is totally ramified of degree four. No embedding E subset K is asserted.

Use $U_A^j = 1 + P_A^j$ and $U_B^j = 1 + Q^j$. BK 3.1.7–9 give the actual groups

```
H=H1(beta)=U_K^1 U_B^(m+1) U_A^(a+1),
J=J1(beta)=U_K^1 U_B^(m+1) U_A^a.
```

In particular J/H has dimension two over F_2. Let theta be the actual full simple character constructed for beta, and let eta be its unique Heisenberg representation on J, of dimension two. The argument below works with this supplied actual theta. It does not replace its values.

Choose the outer minimal simple character theta_gamma from its defining sequence. On H cap U_A^(m+1), the recursion says

```
theta=theta_gamma psi_delta.
```

Moreover H is contained in H1(gamma)=U_B^1 U_A^(a+1). The character theta_gamma is invariant under U_B^1: on U_B^1 it factors through the E-determinant, and on U_A^(a+1) it is the gamma-additive character.

M.3 2. The actual final field has the needed graded line

For every integer j>=1 and k in K cap P_A^j, the minimal-approximation commutator estimate gives

```
k=b+e,  b in Q^j,  e in P_A^(j+n-r).              (1)
```

Indeed [gamma,k]=-[delta,k] belongs to P_A^(j-r), and the minimal corestriction exact sequence for gamma solves its commutator with an error of grade j+n-r. The remaining difference centralizes gamma and therefore belongs to B. This is the usual minimal case of BK 1.4.10.

Applying s to [beta,k]=0 and using (1) gives

```
[c,b] in Q^(j+n-2r).
```

Hence the leading B-grade of b commutes with the leading grade of c. Let R be the complete period-two E-chain shift, with R^2=z I, where z is the chosen uniformizer of E. In the constructor's basis

```
c congruent to R^(-r) modulo Q^(1-r).
```

Because r is odd, the centralizing subspace on every B-grade j is the one-dimensional line spanned by R^j. On the other hand K is a totally ramified maximal field normalizing the complete A-chain, so (K cap P_A^j)/(K cap P_A^(j+1)) has dimension one over F_2. Estimate (1) is injective on the leading grade, so its image is exactly that centralizing line.

This proves the required graded assertion for the actual K, without replacing it by the derived model E[c] or assuming nested fields.

M.4 3. Normality and index of the enlarged group

Set

```
P=J U_B^m.
```

We first prove this is a group. The group U_B^m normalizes U_B^(m+1) and every U_A^j. For k in U_K^1, (1) approximates k by an element of U_B^1 with error in U_A^(n-r+1). Therefore

```
[U_B^m,U_K^1]
   subset U_B^(m+1) U_A^(m+n-r+1)
   subset H,
```

where the last inclusion follows from a>r=2m+1. Thus U_B^m normalizes both H and J, and P is an actual compact subgroup with J normal in P.

The quotient U_B^m / U_B^{m+1} has dimension two. By Section 2 the image of J cap U_B^m on this grade is exactly its centralizing line, of dimension one. For the converse inclusion needed here, the B-approximation of a K-element of grade m differs from it by grade m+n-r>a. That error lies in U_A^a subset J. Thus the whole centralizing line really occurs in the intersection, not only in an abstract associated graded space. Consequently

```
[P:J]=[U_B^m:J cap U_B^m]=2.                    (2)
```

For a concrete representative choose D=diag(1,0) in B and put

```
x=R^m D,  u=1+x.
```

Its leading grade is outside the centralizing line, so u represents the nontrivial coset of P/J. Since $u^2 = 1 + x^2$ in characteristic two, we have u^2 in U_B^(2m) subset U_B^(m+1) subset H.

M.5 4. The actual character has an orbit of length two

Define the character of H

```
lambda(h)=theta(u h u^(-1))/theta(h).
```

For h in H the preceding normality argument gives [u,h] in H cap U_A^(m+1). Since theta_gamma is invariant under u,

```
lambda(h)=psi_delta([u,h]) in {+1,-1}.          (3)
```

Thus lambda has order dividing two, and its values are actual values of the supplied simple character. It is J-invariant, since both theta and its u-conjugate are J-invariant.

It is nontrivial. Take y=R^(m+1)D and h=1+y in U_B^(m+1). The leading commutator in (3), after corestriction, has value

```
psi_E(tr_(M_2(E)/E)(c[x,y]))=-1.
```

Here the commutator remainder has B-grade at least 3m+1, which becomes positive after multiplication by c of grade -2m-1. On the leading grades, writing X=R^m diag(A,B) and Y=R^(m+1)diag(C,D), one obtains

```
tr(R^(-2m-1)[X,Y])=(A+B)(C+D) in F_2.
```

Both sums equal one for the chosen D=diag(1,0). The normalized psi_E is nontrivial on the residue field and trivial on its maximal ideal. For this AS normalization one can check the sign directly from psi_E(1)=psi_F(Tr_(E/F)(alpha))=psi_F(1)=-1.

Hence theta^u differs from theta, eta^u differs from eta, and Clifford theory applied to (2) gives

```
E_carrier=Ind_J^P(eta) irreducible, dim(E_carrier)=4.       (4)
```

M.6 5. An actual nondegenerate symplectic quotient of dimension four

Put H0=ker(lambda) inside H, and theta0=theta restricted to H0. In the two-coset induction model, h in H acts by

```
diag(theta(h) I_2, theta^u(h) I_2).
```

Thus it acts scalarly precisely when h belongs to H0. We check that H0 is the entire scalar preimage and that its quotient is symplectic.

First, lambda is invariant under u. Indeed u^2 belongs to J and theta is J-invariant, so $\lambda^u = \lambda^{-1} = \lambda$ by (3). Consequently H0 is normal in P, and theta0 is P-invariant.

Second, lambda is trivial on U_A^(a+1). There the correction formula is valid, gamma commutes with u, and the delta contribution to a commutator has grade at least a+1+m-r=a-m>0. Therefore it lies in the kernel of the additive character.

Write J=H U_A^a. Since lambda is a character and J-invariant, it kills [H,H] and [H,U_A^a]. It also kills $[U_A^a, U_A^a]$, which lies in U_A^(2a). Hence lambda([J,J])=1. It kills every square in J as well: squares of H have lambda-value one, squares of U_A^a lie in U_A^(2a), and the mixed commutator contributions have just been handled.

Finally lambda([u,H])=1 by u-invariance, and [u,U_A^a] belongs to U_A^(a+m) subset U_A^(a+1), so lambda([u,J])=1. Also lambda(u^2)=1 because u commutes with u^2. It follows that

```
[P,P] subset H0,  g^2 in H0 for every g in P,
[P:H0]=[P:J][J:H][H:H0]=2*4*2=16.
```

Therefore P/H0 is an actual elementary abelian group of dimension four. If an element of J acts scalarly on the carrier, its first eta-block is scalar, so it belongs to H by the original nondegenerate

Heisenberg quotient J/H. It then belongs to H0. An element outside J exchanges the two coset summands and cannot act scalarly. Thus H0 is precisely the scalar preimage.

The pairing

```
(gH0,kH0) |-> theta0([g,k])
```

is alternating and well defined. Since the projective quotient has exponent two, its values lie in {+1,-1}. It is nondegenerate: an element in its radical commutes with the entire irreducible carrier image and therefore acts scalarly by Schur's lemma, forcing it into H0.

This is the actual four-dimensional binary Heisenberg quotient sought for capacity. Its operators are supplied by elements of P.

M.7 6. The carrier occurs in the same supercuspidal candidate

Let pi=c-Ind_N^(GL_4(F))(Lambda) be the existing actual candidate, with N=K^times J. The residue field is F_2, so the compact extended type restricts to eta on J. Since P is contained in U_A^1,

```
N cap P=J.
```

Indeed an element k j in P with k in K^times has k in U_A^1, hence k in U_K^1 subset J. The identity double-coset term in the restriction of compact induction to P is therefore

```
Ind_J^P(eta)=E_carrier.
```

It is realized concretely by the functions supported on N P. Thus the four-dimensional carrier occurs in the same pi, with its already fixed full type character and noncompact extension scalar. No new arithmetic candidate, beta extension, or inverse correspondence is used.

M.8 7. Exact limits: finite image versus literal extraspecial group

The actual finite image is P/ker(theta0), because H0 is the scalar preimage. Its center is the scalar cyclic 2-group theta0(H0), and its commutator subgroup has order two. Its quotient by its center is F_2^4.

If theta0(H0) has order two, this finite image is extraspecial of order 32. If its scalar center is larger, quotienting arbitrary central elements need not preserve its commutator: in a cyclic 2-group the order-two subgroup can lie inside the squares. Thus a literal extraspecial quotient is not justified solely by the calculations above.

The stronger statement proved is the one with full actual character: an actual compact subgroup, actual induced carrier, actual scalar subgroup and nondegenerate actual commutator pairing. Passing to the usual full scalar pushout retains all theta0-values. It does not prove that an independently supplied quadratic refinement, stabilizer action, or source phase agrees with this carrier. Those requirements must be checked separately. No H5 or universal claim 66 closure is asserted.

M.9 Provenance

Uses the audited dyadic parameter/character construction, BK 1.4.10, BK 3.1.7–9, and the defining-sequence character formula. The source normalization and all field/chain data are the actual ones in `dyadic167/tower/DYADIC_AS_TOWER167.md`. This note changes neither that proof nor its recorded exact computation. Clifford induction and the identity compact-induction double-coset term are used in their ordinary finite-index forms, with hypotheses proved above.

N Rank-four normalization and induction in stages

This is a corollary of the enlarged-carrier construction in Appendix M.

Use that note's actual groups and notation:

```
n=2a,  r=2m+1,  a>r,
H subset J=J1(beta) normal in P=J U_B^m,
[P:J]=2,  N=K^times J,
pi=c-Ind_N^G(Lambda),  Lambda|J=eta.
```

The field K normalizes P. Consequently the following are actual groups and actual smooth representations:

```
M=K^times P,
Sigma=Ind_N^M(Lambda),
dim Sigma=4,
Sigma|P=Ind_J^P(eta),
pi is isomorphic to c-Ind_M^G(Sigma).
```

The representation Sigma is irreducible, and M is compact modulo the center of G. Thus the enlarged carrier has an exact arithmetic inducing datum for the same candidate, not merely an occurrence in its restriction.

N.1 1. Normalization by the actual parameter field

The units O_K^times equal U_K^1 because the residue field is F_2. They belong to J and hence normalize P. It remains to check a uniformizer k of K. This element has A-grade one and normalizes A.

The approximation estimate proved for the actual field in Section 2 of the carrier note gives

```
k=b+e,  b in Q^1,  e in P_A^(n-r+1).
```

The leading grade of b is the nonzero centralizing line of the primitive derived parameter. Over F_2 it is exactly the leading grade of R, the period-two E-chain shift. Therefore

```
b=R v,  v in 1+Q^1.
```

In particular b is invertible and normalizes both the complete E-chain and the complete interleaved F-chain. We can write

```
k=b(1+epsilon),  epsilon in P_A^(n-r).
```

For u in U_B^m, the usual filtration commutator bound gives

```
(1+epsilon)u(1+epsilon)^(-1)u^(-1)
   in U_A^(n-r+m).
```

This group is contained in U_A^a subset J, because

```
n-r+m=2a-m-1>a.
```

Conjugation by b preserves both relevant filtrations. Since b normalizes U_B^m, it follows that

```
k U_B^m k^(-1) subset U_B^m J=P.
```

Also kJk^(-1)=J, as K^times normalizes its actual simple-character groups. Thus kPk^(-1) is contained in P and contains J. Its index over J is two, equal to [P:J], so it equals P. This proves normalization by k, its inverse, and hence all K^times.

No equality or inclusion between the fields E and K was used. The element b belongs to the actual outer centralizer B and only approximates k to the stated precision.

N.2 2. The two inducing groups have index two

Since K^times normalizes P, the product M=K^times P is a group. Both P/J and the conjugation action of K^times on it are defined. P/J has order two, whose automorphism group is trivial. Therefore

```
[K^times,P] subset J.
```

Together with J normal in P and K^times normalizing J, this proves N=K^times J normal in M. The intersection K^times cap P is U_K^1, which is contained in J, since P subset U_A^1. Consequently

```
[M:N]=[P:J]=2.
```

The quotient $K^\times/F^\times$ is compact because K/F is a finite totally ramified extension, and P is compact. Hence M is compact modulo F^times. It is open in G because it contains the open subgroup J.

N.3 3. The enlarged inducing representation is irreducible

Let u in P represent its nontrivial coset modulo J. The carrier note proved that theta^u differs from theta, and therefore eta^u differs from eta. It follows that Lambda^u differs from Lambda, since their restrictions to J already differ. Applying finite-index Clifford theory to N normal in M gives

```
Sigma=Ind_N^M(Lambda) irreducible,
dim Sigma=2 dim Lambda=4.
```

There is one N–P double coset in M, and N cap P=J. Thus restriction to P gives the actual four-dimensional Heisenberg carrier:

```
Sigma|P is isomorphic to Ind_J^P(eta).
```

Its central character on F^times is unchanged from Lambda, because F^times is central and lies in N.

N.4 4. Exact recovery by induction in stages

Induction in stages for these open subgroups gives

```
c-Ind_M^G(Sigma)
   is isomorphic to c-Ind_M^G(Ind_N^M Lambda)
   is isomorphic to c-Ind_N^G(Lambda)
   =pi.
```

The second induction is finite-index, so ordinary and compact induction from N to M agree. This is an exact equality of the resulting isomorphism classes and applies to the same fixed Lambda, including its noncompact scalar choice. It introduces no new candidate and no H5 premise.

N.5 Scope

This establishes the arithmetic inducing datum and exact recovery for the enlarged carrier. It leaves unchanged the distinction between the original two-dimensional BK quotient J/H and the new four-dimensional actual quotient P/H0. It also leaves unchanged the source-phase and literal extraspecial-center limitations recorded in the carrier note.

Dependency pin: `RANK4_ENLARGED_CARRIER167.md` SHA256 `1517e26138776fe0f32d74a174d309ec5dd6a0f572a979473d8af3d20b7a4155`.

O Exact enlarged-carrier recovery and comparison with the original contract

Evidence: a bounded contract audit and elementary conditional recovery lemmas. This note does not prove that the proposed compact enlargement is a group, that its induced representation is Heisenberg, or that the source markings attach to it. Those are the arithmetic inputs to be verified by the separate rank-two and rank-four constructions.

Verdict: an enlarged compact carrier is not, merely by being Heisenberg or an equivalent type, a new instance of the original H2 quotient. It can serve as a common assembly carrier for the already supplied H2 targets if its actual occurrence, marked attachment, and same-candidate recovery are proved and retained. The recovery mechanism differs from the finite sector idempotent used when the packet lies inside the original inducing carrier.

O.1 1. What original H2 literally requires

Original Section 10 fixes an actual maximal simple character theta, its actual groups H_theta¹ subset J_theta¹ subset J_theta, and

```
V_theta=J_theta¹/H_theta¹.
```

Its Heisenberg representation is the particular eta_theta containing theta. Definition 11.1 supplies an equivariant symplectic isometry from a source envelope to that type-side quotient, together with the central character, and at p=2 the compatible quadratic refinements and central-extension lift. Standard Fact 10.2 separately supplies the canonical beta extension of this simple-character datum.

Consequently the following implications are invalid without more proof:

```
Xi is a finite Heisenberg representation
   therefore Xi=eta_theta' for a maximal simple character theta';

(P,Xi) is equivalent to a known arithmetic type
   therefore it has that type's J¹/H¹ or canonical beta extension.
```

An equivalence of generated representation categories does not identify the particular finite group quotient in Definition 11.1. If a fixed conductor and torsion profile forces every maximal simple-character carrier in the candidate to have dimension one or two, constructing a larger Xi in that candidate does not refute the dimension theorem. Xi is another arithmetic carrier.

There is nevertheless an important distinction between **replacing an H2 target** and **assembling already supplied H2 targets**. The accepted sector construction itself uses a finite sector that need not be a whole maximal simple-character carrier. Its old actual break targets remain unchanged and are attached to that sector. An enlarged P-carrier can play the analogous assembly role, provided the complete dictionary and recovery below are proved. Calling it merely an arbitrary vector space would understate that result. Calling it a new canonical maximal simple type would overstate it.

O.2 2. Precise conditional setup

Let G=GL_n(F), Z=F×I_n, and let the already constructed candidate be

```
pi=c-Ind_N^G Lambda,
```

with its fixed actual extended type and fixed central character omega. Let J be a compact open normal subgroup of N such that

```
eta=Lambda|J is irreducible,       N/J is infinite cyclic.
```

In the proposed F2-residue, full-degree totally ramified setting, J is the actual compact type group J^1=J, not a new group called J merely to fit this notation. Let P be an actual compact open subgroup of G satisfying

```
J subset P,          N intersect P=J.
```

Define the genuine finite-dimensional compact induction

```
Xi=Ind_J^P eta.                                    (1)
```

Neither irreducibility nor Heisenberg structure of Xi is assumed to follow from its dimension. They must be proved separately when needed.

If the known eta intertwining satisfies I_G(eta)=N, then Xi is irreducible: the finite Mackey endomorphism formula gives

```
End_P(Ind_J^P eta)=End_J(eta)=C,
```

because no nontrivial double coset in P lies in I_G(eta). Finite-dimensional smooth representations of compact P factor through a finite group and are semisimple, so scalar endomorphisms imply irreducibility. This criterion requires its actual group and intertwining hypotheses. Dimension alone is not a substitute.

O.3 3. Xi occurs in the same pi, and can be an equivalent compact type

The subspace of the actual compact-induction model of pi consisting of functions supported on NP is stable under P. Mackey restriction identifies that subspace with

```
Ind_(N intersect P)^P(Lambda|_(N intersect P))=Xi.     (2)
```

Thus Xi is an actual compact P-subrepresentation of the same pi, with no change of arithmetic candidate or noncompact scalar.

Induction in stages also gives the exact G-isomorphism

```
c-Ind_P^G Xi isomorphic to c-Ind_J^G eta.            (3)
```

If (J,eta) is already a type for a stated Bernstein block and Xi is irreducible, then (P,Xi) detects the same irreducible representations:

```
Hom_P(Xi,V) isomorphic to Hom_J(eta,V).
```

This is the precise statement about equivalent types that follows from (1). It does not assert that Xi is the eta of another maximal simple character, or attach a canonical beta extension to Xi. The known canonical extension in Lambda remains the one originally supplied.

O.4 4. Exact recovery before fixing the center: a quotient

Choose u in N mapping to a generator of N/J, and retain the actual matrix Lambda(u). Use the model

```
X=c-Ind_J^G eta,
f(jg)=eta(j)f(g),
```

with G acting by right translation. Define the invertible G-equivariant shift operator

```
(Tf)(g)=Lambda(u)^(-1)f(ug).                       (4)
```

Normality of J and the actual intertwining relation for Lambda(u) ensure that Tf has the same J-covariance. Its normalization explicitly retains the fixed noncompact extension. Changing Lambda(u) changes the relation below.

Define

```
(Qf)(g)=sum_(k in Z) Lambda(u)^(-k)f(u^k g).          (5)
```

The sum is finite on each argument and has the required compact support modulo N. It is N-covariant and therefore lies in pi. It is surjective and satisfies Q(Tf)=Q(f). Decomposing support into N/J-orbits reduces its kernel to the elementary augmentation kernel on finitely supported sequences on Z. That kernel consists exactly of consecutive differences. Hence

```
X/(T-1)X isomorphic to pi.                           (6)
```

Through (3), this is a recovery of pi from the enlarged compact carrier plus the original noncompact relation. It does not select the correct relation from the finite Heisenberg packet alone.

In general this quotient cannot be replaced by a G-equivariant split inclusion before central normalization. A nonzero vector of X has finite support modulo compact J. The valuation of its determinant support is a finite subset of Z. A scalar uniformizer z=tI_n shifts these valuations by n. Consequently X has no nonzero eigenvector for z. Every vector of pi is such an eigenvector, with eigenvalue omega(t). Therefore no nonzero G-map pi -> X exists. In particular (6) does not split.

This is why the Block159 sector summand projector cannot simply be quoted: there the finite sector was inside Lambda and its stabilizer contained the noncompact center. Here Xi is larger than Lambda and lies in pi|P, with P compact. These are different induction problems.

O.5 5. After retaining the center: a finite Hecke idempotent

There is also an exact summand version once the already fixed central character is imposed. Put J_Z=ZJ and P_Z=ZP. Assume, as in the proposed totally ramified full-degree setting, that

```
N/J_Z is finite cyclic of order ell
```

(here ell=n). Let Lambda_0=Lambda|J_Z. Because Xi occurs in the same pi, its action on Z intersect P agrees with omega. It therefore extends to P_Z by letting Z act through omega. Call this Xi_omega. Induction in stages gives

```
Y=c-Ind_(P_Z)^G Xi_omega
  isomorphic to c-Ind_(J_Z)^G Lambda_0.              (7)
```

Using the same normalized shift (4), now on Y, one has T^ell=1. Indeed u^ell belongs to J_Z and the J_Z covariance cancels Lambda(u)^ell. The finite operator

```
e_Lambda=(1/ell) sum_(j=0)^(ell-1) T^j               (8)
```

is a G-equivariant idempotent whose image is exactly the fixed pi. To see this directly, N-covariant functions embed in J_Z-covariant functions because N/J_Z is finite. On that embedded pi the finite version of (5) equals ell times the identity. Its average is precisely (8), and its image consists exactly of the N-covariant functions.

Equivalently, Ind_(J_Z)^N Lambda_0 is Lambda tensored with the regular representation of N/J_Z. Formula (8) selects the Lambda summand. It uses the already fixed Lambda(u), including its root choice, so it preserves the same candidate. Other root choices select the other extensions in this finite induction. They are not interchangeable input data.

This is a finite Hecke/induction projector after normalization of the central character. It is not the original finite projector in the image algebra onto a sector of eta. A final artifact must retain (7), (8), and the normalization Lambda(u), rather than describing recovery merely as “the carrier is an equivalent type.”

O.6 6. The exact remaining admissibility checks

For either proposed low-rank enlargement, the new proof must supply all of the following concrete inputs:

1. **Actual compact group:** prove that the proposed P is a subgroup, is compact open, contains the actual J, and satisfies P intersect N=J. Compute [P:J] and the resulting Xi dimension.
2. **Actual carrier:** verify eta=Lambda | J, its actual intertwining if the irreducibility criterion is used, and the Mackey realization (2).
3. **Actual finite Heisenberg structure:** exhibit the scalar preimage in P and the resulting elementary abelian projective quotient. Compute its represented commutator and prove nondegeneracy. An irreducible carrier of dimension two or four need not automatically have this structure.
4. **Original attachments:** attach the unchanged supplied actual H2 break targets, retaining their full source character values and dyadic finite extension/lift/square markings. The precise distinction between transported and native markings remains the one proved in `DYADIC_MARKINGS167.md`.
5. **Recovery data:** retain the actual Lambda, central character and noncompact generator normalization, and prove the isomorphisms and quotient/idempotent above for those exact groups.

When these are supplied, the result is stronger than occurrence of an unrelated finite vector space: it is a marked arithmetic carrier in the same candidate, equivalent through explicit induction and recovering that candidate exactly. For C={1} and one vertex, it can repair the failed low-rank **assembly-carrier** realization under the retained scalar-pushout contract. The original H2 targets remain their original simple-character quotients. They are not renamed Xi.

If the intended target instead requires the source packet itself to equal J_theta'[1]/H_theta'[1] for a maximal simple character in this same candidate, the enlargement does not solve it. The retained low-rank dimension obstruction still applies. A separate theorem identifying Xi with such an eta would be needed, and under the fixed obstructed profile it cannot be inferred from type equivalence.

No H5 condition is added or discharged. If H5 is subsequently supplied, it must concern this fixed recovered candidate. Nontrivial stabilizer actions, canonical native quadratic comparison, and arbitrary transport graphs remain outside this bounded argument.

O.7 Evidence and self-review

Read directly: original Section 10 and Definition 11.1 in the raw manuscript; the Block159 `NONINVARIANT_SECTOR_RECONSTRUCTION159.md`; current `PROOF167.md` and `TARGET167.md`; the retained dyadic marking theorem. The Mackey, induction, shift-quotient, and central-normalized projector arguments above are proved conditionally for the displayed groups, rather than assumed for the proposed congruence formula. No actual low-rank P computation or new Lean execution is claimed in this contract note.

Reading scope

This guide follows the chapter's mathematical route from finite Frobenius packets to finite wild comparison, then explains the actual arithmetic constructions developed in the detailed odd-prime and dyadic construction appendices.

The general arithmetic realization endpoint is stated as **Conjecture 66**. The comparison with the established local Langlands correspondence remains a theorem conditional on an actual realization and H5 for that same candidate.

All mathematical artwork is deterministic Python/Matplotlib vector output. The complete editable source and its figure generator accompany this guide.

How to use this companion

Read the first two parts as an atlas of finite mathematical objects. The third part explains where finite objects acquire an actual arithmetic carrier. The final part separates the remaining realization conjecture from the conditional comparison theorem.

Each spread develops one construction or one distinction. Displays preserve the normalizations used in the accompanying mathematical text. The source line identifies an original manuscript section or a retained proof note. These are retained source anchors, rather than a claim that every argument has been newly formalized. The separate research atlas provides the later reconciliation of conductors, occurrence and native markings.

The symbol K denotes the original local field in the discussion of the finite theory. In the explicit arithmetic constructions, $F = \mathbb{F}_p((t))$ is the base field and $K = F[\beta]$ is its totally ramified parameter field. A symplectic quotient dimension and a Heisenberg representation dimension are different quantities.

Theorem numbering. The historical proof obligation called "66" corresponds to the endpoint printed as Theorem 16.2 in the original manuscript. Conjecture 66 now isolates its general arithmetic realization requirement. It is not a claim that row 66 of the historical theorem register is this endpoint.

Supplementary materials. The source collection includes detailed proofs and construction notes. Their scope distinguishes established results, conditional results and the remaining obligations of Conjecture 66.

Evidence. The odd-prime and dyadic constructions have ordinary mathematical proofs using the stated classical type-theory results. Their bounded exact computations support specified identities. They are not fresh Lean certificates for the arbitrary-length arithmetic theorems. The separate Lean guide states the actual formalization scope.

Two visual routes, one claim map

The core visual guide explains the mathematical objects and restricted arithmetic constructions. The research atlas develops the comparison tests, failed implications and remaining certificate. Read the two as complementary routes through the argument.

Start with the question	Continue to the linked reader
What is being realized?	Monograph realization contract and Plate XI.1. Finite comparison and arithmetic existence are different assertions.
How does recovery preserve the candidate?	Monograph restricted constructions and Plate XI.10. A changed assembly carrier does not mean a changed inducing representation.
Why do numerical tests not settle attachment?	Progress Sections 22–25 and Plates XI.11–XI.19. The full and skipped rank-eight profiles have capacities six and four despite the same three numerical invariants.
What does a dyadic marking retain?	Progress Sections 26–29 and Plates XI.20–XI.29. Squares, section products, native choices and phase data must not be collapsed into one commutator form.
What is formally checked?	Lean guide: the existence input and the conditional signature. A supplied field in a structure is not constructed by typesetting its declaration.

Keep the five reader PDFs together. These links use the actual companion pages, while the original lessons keep their source-note and section anchors. No diagram in either guide certifies arithmetic inputs that its source argument leaves open.

Reading corrections without changing the contract

One candidate throughout. A source-defined induction candidate and a directly constructed type candidate are not identified merely by notation. Occurrence, full-character normalization and the noncompact extension must concern the same representation. The Part II occurrence analysis retains the excluded original route and the corrected route's remaining obligation.

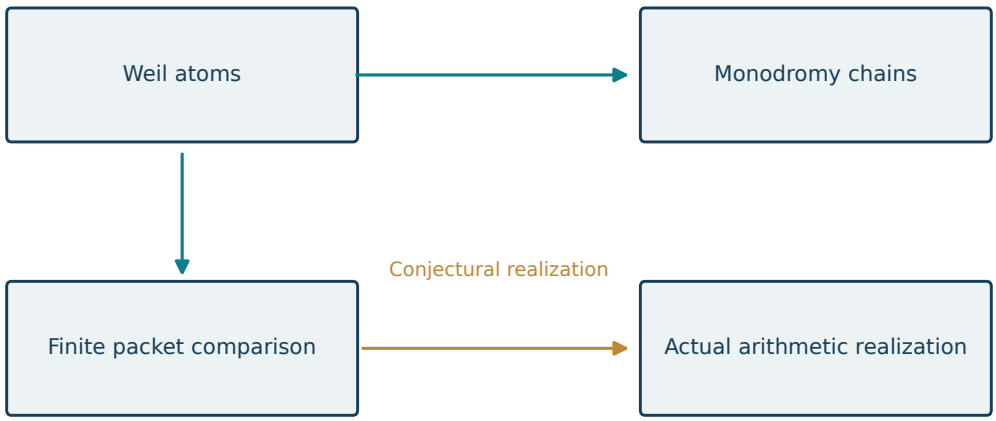
A transported mark is not a prescribed native mark. The positive scalar-pushout attachment carries the supplied finite marking through a center-fixing homomorphism. It does not identify that output with an independently fixed host subgroup. Conversely, the stronger native problem must not be inserted as a new premise into the different transported-marking result.

The equal-capacity example is conditional. At rank eight the full profile has exactly six quotient dimensions. The finite Arf test applies when the actual native refinement is independently prescribed. The abstract six-dimensional forms in the research atlas are examples, not a computation of that candidate's native square bits.

A successful finite repair has inputs. The transvection starts with an allowed symplectic map and an isotropic discrepancy vector. The odd-action correction starts with genuine supplied finite actions. Neither constructs the arithmetic normalizer or chooses every honest phase. See Plates XI.25–XI.29.

Evidence and scope

The finite illustrations and ordinary construction arguments retain their stated hypotheses and evidence boundaries. The formal companion records the separate compiler replay and its scope. A PDF build does not certify arithmetic constructors.



The source ledger distinguishes recorded verification from the open arithmetic endpoints. The retained source audit documents the checked Henniart–Lemaire interface and its normalization conventions. The complete editable archive for Block 2 remains unavailable. Its pages in the research reader are preserved. No external peer review is claimed.

For the final same-candidate comparison, read the monograph comparison proposition alongside Plate XI.32. The conjecture itself does not assert the independent H5 step.

PART I / FINITE TAME COORDINATES

1 Three mathematical objects

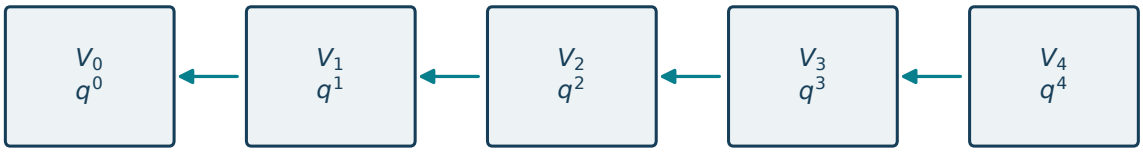
Source: Original manuscript, Sections 2, 11, 16; contract audit 162.

The finite comparison does not create the arithmetic witness.

An atom, its finite packet data, and its arithmetic realization have different roles.

A Weil atom is an irreducible Weil representation. A finite packet records selected quotient spaces, projectors, central extensions, phases, and transports. An arithmetic realization is an actual admissible representation of the required general linear group together with a comparison and recovery of that packet.

Monodromy organizes an atom into a finite Weil–Deligne chain. It does not supply an atom that is missing. Likewise a finite Heisenberg comparison identifies already supplied finite representations, rather than automatically constructing a representation of $\mathrm{GL}_n(K)$.



Reading the diagram. The final existence arrow is the content of Conjecture 66. Finite comparison, arithmetic construction, and local-factor characterization are separate steps.

PART I / FINITE TAME COORDINATES

2 Monodromy is a finite transfer chain

Source: Original Section 2.

$$F = \mathrm{diag}(1, q, q^2, q^3, q^4), \qquad FNF^{-1} = q^{-1}N$$

$$N(V_j) \subseteq V_{j-1}; \qquad N^5 = 0$$

The arrows point from V_j to V_{j-1}, the direction of N.

Put $V = \bigoplus_{j=0}^{m-1} V_j$ and let P_j be the coordinate projector. If $N(V_j) \subseteq V_{j-1}$ and $N(V_0) = 0$, then

$$N = \sum_{j=1}^{m-1} P_{j-1} N P_j, \qquad N^m = 0.$$

Every term in N^r follows a path of length r down the chain. There is no path of length m. With $F = \mathrm{diag}(1, q, \dots, q^{m-1})$, each nonzero transfer block gains the conjugation factor $q^{j-1}q^{-j} = q^{-1}$.

Reading the diagram. Nilpotence and covariance follow from the displayed block structure. Assigning the initial supercuspidal atom is a separate arithmetic input.

PART I / FINITE TAME COORDINATES

3 Fourier projectors isolate tame inertia

Source: Original Section 3; geometric Frobenius convention.

Let t generate a finite tame quotient of order M, with $(q, M) = 1$. For $j \in \mathbb{Z}/M\mathbb{Z}$ define

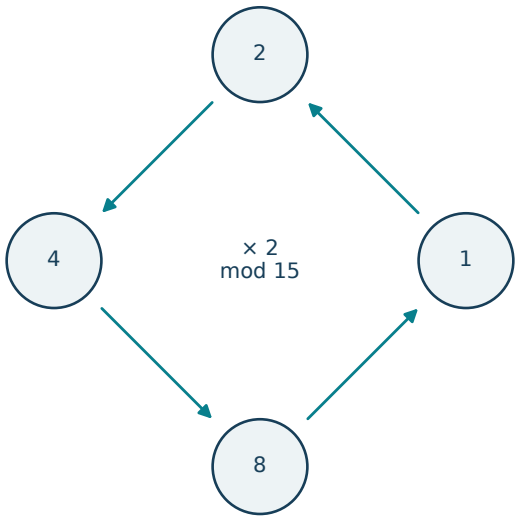
$$P_j = \frac{1}{M} \sum_{a=0}^{M-1} \zeta_M^{-ja} r(t)^a, \qquad \zeta_M = e^{2\pi i/M}.$$

The finite Fourier identities give $P_j P_k = \delta_{jk} P_j$ and $\sum_j P_j = I$. Thus $P_j V$ is the ζ_M^j character space for $r(t)$. The guide uses geometric Frobenius with

$$\Phi^{-1} r(t) \Phi = r(t)^q.$$

Equivalently $\Phi r(t) \Phi^{-1} = r(t)^{q^{-1}}$, where the inverse is taken modulo M. Substituting in the Fourier sum gives

$$\Phi P_j \Phi^{-1} = P_{qj}.$$



Scope. If the forward relation $\Phi r(t) \Phi^{-1} = r(t)^q$ is used instead, the projector label is $q^{-1}j$. The two directions have the same orbit sets but different conjugation identities. The geometric Frobenius convention is used consistently here.

Reading the diagram. A packet is an actual eigenspace selected by an idempotent. Frobenius carries it to the next character packet.

PART I / FINITE TAME COORDINATES

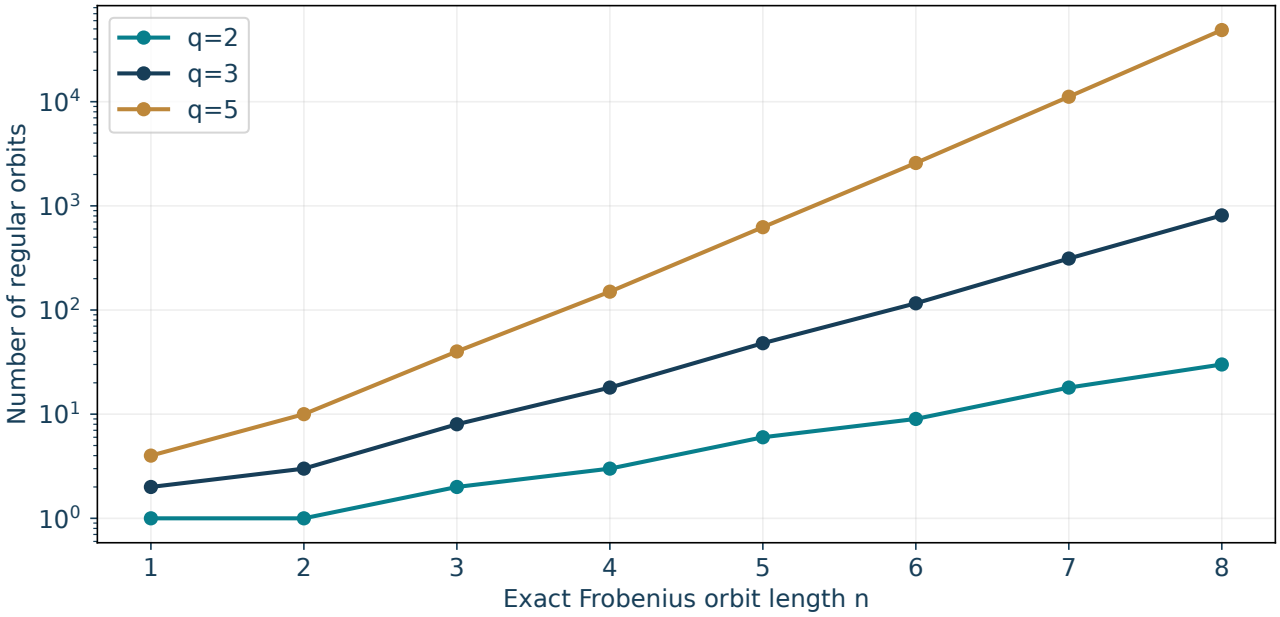
4 One orbit gives one tame atom

Source: Original Theorem 3.2.

For $q = 2$ modulo 15, the displayed geometric projector orbit is $(1, 2, 4, 8)$.

For an irreducible tame Weil representation, a union of Frobenius orbits of nonzero inertia packets would give a stable subspace. Irreducibility therefore forces one orbit, of some length f.

The stabilizer of a packet is $W_{K_f} = \langle I_K, \Phi^f \rangle$, where K_f/K is the unramified extension of degree f. Inertia acts on the packet by one scalar character. Its remaining stabilizer action is generated by Φ^f. An irreducible complex action of this cyclic quotient is one dimensional. Hence



$$\tau \simeq \operatorname{Ind}_{W_{K_f}}^{W_K} \xi, \qquad \dim \tau = f.$$

Reading the diagram. Orbit transitivity supplies both the dimension and the induced model. It is a theorem about the tame case.

PART I / FINITE TAME COORDINATES

5 Regular orbits have exact counts

Source: Original Proposition 3.6.

Exact integer counts. The vertical scale is logarithmic.

Characters of $\mathbb{F}_{q^n}^{\times}$ are indexed modulo $q^n - 1$. Characters fixed by a Frobenius power of degree $r \mid n$ number $q^r - 1$. Möbius inversion removes those belonging to smaller orbits:

$$c_n(q) = \frac{1}{n} \sum_{d \mid n} \mu(d)(q^{n/d} - 1).$$

For $q = 2, n = 4$, the regular exponent orbits modulo 15 are

$$(1, 2, 4, 8), \quad (3, 6, 12, 9), \quad (7, 14, 13, 11).$$

Their number is $\frac{1}{4}(15 - 3) = 3$. The plotted values are computed by the exact divisor sum and retained in `figure_data.json`.

Reading the diagram. Regularity is an exact orbit property. The plot illustrates an integer formula rather than supplying its proof.

PART I / FINITE TAME COORDINATES

6 A primitive projector selects a cuspidal block

Source: Original Section 4.

Let $G_n = \mathrm{GL}_n(\mathbb{F}_q)$ and $T_n \simeq \mathbb{F}_{q^n}^\times$ be an elliptic torus. A regular torus character determines an irreducible cuspidal representation κ_θ by the classical finite-field construction. If its character is χ_θ and degree is d_θ, then

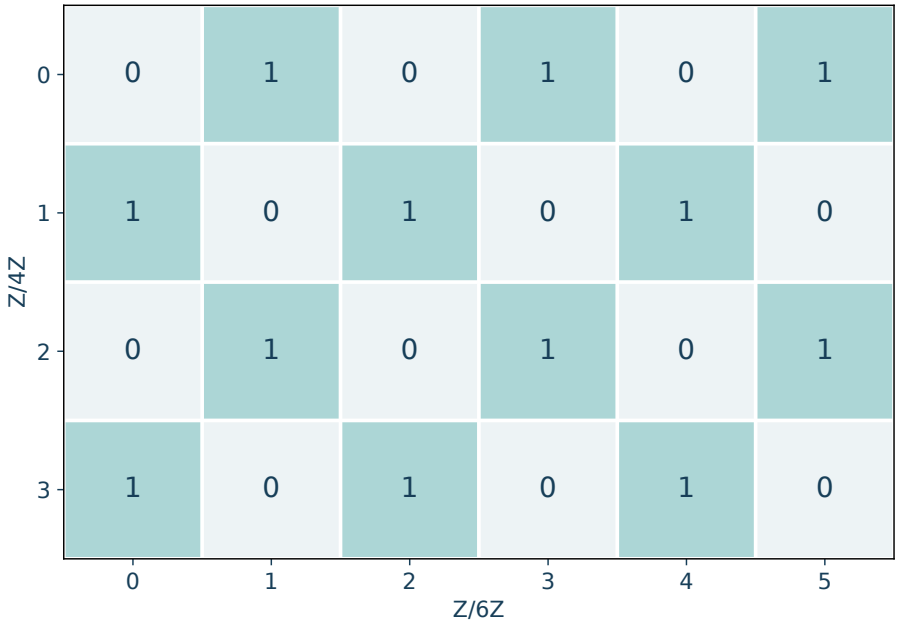
$$e_\theta = \frac{d_\theta}{|G_n|} \sum_{g \in G_n} \chi_\theta(g^{-1}) g$$

is its primitive central idempotent in $\mathbb{C}[G_n]$.

On an irreducible representation with character ψ, this central element acts by a scalar. Taking traces and using character orthogonality makes the scalar 1 on κ_θ and 0 on every other irreducible block.

For a proper parabolic $P = LU$, averaging over its unipotent radical gives

$$e_U = |U|^{-1} \sum_{u \in U} u, \qquad e_U e_\theta = e_\theta e_U = 0.$$



The average selects U-fixed vectors. The cuspidal block has none.

Scope. The existence and classification of κ_θ are classical inputs. The idempotent calculation explains its exact finite selector.

PART I / FINITE TAME COORDINATES

7 Tensor refinement is a diagonal orbit problem

Source: Original Theorem 5.1.

The 4×6 grid separates into two diagonal translation orbits, labeled 0 and 1.

The simultaneous translation action on $\mathbb{Z}/n\mathbb{Z} \times \mathbb{Z}/m\mathbb{Z}$ has

$$d = \gcd(n, m) \quad \text{orbits, each of length} \quad L = \operatorname{lcm}(n, m).$$

Mackey decomposition then gives

$$\operatorname{Ind}_{W_{K_n}}^{W_K} \xi \otimes \operatorname{Ind}_{W_{K_m}}^{W_K} \eta \simeq \bigoplus_{i=0}^{d-1} \operatorname{Ind}_{W_{K_L}}^{W_K} \left(\xi_{L,n} \eta_{L,m}^{\Phi^i} \right).$$

Here the subscripts denote norm lifts and the Frobenius superscript follows the fixed source convention. The dimension identity is exact: $dL = nm$.

Scope. These are interaction packets before combining isomorphic summands. A refined induced summand need not remain irreducible.

PART I / FINITE TAME COORDINATES

8 Exponent coordinates test inertia triviality

Source: Original Proposition 5.3.

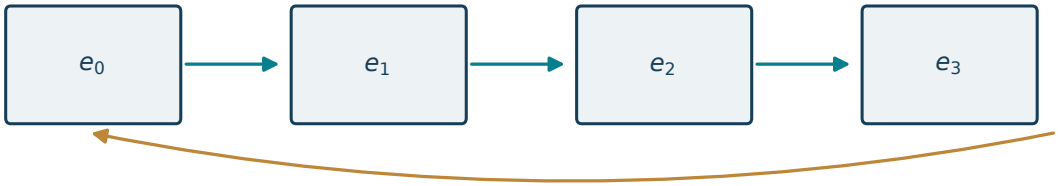
Write the residue character exponents as $a \bmod (q^n - 1)$ and $b \bmod (q^m - 1)$. The ith refined packet has exponent

$$c_i = a\frac{q^L - 1}{q^n - 1} + bq^i\frac{q^L - 1}{q^m - 1} \pmod{q^L - 1}.$$

Norm lifting multiplies an exponent by the quotient of group orders. Shifting the second character by Frobenius multiplies its exponent by q^i. Multiplication of characters adds the two terms.

For $q = 2, n = 4, m = 6$, the common modulus is $2^{12} - 1 = 4095$. Taking $a = b = 1$, the two packets have

$$c_0 = 273 + 65 = 338, \qquad c_1 = 273 + 130 = 403.$$



Both are nonzero modulo 4095, so neither packet contributes inertia invariants.

Reading the diagram. The test is $c_i = 0$ in the common modulus. A numerical-looking residue formula is an exact character calculation.

PART I / FINITE TAME COORDINATES

9 The closing scalar carries noncompact information

Source: Original Propositions 3.5 and 4.4.

Closing edge a: characteristic polynomial $X^4 - a$

The closing scalar is independent of the basis after multiplication around the cycle.

In an orbit basis let $\Phi e_j = e_{j+1}$ for $j < n-1$ and $\Phi e_{n-1} = a e_0$. Then

$$\det(XI - \Phi) = X^n - a, \qquad \det \Phi = (-1)^{n-1} a.$$

Rescaling the individual basis vectors changes edge coefficients, but their product remains a. An unramified twist ν does not change the inertia orbit and sends the closing scalar to $a\nu(\Phi)^n$.

Reading the diagram. Compact inertia information alone does not determine the unramified completion. The cyclic scalar is additional data.

PART I / FINITE TAME COORDINATES

10 Local polynomials and fixed vectors

Source: Original Propositions 5.4–5.8.

For a packet of orbit length r and closing scalar a,

$$\det(I - u\Phi \mid V^{I_K}) = \begin{cases} 1 - au^r, & \text{if inertia acts trivially,} \\ 1, & \text{otherwise.} \end{cases}$$

Thus tame tensor local factors multiply $(1 - a_i u^{r_i})^{-1}$ over precisely the refined packets whose inertia exponent vanishes.

An inertia-trivial companion cycle has a Weil-fixed vector exactly when $a_i = 1$, and then its fixed space is one dimensional. Therefore

$$\dim(\tau_{\xi^\vee} \otimes \tau_\eta)^{W_K} = \#\{i : c_i = 0,\ a_i = 1\}.$$

For an irreducible nontrivial tame atom of dimension $n > 1$, wild inertia acts trivially and inertia has no fixed vectors. Hence

$$\mathrm{Sw}(\tau) = 0, \qquad \mathrm{Art}(\tau) = n.$$

Scope. These exact tame formulas do not establish the full wild pair-factor identities required by H5.

PART I / FINITE TAME COORDINATES

11 Finite Gauss phases are unit scalars

Source: Original Section 6.

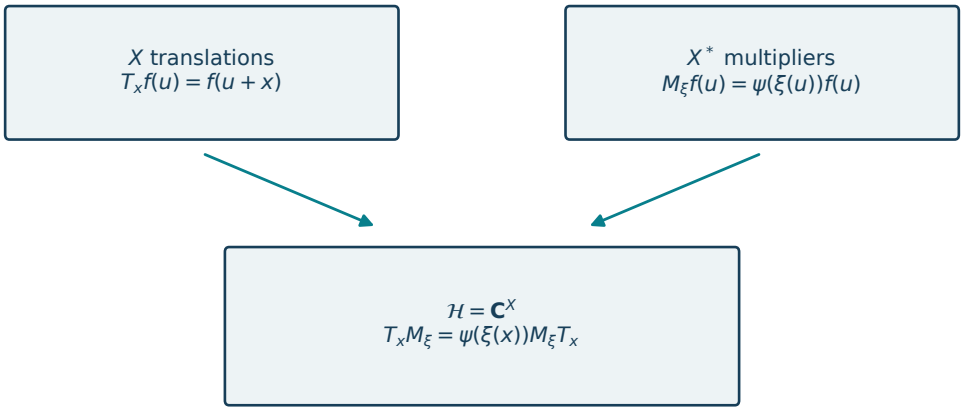
For a nontrivial additive character ψ of $\mathbb{F}_q$ and a nontrivial multiplicative character χ of $\mathbb{F}_q^\times$, define

$$G(\chi,\psi)=\sum_{x\in\mathbb{F}_q^\times}\chi(x)\psi(x),\qquad \gamma(\chi,\psi)=q^{-1/2}G(\chi,\psi).$$

The exact identities are

$$|G(\chi,\psi)|^2=q,\qquad \gamma(\chi,\psi)\gamma(\chi^{-1},\psi)=\chi(-1).$$

The magnitude calculation substitutes $x=ty$ in the double sum. The inner sum is $q-1$ for $t=1$ and -1 otherwise. Orthogonality of multiplicative characters supplies the result.



The normalized scalar therefore lies on the unit circle. Its value depends on the declared additive character and lifting normalization. Finite Gauss phases capture a part of normalization arising from the residue field.

Scope. A full wild local factor also contains ramification depth, conductor of the additive character, measure normalization, and pair interaction data. One finite phase is not that full factor.

PART II / FINITE WILD COMPARISON

12 Translations and multipliers create Heisenberg packets

Source: Original Section 7.

Noncommuting operators generate the full matrix algebra.

The commutator is central and nontrivial when the pairing is nonzero.

For odd p let $V = X \oplus X^*$ and

$$b((x,\xi),(y,\eta)) = \eta(x) - \xi(y).$$

The group $H(V) = V \times \mathbb{F}_p$ has product

$$(v,z)(w,t) = (v+w, z+t+\tfrac{1}{2}b(v,w)).$$

On $\mathcal{H} = \mathbb{C}^X$ the Schrödinger operator is

$$(\rho(x,\xi,z)f)(u) = \psi(z+\xi(u)+\tfrac{1}{2}\xi(x))f(u+x).$$

Translations and character multipliers generate every matrix unit by finite Fourier inversion. Thus the representation is irreducible and has dimension $|X| = \sqrt{|V|}$.

PART II / FINITE WILD COMPARISON

13 An isotropic average selects one line

Source: Original Propositions 7.3–7.6.

The Schrödinger character is supported on the center:

$$\operatorname{Tr}\rho(v,z)=\begin{cases}|X|\psi(z), & v=0,\\ 0, & v\neq 0.\end{cases}$$

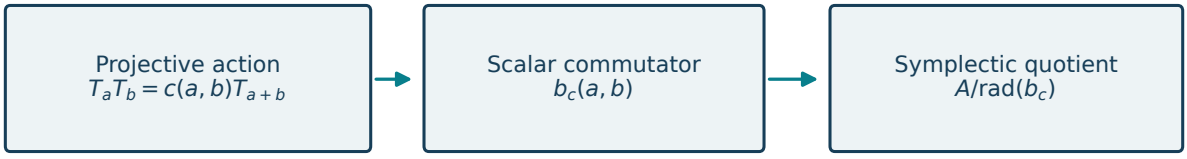
A nonzero translation has no fixed coordinate. A nontrivial multiplier has vanishing character sum.

For a maximal isotropic subspace L and a subgroup lift $\widetilde{L}$ with trivial central coordinate, the average

$$P_L=\frac{1}{|L|}\sum_{\ell\in\widetilde{L}}\rho(\ell)$$

is a self-adjoint idempotent. Its trace is $|X|/|L|=1$, because only the identity contributes. Its range is therefore one dimensional.

For $L=X$ this range consists of constant functions:



$$(P_Lf)(u)=|X|^{-1}\sum_{x\in X}f(u+x).$$

Reading the diagram. The projector onto the complementary line later used in arithmetic attachment is an exact operator in the Heisenberg image algebra. Its existence is finite representation theory.

PART II / FINITE WILD COMPARISON

14 Projective choices leave a commutator invariant

Source: Original Section 8.

Radical directions commute with every projective generator.

A cocycle contains choices. Its alternating commutator forgets scalar rescaling.

For $T_aT_b = c(a,b)T_{a+b}$ define $b_c(a,b) = c(a,b)c(b,a)^{-1}$. Replacing T_a by $\lambda_a T_a$ multiplies c by the symmetric coboundary $\lambda_a\lambda_b\lambda_{a+b}^{-1}$, so b_c is unchanged.

The radical consists of a commuting projectively with every b. Its quotient carries a nondegenerate alternating pairing. In the nondegenerate case the twisted group algebra has scalar center and is a full matrix algebra:

$$\mathbb{C}_c[A] \simeq M_{\sqrt{|A|}}(\mathbb{C}).$$

Scope. This constructs the finite envelope for a supplied projective action. It does not produce a canonical action for every arbitrary wild inertia atom.

PART II / FINITE WILD COMPARISON

15 Clifford multiplicity is the correct action space

Source: Original Section 9.

Supply finite groups $N \triangleleft G$, elementary abelian quotient $A = G/N$, and irreducibles Π and ρ, with ρ fixed up to isomorphism by G and $\Pi|_N$ isotypic. The multiplicity space is

$$M_\rho = \mathrm{Hom}_N(W, X), \qquad W \otimes M_\rho \simeq X.$$

For a section $s : A \to G$ and intertwiners I_a of ρ, write

$$\Pi(s(a)) = I_a \otimes T_a.$$

The operators T_a give a projective action on M_ρ. Section and intertwiner changes alter it only by scalar changes and conjugation. Its commutator, radical, and symplectic quotient are intrinsic to this supplied datum.

If the commutator is nondegenerate, $\dim M_\rho = \sqrt{|A|}$. A tame stabilizer acting by automorphisms of the datum preserves the induced symplectic form.

Scope. The normal group, isotypic constituent, and one-break interpretation are assumptions of the restricted construction. They have not been constructed for every wild atom.

PART II / FINITE WILD COMPARISON

16 The type-side quotient is an actual group quotient

Source: Original Section 10.

For an actual maximal simple character θ of $\mathrm{GL}_n(K)$, classical simple-type theory supplies

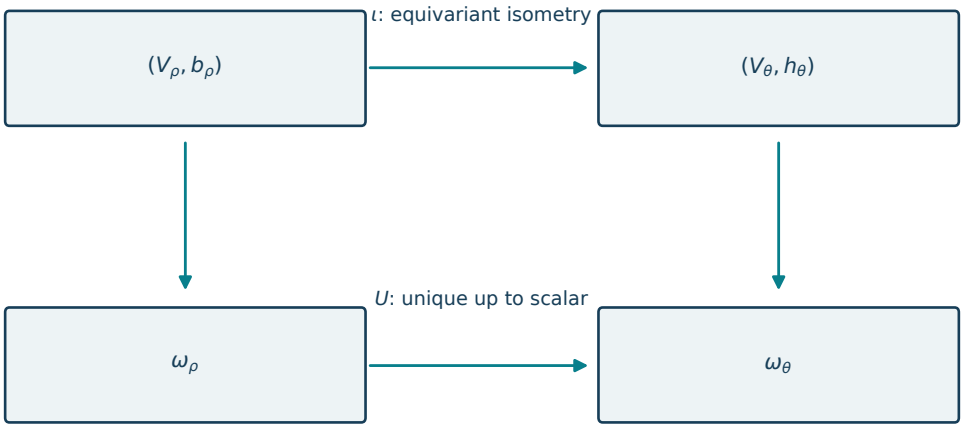
$$H_\theta^1 \subseteq J_\theta^1 \subseteq J_\theta, \qquad V_\theta = J_\theta^1 / H_\theta^1.$$

The commutator pairing is encoded by

$$\psi_0(h_\theta(\bar{x}, \bar{y})) = \theta([x, y]).$$

It is nondegenerate and alternating. The corresponding irreducible Heisenberg representation η_θ of J_θ^1 contains θ and satisfies

$$\dim \eta_\theta = \sqrt{|J_\theta^1 / H_\theta^1|}.$$



The canonical beta extension supplies a normalized extension of this representation using the declared type-theory data and finite corrections.

Scope. An arbitrary abstract symplectic space is not automatically a quotient of an actual simple character. An equivalent inducing carrier need not have this original quotient or a newly invented canonical beta extension.

PART II / FINITE WILD COMPARISON

17 A supplied bridge reduces comparison to a scalar

Source: Original Section 11.

A cyclic generator phase removes the discrepancy character.

The symplectic isometry is an input. Stone–von Neumann supplies the lower intertwiner.

Supply an equivariant symplectic isometry $\iota : V_\rho \to V_\theta$, a common nontrivial central character, and, in characteristic two, the compatible refinements and lift of central extensions.

The two pulled-back irreducible Heisenberg representations then have the same central character. Stone–von Neumann gives an invertible U with

$$U\omega_\rho(h) = \omega_\theta(\iota_H(h))U.$$

Schur's lemma makes U unique up to a nonzero scalar. After honest cyclic stabilizer linearizations, their discrepancy is a character $\delta : C \to \mathbb{C}^\times$. Equality at one generator kills this character.

Scope. Finite linearization does not identify the stabilizer action with an arithmetic action on a newly constructed common candidate.

PART II / FINITE WILD COMPARISON

18 Odd phases have a determinant certificate

Source: Original Section 12.

For an odd prime p, a symplectic space V of dimension $2r$, and fixed-point-free $g \in \mathrm{Sp}(V)$, the declared finite Weil normalization gives

$$\Phi_p(g, V) = \left(\frac{-1}{p}\right)^r \left(\frac{\det(g - I)}{p}\right).$$

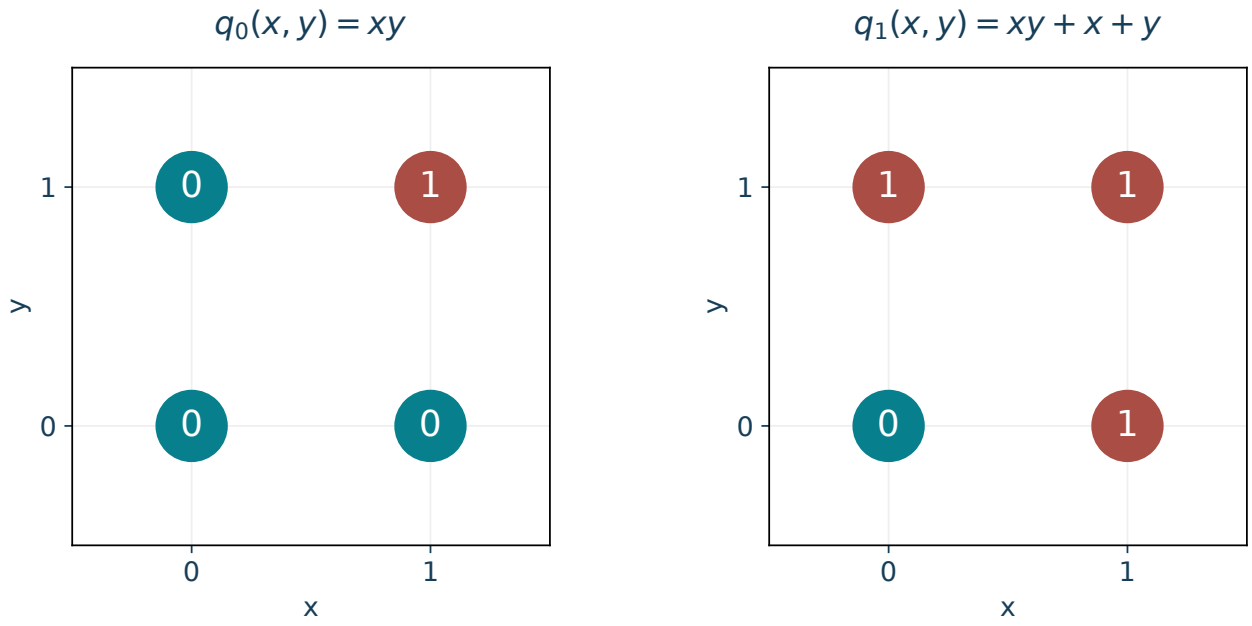
With $P_g(X) = \det(XI - g)$, even dimension gives $\det(g - I) = P_g(1)$. The phase is therefore read from a characteristic polynomial and a square class.

For a hyperbolic space $U \oplus U^*$ with $g = (a, (a^{-1})^*)$ and $a - I$ invertible,

$$\Phi_p(g, U \oplus U^*) = \left(\frac{\det a}{p}\right).$$

If g has order prime to p, then

$$V = \ker(g - I) \perp \mathrm{im}(g - I).$$



The moving summand is nondegenerate and fixed-point-free. Orthogonal block phases multiply.

Scope. The fixed-point-free formula applies to the moving part. The full trace with a fixed part requires its declared normalization data.

PART II / FINITE WILD COMPARISON

19 Two dyadic refinements can have opposite signs

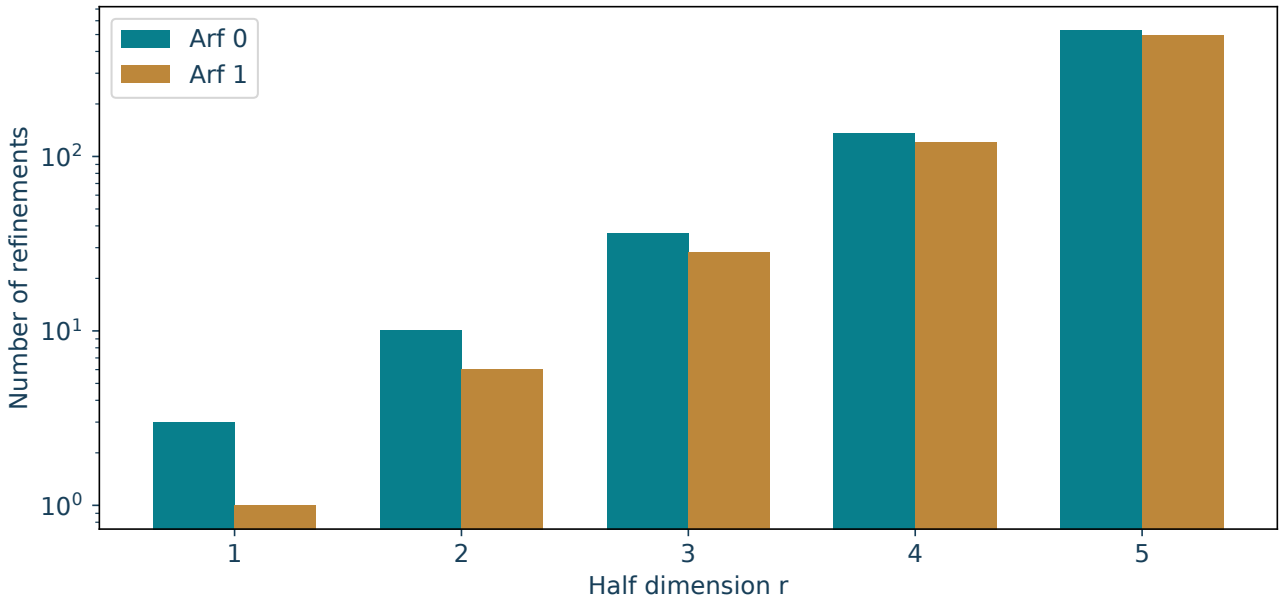
Source: Original Section 13.

The entries are exact values in $\mathbb{F}_2$. Both polar forms are $xy' + x'y$.

A quadratic refinement satisfies $q(x+y) + q(x) + q(y) = b(x,y)$. On a plane,

$$q_0(x,y) = xy, \qquad q_1(x,y) = xy + x + y.$$

For q_0 there are three zeros and one one, so its Gauss sum is 2. For q_1 there is one zero and three ones, so its sum is -2. The alternating forms agree but the Arf invariants differ.



$$\sum_{x \in V} (-1)^{q(x)} = (-1)^{\mathrm{Arf}(q)} 2^r, \qquad \dim V = 2r.$$

Reading the diagram. Keeping the alternating form alone loses dyadic phase information. The refinement and the marked central extension must travel with the packet.

PART II / FINITE WILD COMPARISON

20 Refinements form an affine family

Source: Original Propositions 13.2 and 13.8–13.9.

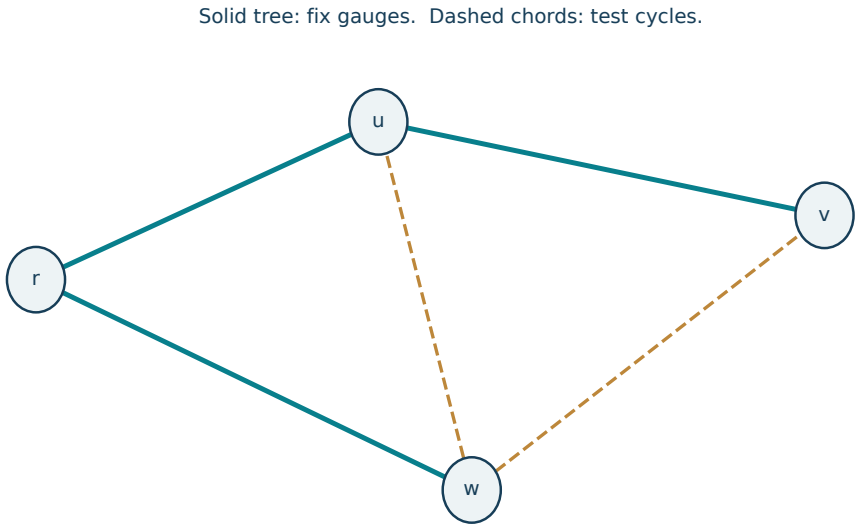
Exact counts of refinements of a fixed nondegenerate alternating space.

The difference between two refinements is linear. Nondegeneracy identifies every linear form with $b(v,\cdot)$, so all refinements are

$$q_v(x) = q(x) + b(v,x), \qquad \mathrm{Arf}(q_v) = \mathrm{Arf}(q) + q(v).$$

The numbers of the two Arf types are

$$2^{r-1}(2^r+1), \qquad 2^{r-1}(2^r-1).$$



For $r = 1$ these are 3 and 1. For $r = 3$ they are 36 and 28. Orthogonal sums add Arf invariants and multiply normalized Gauss signs.

Reading the diagram. Equal dimension and equal alternating form do not force equal refinement. An embedding fixed in advance must preserve q pointwise.

PART II / FINITE WILD COMPARISON

21 A spanning tree fixes the vertex gauges

Source: Original Theorem 14.2.

Four vertices and five edges leave two fundamental cycle tests.

Let $A_e : V_u \to V_v$ and $B_e : W_u \to W_v$ be invertible transports, with reverse-edge inverses. Fix a root comparison U_r.

Choose a spanning tree. Along its unique root path p_v define

$$U_v = B_{p_v} U_r A_{p_v}^{-1}.$$

This forces every tree-edge equation $U_v A_e = B_e U_u$. Each non-tree edge closes one fundamental cycle. Its edge equation holds exactly when the root comparison intertwines that cycle's holonomy.

Reading the diagram. All edge equations are equivalent to the fundamental cycle identities $U_r A_\gamma = B_\gamma U_r$. Holonomy need not be individually trivial. The two holonomy representations must agree through the root map.

PART II / FINITE WILD COMPARISON

22 Cycle defects measure edge residuals exactly

Source: Original Proposition 14.6.

For a non-tree edge $e : u \to v$, let

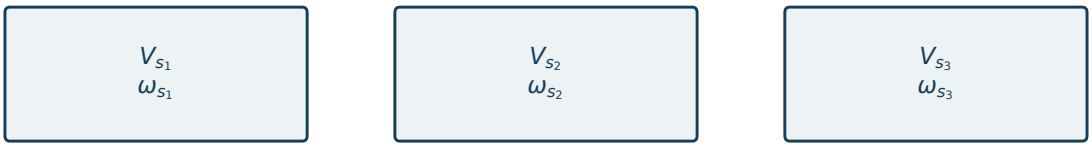
$$D_e = U_r A_{p_v}^{-1} A_e A_{p_u} - B_{p_v}^{-1} B_e B_{p_u} U_r.$$

Substituting the tree-defined gauges gives the exact identity

$$U_v A_e - B_e U_u = B_{p_v} D_e A_{p_u}^{-1}.$$

Consequently

$$\|U_v A_e - B_e U_u\| \le \|B_{p_v}\| \, \|D_e\| \, \|A_{p_u}^{-1}\|.$$



Small cycle defects give small edge residuals when the tree transports are conditioned. Zero defects give exact finite gluing. In the scalar case there are $|E| - |V| + 1$ independent tests on a connected graph.

Scope. The theorem assumes both sets of fibers and transports already exist. Gauge propagation is not an arithmetic existence theorem.

PART II / FINITE WILD COMPARISON

23 Orthogonal breaks become tensor factors

Source: Original Section 15.

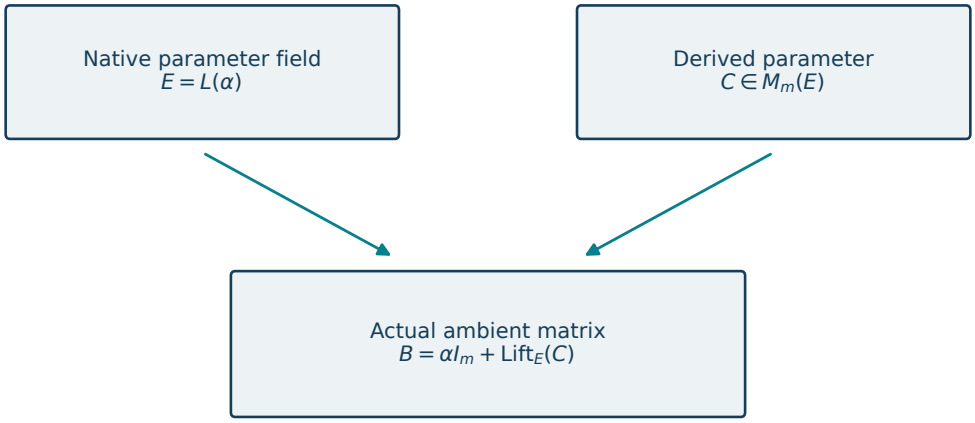
$$V = V_{s_1} \perp V_{s_2} \perp V_{s_3}$$

$$\omega_V \simeq \omega_{s_1} \otimes \omega_{s_2} \otimes \omega_{s_3}$$

Symplectic direct sum and Heisenberg tensor product are compatible.

For $V = \perp_s V_s$ and compatible central characters,

$$\omega_V \simeq \bigotimes_s \omega_{V_s}, \qquad \prod_s \sqrt{|V_s|} = \sqrt{|V|}.$$



The groups combine by a central product. Tensoring the individual intertwiners gives the full finite bridge, once the stabilizer actions and phases agree. Compatibility on the transport graph is then the matrix holonomy condition.

Scope. Separate actual type quotients at each break do not, merely by tensoring, become one actual maximal simple type in the source atom's rank. Constructing a common arithmetic carrier and recovering a candidate are the extra realization requirements.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

24 A recursive matrix gives a literal parameter

Source: Odd-prime and dyadic constructions: tower notes.

The derived field and the final field are not identified.

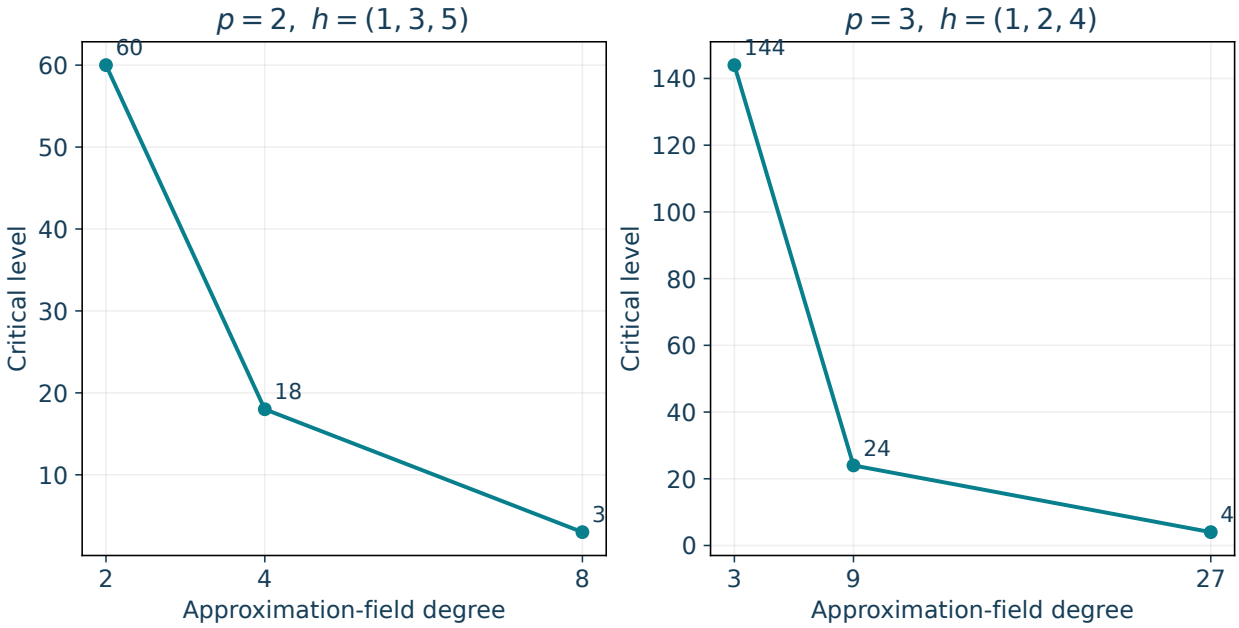
The recursive lift is an actual filtered right inverse of normalized corestriction.

Start over a coefficient field L with uniformizer t_L and form

$$E = L(\alpha), \qquad \alpha^p - \alpha = t_L^{-q}.$$

At a recursive stage, C is an actual matrix over E. The outer matrix is

$$B = \alpha I_m + \mathrm{Lift}_E(C).$$



The lift has prescribed corestriction and preserves its exact filtration valuation. The field and simple-stratum proof uses the actual displayed matrix, together with the cited type-theory derived-stratum criterion.

Scope. The derived field $E[C]$ is not identified with the final field $L[B]$. The recursion proves a literal defining sequence without silently declaring intermediate fields to be nested inside the final field.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

25 The approximation degrees and critical levels

Source: Odd-prime and dyadic constructions: combined arithmetic statements.

These examples were recomputed exactly. The assertions for all lengths are proved separately.

For increasing permitted $h_1 < \cdots < h_d$, put $q_i = (p+1)h_i$ and $N = p^d$. The approximation-field degrees are $p, p^2, \ldots, p^d$, with

$$n_j = p^{d-j} q_{d-j+1}.$$

For odd p, require $p \nmid h_i$. For $p = 2$, require all h_i odd and positive. The leading ambient level is n_1, and $n_2, \ldots, n_d$ are the successive critical approximation levels.

Scope. Every amplified ambient approximation still has leading level n_1. The declining values plotted here are critical levels, not new leading valuations for those ambient matrices.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

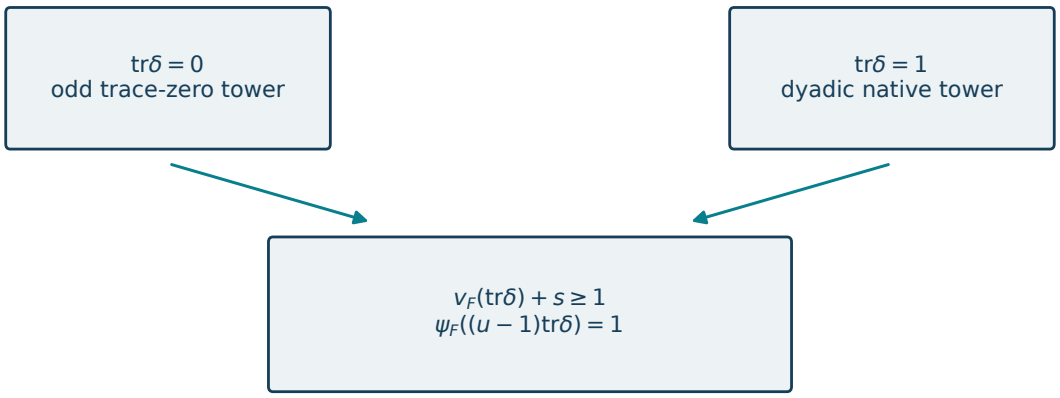
26 Odd towers retain native trace zero

Source: Odd-prime construction: recursive tower and full-character proofs.

For odd p, $\mathrm{Tr}_{E/L}(\alpha) = 0$. Choose b with $qb \equiv -1 \pmod{p}$, let $a = (qb+1)/p$, and set $z = t_L^a \alpha^b$. Then z is a uniformizer.

For its Eisenstein polynomial f and constant-coordinate projection P_0, the normalized corestriction uses $\kappa = -f'(z)/z^{p-1}$. Writing $u_0 = s(P_0)$,

$$\mathrm{Lift}_E(C) = u_0^{-1} C P_0, \qquad \mathrm{tr}_L \,\mathrm{Lift}_E(C) = \mathrm{Tr}_{E/L}(\kappa^{-1}\,\mathrm{tr}_E\, C).$$



If $\mathrm{tr}_E\, C = 0$, the lift has trace zero. Adding αI_m preserves trace zero. Induction therefore gives trace zero at every native stage and every native correction.

Reading the diagram. This is stronger than the automatic ambient trace cancellation from a multiplicity divisible by p. Native trace controls the scalar restriction used in full-character construction.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

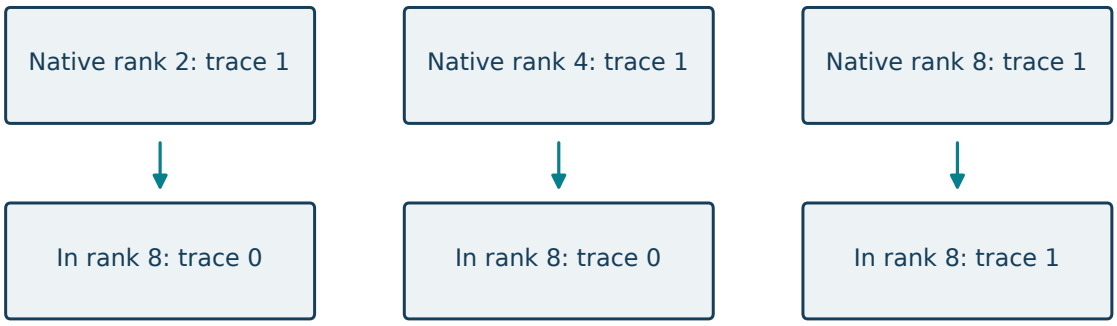
27 Dyadic trace one is deep enough

Source: Dyadic construction: depth invariant.

The scalar correction disappears when its argument lies in $t\mathcal{O}_F$.

Fix ψ_F of conductor $t\mathcal{O}_F$. On a scalar unit $u \in U_F^s$, the additive correction sees $(u-1)\,\mathrm{tr}\,\delta$. Hence

$$v_F(\mathrm{tr}\,\delta) + s \geq 1 \quad \Longrightarrow \quad \psi_F((u-1)\,\mathrm{tr}\,\delta) = 1.$$



The dyadic native corrections have trace 1. Its valuation is 0, so $s = 1$ already satisfies the inequality. Thus trace zero is sufficient but unnecessary.

Scope. Euler's weighted-visibility viewpoint motivated this step. No Euler coefficient theorem is an arithmetic proof input here. In characteristic two, the weights are uniformizer depths, not integer powers of two in the coefficient field.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

28 Native trace and ambient trace are different

Source: Dyadic construction: exact trace transport.

Native trace and amplified ambient trace have different roles.

A trace-one native matrix amplified by an even multiplicity has ambient trace zero.

For odd q, let $a = (q+1)/2$ and $z = t_L^a \alpha$. Then

$$z^2 + t_L^a z + t_L = 0, \quad \mathrm{Tr}_{E/L}\,\alpha = 1, \quad \mathrm{Lift}_E(C) = (z^2/t_L)CP_0.$$

The trace identity is

$$\mathrm{tr}_L\,\mathrm{Lift}_E(C) = \mathrm{Tr}_{E/L}(\alpha\,\mathrm{tr}_E\,C).$$

It sends inner trace 1 to outer trace 1. At native rank 2^j, every constructor has trace 1. Its next native correction has trace $1 - 2 \cdot 1 = 1$. In rank 8, the earlier amplified approximations instead have traces $0, 0$, and the final matrix has trace 1.

Reading the diagram. Only the appropriate native trace establishes the scalar-character compatibility at each recursive stage.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

29 Full characters require shallow compatibility

Source: Odd-prime and dyadic constructions: central character induction.

The full-character induction has an essential order. First construct the full native character, then transfer it to a higher multiplicity, add the actual correction on its forced domain, and extend at the next maximal native parameter field.

On a scalar $u \in U_F^1$, multiplicity p transfer gives

$$\Theta_j(uI) = \theta_j(u^p) = 1.$$

The correction is trivial on the scalar intersection by trace zero in the odd case, or integral trace and the depth inequality in the dyadic case. The forced deep character therefore agrees with the imposed trivial scalar character on their intersection. A finite abelian unit-character extension supplies the full next character.

For an odd dyadic critical level r, put $m = \lfloor r/2 \rfloor$. The endpoint satisfies $2(m+1) - r = 1$, making the additive cross term lie in the character's radical.

Scope. Checking a leading trace alone does not check shallow forced values. The earlier fixed-field central argument failed on an actual scalar unit. The recursive native-field proof repairs that problem.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

30 The same arithmetic candidate has exact profiles

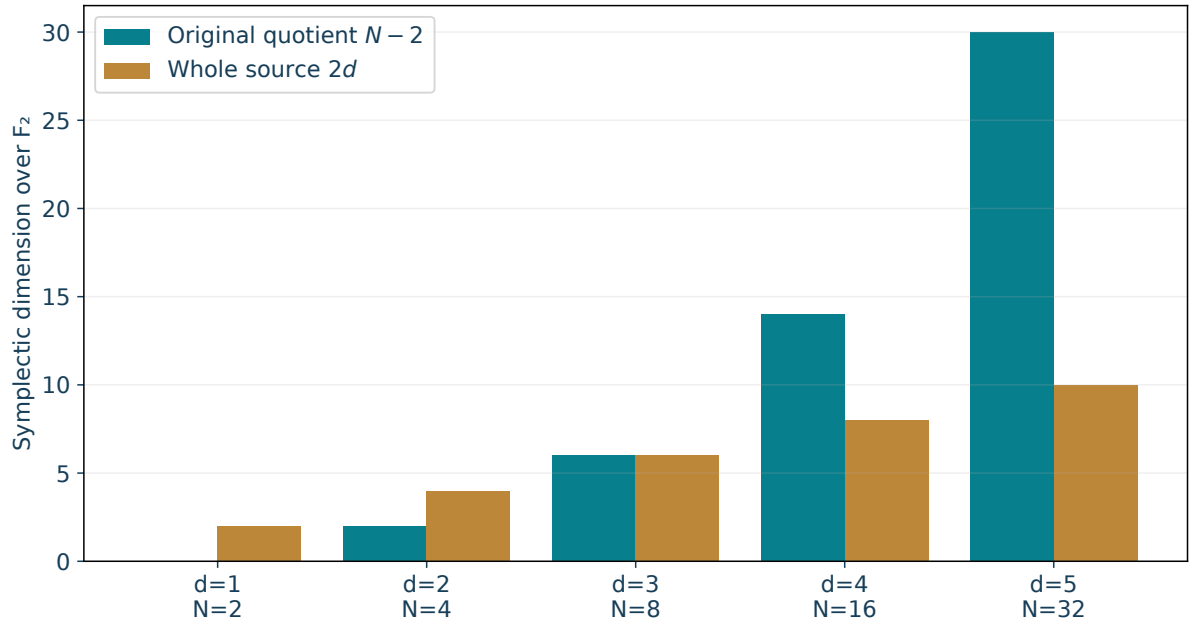
Source: Combined statements 166–167.

Let $N = p^d$ and retain the constructed full character, canonical beta extension, and compatible central completion. Both families give an actual irreducible admissible supercuspidal candidate of $\mathrm{GL}_N(F)$ with torsion number 1.

For odd p,

$$\mathrm{Sw}(\pi) = p^{d-1}(p+1)h_d,$$
$$\dim_{\mathbb{F}_p}(J^1/H^1) = N-1, \quad \dim \eta = p^{(N-1)/2},$$
$$a(\pi^\vee \times \pi) = p^{2d} - 1 + \sum_{i=1}^{d}(p^{2i} - p^{2i-2})h_i.$$

For $p = 2$,



$$\mathrm{Sw}(\pi) = 3\,2^{d-1}h_d,$$
$$\dim_{\mathbb{F}_2}(J^1/H^1) = N-2, \quad \dim \eta = 2^{N/2-1},$$
$$a(\pi^\vee \times \pi) = N^2 - 1 + \sum_{i=1}^{d} 3\,4^{i-1}h_i.$$

Scope. These identities belong to the same constructed candidate. Matching numerical profiles does not identify a source Weil atom, an endo-class, or H5 pair factors.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

31 Dyadic capacity has two distinct dimensions

Source: Dyadic construction: capacity proof.

Compare symplectic dimensions first. The original low-rank quotient remains too small.

The host symplectic quotient has dimension $N-2$ over $\mathbb{F}_2$, and the supplied whole source of d planes has dimension $2d$. Its original-type embedding is possible by dimension exactly when $d \geq 3$.

N	host quotient	source quotient	host carrier	source carrier
2	0	2	1	2
4	2	4	2	4
8	6	6	8	8
16	14	8	128	16

Scope. The low-rank obstruction concerns the original maximal-simple-character carrier. Enlarged actual arithmetic carriers repair ranks 2 and 4 without changing this quotient theorem.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

32 A sector can retain the whole source packet

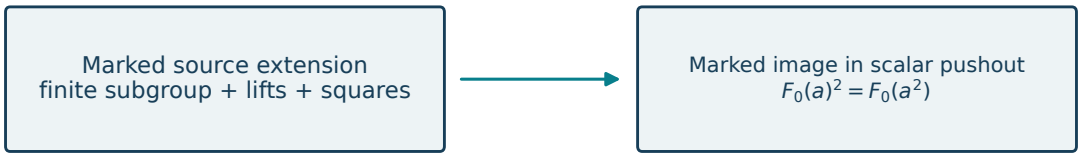
Source: Odd-prime and dyadic constructions: scalar-pushout attachment.

Suppose the supplied full break characters have labeled plane quotients and satisfy the one-vertex scalar-pushout assembly contract, initially with $C = 1$. Their source representation has dimension $p^d = N$.

For odd p, the actual leading subspace has dimension $(p-1)p^{d-1} \geq 2d$. For dyadic $d \geq 3$, use the host quotient dimension $N - 2 \geq 2d$. Choose the declared symplectic embedding into the actual host.

An orthogonal splitting $W = V_{\mathrm{src}} \perp V_{\mathrm{src}}^{\perp}$ gives

$$\eta_W \simeq \eta_{\mathrm{src}} \otimes \eta_{\perp}.$$



A maximal-isotropic average on the complementary Heisenberg factor selects a one-dimensional representation line. Tensoring its projector with the identity gives a rank-N projector in the image algebra. The retained induction/recovery theorem recovers the same Λ and then the same π.

Scope. For $p > 3$, genuinely supplied plane data are required: a native minimal rank-p quotient has dimension $p - 1$ and is not automatically a plane. The construction retains source labels but does not prove their old numerical depth placement.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

33 Retain the whole marked finite extension

Source: Dyadic construction: markings proof.

The whole finite subgroup travels through the map.

A separately fixed native marking needs its own comparison.

Squares are preserved by the actual map of marked extensions.

For a full character θ_i, its scalar pushout is

$$\mathcal{P}_i = (\mathbb{C}^\times \times J_i^1)/\{(\theta_i(h)^{-1}, h) : h \in H_i^1\}.$$

A center-fixing comparison retains every supplied character value. In the dyadic case retain the image of the entire marked finite subgroup, its central embedding, lifts, squares, refinements, and phases. An actual extension map F_0 obeys $F_0(a)^2 = F_0(a^2)$.

Scope. The unmarked complex pushouts of D_8 and Q_8 coincide, while their marked finite μ_2 extensions differ. Retaining only the central $\{\pm 1\}$ loses that distinction. Invisible kernel elements already removed by the central character cannot be recovered by pushout.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

34 A native quadratic marking adds an embedding condition

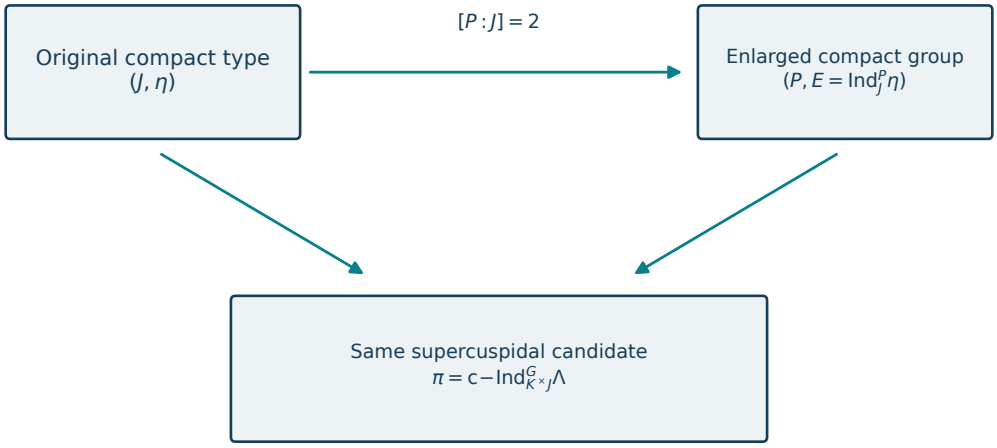
Source: Dyadic construction: markings theorem.

Transported source markings and an independently prescribed native host marking are different inputs. If the native host refinement q_W is independently supplied, a prescribed embedding f must satisfy

$$q_W(f(v)) = q_{\mathrm{src}}(v) \quad \text{for every } v.$$

With a free embedding and equal dimensions, quadratic classification requires equal Arf invariants. This is the rank-eight case: both quotient spaces have dimension 6.

For $d \geq 4$, the dyadic host has at least one spare symplectic plane. The complement's Arf type can absorb the difference, so either source Arf type admits an embedding into the supplied native quadratic host.



Reading the diagram. Dimension controls symplectic room. Arf controls a quadratic isometry class. A pointwise equation controls an already chosen embedding.

Scope. Capacity does not manufacture a canonical native finite marking or identify it with the transported marking. That comparison remains outside the general realization proof.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

35 Low-rank repair enlarges an actual compact group

Source: Dyadic construction: low-rank constructions.

The new carrier occurs in the original candidate. It is not an abstract extra tensor factor.

At rank two, write $q = 2m + 1$, $m \geq 1$, and use

$$J = U_K^1 U_A^{m+1}, \qquad P = U_K^1 U_A^m.$$

Then $J \triangleleft P$, $[P : J] = 2$, and $P \cap (K^\times J) = J$. The conjugate character ratio $\lambda = \theta^g / \theta$ is nontrivial and sign-valued. With $H_0 = \ker \lambda$,

$$P / H_0 \simeq \mathbb{F}_2^2, \qquad E = \mathrm{Ind}_J^P \theta, \quad \dim E = 2.$$

The represented diagonal sign and off-diagonal generators anticommute, proving the nondegenerate Heisenberg structure.

Scope. The original quotient J^1 / H^1 is still zero-dimensional. The new pair is a separate arithmetic assembly carrier.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

36 Rank four gains a four-dimensional carrier

Source: Dyadic construction: rank-four enlarged carrier proof.

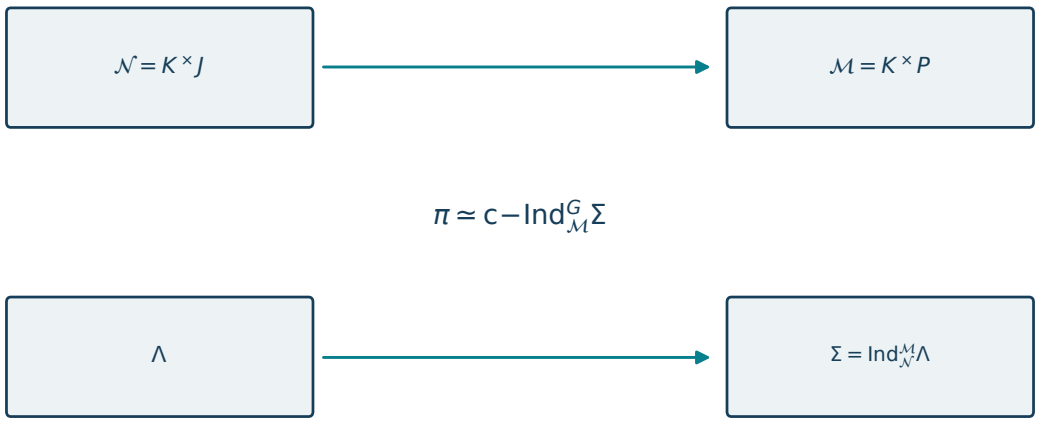
Let E_0/F be the actual outer quadratic approximation field and $B = \mathrm{End}_{E_0}(F^4)$. With lower odd critical level $r = 3h_1 = 2m + 1$ and half leading level $a = 3h_2 > r$, define

$$P = J\,U_B^m.$$

The estimate for the filtered centralizer proves this is a compact group with J normal of index two. It does not assume $E_0 \subset K$.

For a new coset representative u, the ratio $\lambda = \theta^u/\theta$ on the actual H^1 is nontrivial and sign-valued. Setting $H_0 = \ker \lambda$ gives

$$P/H_0 \simeq \mathbb{F}_2^4, \qquad E = \mathrm{Ind}_J^P \eta, \quad \dim E = 4.$$



Its represented commutators are scalar, and the quotient has exponent two. Irreducibility and the exact scalar preimage prove nondegeneracy. The finite scalar center can exceed μ_2.

Scope. No literal extraspecial quotient is claimed. Full character values and marked attachment are retained through the actual finite extension.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

37 Induction in stages recovers the same candidate

Source: Dyadic construction: low-rank recovery proof.

The noncompact extension Λ is fixed before forming Σ.

At both low ranks, $K^\times$ normalizes P. Put

$$\mathcal{N} = K^\times J, \quad \mathcal{M} = K^\times P, \qquad \Sigma = \mathrm{Ind}_{\mathcal{N}}^{\mathcal{M}} \Lambda.$$

The subgroup $\mathcal{N}$ is normal of index two, $\Sigma|_P \simeq E$, and Σ is irreducible. Induction in stages proves

$$\pi \simeq \mathrm{c\text{-}Ind}_{\mathcal{M}}^{G} \Sigma.$$

Reading the diagram. The parameter, full character, original canonical beta-extension data, central character, and noncompact scalar remain those of the original candidate. The inducing carrier changes.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

38 Compact recovery must remember the noncompact root

Source: Dyadic construction: enlarged-carrier contract.

Let $X = \mathrm{Ind}_J^G \eta$ and retain $A_0 = \Lambda(\varpi_K)$. Define the normalized shift

$$(Tf)(g) = A_0^{-1} f(\varpi_K g).$$

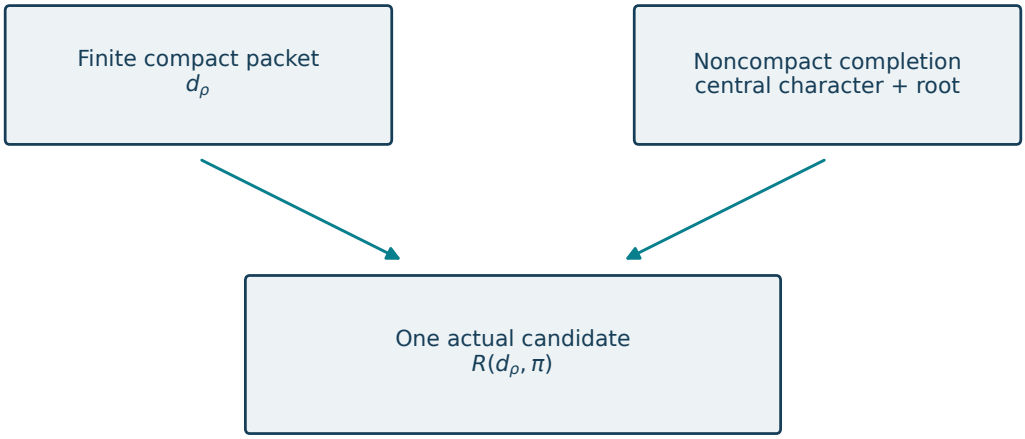
The original candidate is the quotient

$$X/(T-1)X \simeq \pi.$$

This does not split before central normalization: a vector of X has finite support modulo compact J, whereas a scalar uniformizer shifts determinant valuations. It has no nonzero eigenvector with the required central eigenvalue.

After imposing the already fixed central character, the relevant quotient is cyclic of order N. Then $T^N = 1$ and the finite average

$$e_\Lambda = \frac{1}{N} \sum_{i=0}^{N-1} T^i$$



selects the same extension. The operator acts on a complex representation space, where division by N is valid.

Scope. This is a different recovery mechanism from a finite sector inside the original η. The root is retained, not reconstructed from the compact packet alone.

PART III / ACTUAL ARITHMETIC CONSTRUCTION

39 Central completion is a construction choice

Source: Odd-prime and dyadic constructions: full-character completion.

This diagram starts with an already constructed compatible arithmetic host.

The full character is trivial on U_F^1. Residue data and the noncompact scalar can then match a prescribed smooth central quasicharacter ω trivial on U_F^1, when completion choices are free or already compatible. For $F = \mathbb{F}_2((t))$, the residue unit group is trivial, so these covered central characters are unramified. An Nth root in $\mathbb{C}^\times$ fixes the action required by $\omega(t)$. All choices are recorded before invoking H5.

Scope. An incompatible immutably supplied completion is not silently replaced. Nor is an arbitrary one-factor wild determinant assumed trivial. The source central character must belong to the covered class.

Reading the diagram. A root choice completes an existing candidate. It does not prove the general realization conjecture or the same candidate's pair-factor equalities.

PART IV / REALIZATION AND COMPARISON

40 Why nontrivial stabilizer actions need another step

Source: Odd-prime construction: stabilizer contract.

For the current totally ramified degree-p^r maximal-type host, character-preserving normalizers have

$$N/(F^\times J^1) \simeq \mathbb{Z}/p^r\mathbb{Z}.$$

A native action of a finite prime-to-p group C on the quotient therefore factors through a p-group and is trivial.

The kernel of the action of center-fixing scalar-extension automorphisms on W is $\mathrm{Hom}(W, \mathbb{C}^\times)$, an elementary abelian p-group. Hence the full native scalar-extension action is trivial as well. Honest implementers on an irreducible Heisenberg carrier are scalar by Schur's lemma.

Scope. This is an obstruction to the native inner-normalizer route for this host. It does not refute the original finite contract or Conjecture 66. Original breakwise H2 may supply a genuinely nontrivial symplectic action on separate actual type targets. Transporting abstract operators does not by itself identify a common arithmetic action.

PART IV / REALIZATION AND COMPARISON

41 Genuine scalar phases can descend from a finite cover

Source: Odd-prime construction: scalar native attachment.

There is a proved extension beyond $C = 1$ when the prime-to-p stabilizer acts trivially on the source extension and its honest operators on the entire rank-N source carrier are $\chi(c)I_N$ in the actual inertia image.

Under the same-source determinant central-character condition, the required scalar phase can be implemented by actual central matrices after a finite cover $\widetilde{C} \twoheadrightarrow C$. The kernel acts trivially on the whole recovered candidate, so the represented action descends to C.

Reading the diagram. A cover may be needed even when the represented operator is a scalar. A direct matrix homomorphism from C need not exist.

Scope. The theorem requires a genuine inertia phase on the whole carrier, the fixed reciprocity convention, and compatible completion. It does not apply merely because an arbitrary abstract phase on a multiplicity subspace is scalar. It does not change a fixed canonical beta extension to force a desired action.

PART IV / REALIZATION AND COMPARISON

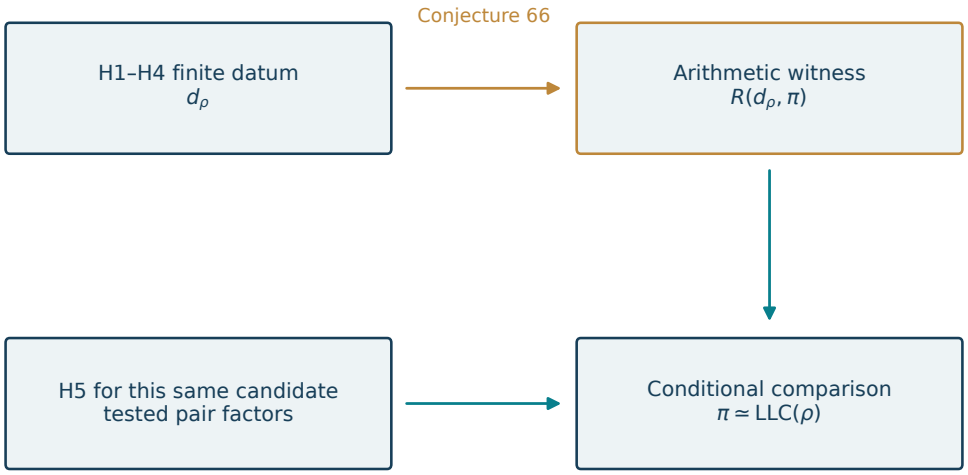
42 Numerical matching does not construct realization

Source: Profile and quotient-capacity comparisons.

For compact $J \subset \mathrm{GL}_n(F)$, the homomorphism $v_F \circ \det$ has finite image in $\mathbb{Z}$, hence image zero. An unramified character

$$\nu_a(g) = a^{v_F(\det g)}$$

is therefore trivial on J. The compact packet restrictions of π and $\pi \otimes \nu_a$ agree, while the central character changes by a^n on a scalar uniformizer. Choosing $a^n \neq 1$ gives a different atom.



The dyadic construction also gives a rank-eight skipped-degree $8 \to 2$ host with the same torsion, Swan, and self-pair conductor as the full tower, but quotient dimension 4 rather than 6.

Reading the diagram. The finite packet, numerical profiles, and noncompact normalization contain different information. No one of these alone is a substitute for an arithmetic witness preserving the full declared datum.

PART IV / REALIZATION AND COMPARISON

43 Conjecture 66 isolates the missing existence claim

Source: Historical Theorem 16.2; current realization contract.

The upper existence arrow is conjectural. The lower comparison follows conditionally.

Conjecture 66 (arithmetic packet realization). Fix the declared class $\mathcal{A}$ of wild atoms and the paper's normalizations. For every $\rho \in \mathcal{A}$ with supplied H1–H4 assembled finite datum d_ρ, there is one actual admissible supercuspidal representation π of $\mathrm{GL}_{\dim \rho}(F)$ and an arithmetic realization witness $R(d_\rho, \pi)$ recovering the packet and preserving its declared stabilizer action, central-extension and phase data, and compatible transports.

Here R includes actual arithmetic inducing data and explicit comparison and recovery. It is not merely the existence of abstract operators with the right commutators.

Scope. The conjecture is restricted to the declared admitted class. It does not assert that arbitrary coefficient targets, arbitrary partial hosts, or independently conflicting completion choices can all be extended.

PART IV / REALIZATION AND COMPARISON

44 H5 compares this same actual candidate

Source: Contract audit 162; conditional comparison proposition.

Suppose π is an actual admissible supercuspidal representation of the correct rank and $R(d_\rho, \pi)$ is supplied. If H5 gives equality of its required pair local factors with those of $\mathrm{LLC}(\rho)$ on the stipulated characterizing twist family, with the fixed normalizations, then

$$\pi \simeq \mathrm{LLC}(\rho).$$

The proof applies the supplied local-factor characterization to these two actual representations. It does not need existence for other diagrams or H5 for every alternative completion.

There is a logical difference between

$$\forall \pi\, [R(d, \pi) \Rightarrow \mathrm{H5}(\pi)] \quad \text{and} \quad \exists \pi\, [R(d, \pi) \wedge \mathrm{H5}(\pi)].$$

The first statement can be vacuous. The second includes an actual witness. Choosing the established reference atom only supplies an object with a matching profile. It leaves its recovery of d unproved.

Reading the diagram. H5 remains a conditional premise about the same independently constructed candidate. It is not renamed as an unconditional theorem comparing factors.

PART IV / REALIZATION AND COMPARISON

45 What the restricted realizations establish

Source: Odd-prime and dyadic constructions: final composition reviews.

- Actual totally ramified parameter fields, literal defining sequences, full simple characters, and covered central completions exist throughout the stated odd-prime and dyadic families.
- Under the one-vertex, $C = 1$, supplied full-character scalar-pushout contract, the whole marked packet has an actual arithmetic assembly carrier and same-candidate recovery.
- In the dyadic low ranks, the actual enlarged carriers restore capacity without changing the original maximal-simple quotient.
- Genuine scalar inertia phases have the separately stated finite-cover descent result.

The remaining general obligations include nontrivial prescribed symplectic stabilizer actions on a common arithmetic candidate, general sources and transport diagrams, comparison with independently fixed canonical native markings, and numerical layer placement when the declared contract requires it.

Scope. The constructions are substantial restricted realization theorems. Their scopes do not close universal Conjecture 66, and their profile identities do not prove H5.

PART IV / EVIDENCE AND REPRODUCIBILITY

46 Exact computation checks a bounded identity

Source: Dyadic construction: computation contract; final verification records.

The rank-eight run for $h = (1, 3, 5)$ produces an actual matrix with 25 nonzero Laurent polynomial entries. Its checked leading and adjacent-correction grades are

$$-60, \quad -18, \quad -3.$$

It checks normalized lifts, actual matrix identities, native traces 1, and amplified ambient traces $0, 0, 1$. The odd $p = 3$ example $h = (1, 2, 4)$ has levels $144, 24, 4$ and native trace zero.

The finite outputs have explicit contracts, scripts, inputs and execution records. Critical exponents, simplicity, full-character existence and arbitrary-length assertions use separate ordinary mathematical arguments.

Scope. A bounded matrix run cannot establish the universal realization claim. The arbitrary-length arithmetic constructions have ordinary proofs. Their formal coverage is stated separately in the formal companion.

CHAPTER XII

Patching Support and Hecke Packets

Conditional automorphic completion

The arithmetic sequence culminates in a conditional argument using patching support, Hecke compatibility and the stated representation-theoretic inputs.

Patching support and compatible Hecke packets complete a conditional arithmetic argument. Each application must supply the geometric, automorphic and representation-theoretic inputs that the theorem uses.

Formal companion 2617

Sources and references 2702

Scope

Actual residual and deformation data, applicable patching and full support, a compatible same-field Hecke point, classicality and an attached representation are required. Comparisons of compatible families assume those families already exist. Chapter XI's Conjecture 66 is not assumed proved.

The formal companions at the back of the book describe their own precise coverage. The glossary provides a route back to the principal definitions.

A reading map

This volume develops the algebraic steps in conditional automorphic completion. Read its support and packet theorems as deductions for the rings, modules, complexes, and arithmetic inputs that are actually supplied. They do not create missing residual occupancy or missing classicality.

The companion visual guide gives 27 worked lessons. The formal companion exposes the production sources, the 49-claim crosswalk, and the hypotheses of the formal interfaces. The links below are reading routes, not additional theorem certificates.

Topic	Main statement	Visual	Lean section
Local conditions	3.1	Plate XII.3	4
Support and quotients	6.9	Plate XII.10	8
Derived support	6.16	Plate XII.11	9
Hecke packets	8.2	Plate XII.12	10
Stable cores	8.11	Plate XII.15	11
Companion completion	10.5	Plate XII.23	11
Conditional realization	12.6	Plate XII.17	12

What the verification record means

The inherited formal record covers all 49 revised internal claims. The ledger of original wording remains separate: 41 complete, seven partial, and one unchecked. Amended statements are distinguished from their stronger predecessors.

The formal companion identifies the recorded Lean compilation and the separate source, computation and correspondence checks. Representability, applicable patching, classicality, attached representations, Frobenius density, and the comparison inputs retain their stated external status.

The final theorem requires a compatible Hecke point over the stated field. The propagation step compares two already existing families associated with the same automorphic object. Chapter XI's general realization conjecture is not an input to this chapter.

ABSTRACT. Let $\bar{\rho}$ be a residual Galois representation and let R be a global deformation ring with declared local conditions. We separate the global automorphy problem into residual occupancy, deformation support, Hecke occupancy, and arithmetic realization. Local conditions are encoded by quotient rings rather than by idempotents, since irreducible components of a local deformation ring need not be clopen. For an ordinary or derived patching datum, full support descends through the augmentation quotient. Near faithfulness is shown to be equivalent to full support for finite modules over Noetherian rings. An isomorphism $R \cong \mathbb{T}$ transports support, Fitting ideals, and point fibers, but a quotient map can erase an entire component. Finite Hecke algebras are resolved into canonical Artin packets, so simultaneous generalized eigenspaces are available without assuming semisimplicity. Nested packets in one finite carrier stabilize. For changing finite carriers, nonzero stable cores give compatible inverse limit vectors. These results give a pointwise criterion: a characteristic zero deformation point in automorphic support produces a Hecke eigensystem. With attached Galois representations, local global compatibility, and classicality, the point is automorphic. A fixed compatible system then propagates the conclusion to every coefficient place. For finite coefficient quotients, compatible conjugacy classes admit compatible continuous representatives. Declared polynomial quotient conditions survive their adic reconstruction. These completion statements require explicit finite occupancy, continuity, and integral Frobenius data. Universal companion existence and unrestricted reciprocity are not proved.

The realization boundary

Theorem 12.6 brings the five realization requirements into one statement. The diagrams throughout the chapter distinguish supplied arithmetic data from algebraic deductions. The formal companion maps each claim to its source and describes the scope of the recorded verification.

Formal evidence is mapped to all forty-nine revised internal claims. The original formulations have a separate record: forty-one complete, seven partial and one unchecked. The stronger original formulations and the revised statements are different contracts. The completed tensor and point-factorization results are algebraic deductions for supplied deformation data. Representability, residual occupancy, applicable patching and classicality theorems, attached Galois representations, Frobenius density, semisimplification, and the general Brauer–Nesbitt theorem remain external arithmetic or algebraic inputs. Neither Chapter XI's general Conjecture 66 nor universal companion existence is assumed.

1 Introduction

Automorphy lifting joins several kinds of mathematics that are easy to conflate. A residual representation must first occur in an automorphic carrier. The chosen characteristic zero representation must lie on a deformation problem controlled by local conditions. A patching argument must show that the automorphic module reaches the relevant part of the deformation space. A comparison such as $R \cong \mathbb{T}$ must identify the arithmetic and Hecke coordinates. Finally, the resulting Hecke point must be classical and must carry the expected Galois representation with the required local compatibility.

None of these steps is merely a change of notation. A deeper lift above one residual representation cannot create a missing residual companion. Freeness over an auxiliary group algebra does not imply that every component of a deformation ring is occupied. An isomorphism of rings transports support that already exists, but it does not create a nonzero automorphic vector. A nonzero class in completed or torsion cohomology need not be classical without a theorem that says so.

The Taylor Wiles method and its later forms solve these problems in many important settings [27, 24, 9, 14, 12]. Higher dimensional and derived versions use a broader range of local deformation rings, residual image conditions, torsion classes, and cohomological carriers [8, 3, 6, 25, 17, 22, 7, 19].

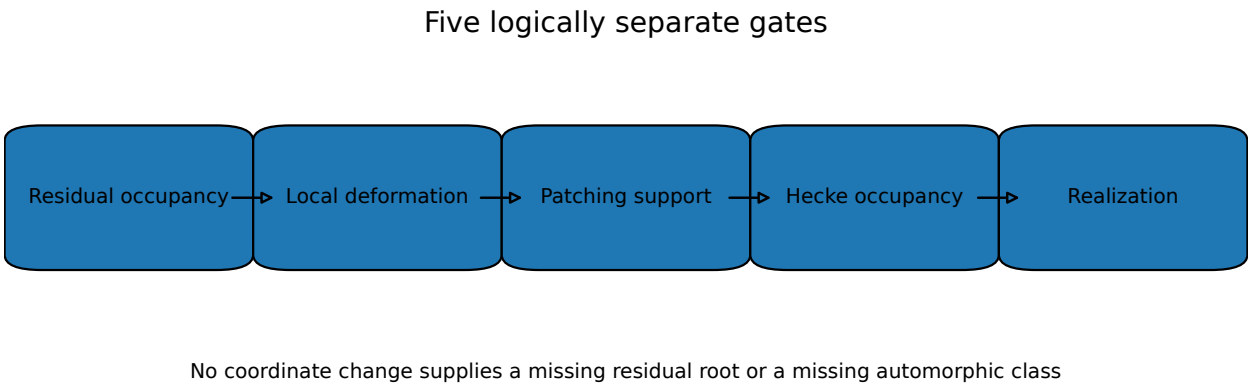

Figure 1. The global argument has several logically separate gates.

The present chapter does not replace those theorems. It isolates the algebraic support statements that explain exactly what a patching package supplies once its arithmetic hypotheses have been verified.

The first correction concerns local packets. A local deformation ring is usually complete and local. Its irreducible components are rarely open and closed. They cannot generally be represented by central idempotents. The correct object is a quotient ring defining a local condition, together with the support of a module or complex on the resulting spectrum. Central idempotents reappear later, where they belong, inside finite Artin Hecke algebras and finite dimensional characteristic zero carriers.

The second correction concerns patching. The useful global conclusion is full support, often expressed as near faithfulness. For a finite module over a Noetherian ring, near faithfulness is equivalent to full support. Full support descends through the quotient that removes the auxiliary variables. This statement is elementary, but it is the exact bridge from a patched module to componentwise occupancy at finite level. The same conclusion holds for perfect complexes through derived support.

The third correction concerns Hecke packets. Semisimplicity is not required to isolate a maximal Hecke packet. Every finite commutative algebra over a field is a product of Artin local algebras. Its canonical central idempotents project onto simultaneous generalized eigenspaces. Trace is only a secondary criterion in characteristic zero. Support and localization are the primary notions.

The last part assembles these statements into a conditional theorem. A characteristic zero point of R is automorphic when it lies in the support of the automorphic carrier, the comparison with the Hecke algebra is available, and the corresponding Hecke fiber satisfies the declared realization theorem. If the point belongs to a fixed strictly compatible system, equality of Frobenius polynomials propagates the automorphic identification to every coefficient place by Chebotarev density and Brauer Nesbitt [5, 18, 12].

Local quotient conditions are developed in section 3. Adequacy and residual occupancy appear in section 4. Auxiliary group algebras are treated in section 5. Ordinary and derived patching support appear in section 6. The effect of $R \cong \mathbb{T}$ is isolated in section 7. Finite Hecke packets and infinite occupancy are developed in section 8. Pointwise automorphy and compatible systems appear in sections 9 and 10. The coefficient prime two is discussed in section 11. The final conditional theorem is stated in section 12.

2 Global deformation data and exact boundaries

Throughout, S is a finite set of places. Frobenius elements are geometric Frobenius elements. All Hecke polynomials, attached representations, and common algebraic spines use that same convention and the normalization specified by the declared realization theorem.

Let F be a number field. Fix a prime p, a finite extension $E/\mathbb{Q}_p$, its valuation ring $\mathcal{O}$, uniformizer ϖ, and residue field k. Let

$$\bar{\rho} : G_{F,S} \longrightarrow \mathrm{GL}_n(k)$$

be a continuous residual representation, where S is a finite set of places containing every place at which the deformation problem is allowed to ramify.

Definition 2.1 (Global deformation datum)**.** A global deformation datum consists of the following objects.

(1) A residual representation $\bar{\rho}$.
(2) For every $v \in S$, a framed local deformation ring $R_v^{\square}$.
(3) A quotient $R_v^{\tau_v}$ representing the chosen local condition whenever such a quotient is known to exist.
(4) A global deformation ring $R^{\square}$ with a continuous local map
$$R^{\mathrm{loc}} := \widehat{\otimes}_{v\in S,\mathcal{O}} R_v^{\square} \longrightarrow R^{\square}.$$
(5) The induced global ring with local conditions
$$R^{\tau} := R^{\square} \,\widehat{\otimes}_{R^{\mathrm{loc}}}\, R^{\mathrm{loc},\tau}, \qquad R^{\mathrm{loc},\tau} := \widehat{\otimes}_{v\in S,\mathcal{O}} R_v^{\tau_v}.$$

Representability of deformation functors and the construction of local condition quotients require hypotheses. The standard foundations are due to Mazur and Schlessinger, with many later refinements for local conditions and pseudorepresentations [16, 21, 4].

Standard Fact 2.2 (Represented deformation problem)**.** Under the usual finiteness and Schur type hypotheses, framed lifts of $\bar{\rho}$ are represented by complete Noetherian local $\mathcal{O}$ algebras. A declared local deformation condition is represented by a quotient when the corresponding subfunctor is representable. Tangent and obstruction spaces are described by the appropriate first and second cohomology groups.

Standard Fact 2.3 (Automorphy lifting package)**.** Published automorphy lifting theorems begin with residual automorphic occupancy and impose hypotheses on the residual image, local deformation conditions, regularity, and the global deformation problem. They then use ordinary or derived patching to compare a deformation ring with a Hecke algebra and to prove automorphy for characteristic zero points in the supported locus. The precise assumptions depend on the theorem being used [8, 3, 6, 25, 17, 1].

The chapter treats standard facts 2.2 and 2.3 as external inputs. Its results begin after the relevant rings, modules, complexes, and comparison maps have been supplied.

Definition 2.4 (Residual automorphic occupancy)**.** The residual datum $(\bar{\rho}, \tau)$ is automorphically occupied when a nonzero localized automorphic or cohomological Hecke carrier realizes the residual representation and the declared local conditions.

This is a depth zero hypothesis. A positive depth deformation argument above another residual root cannot produce it.

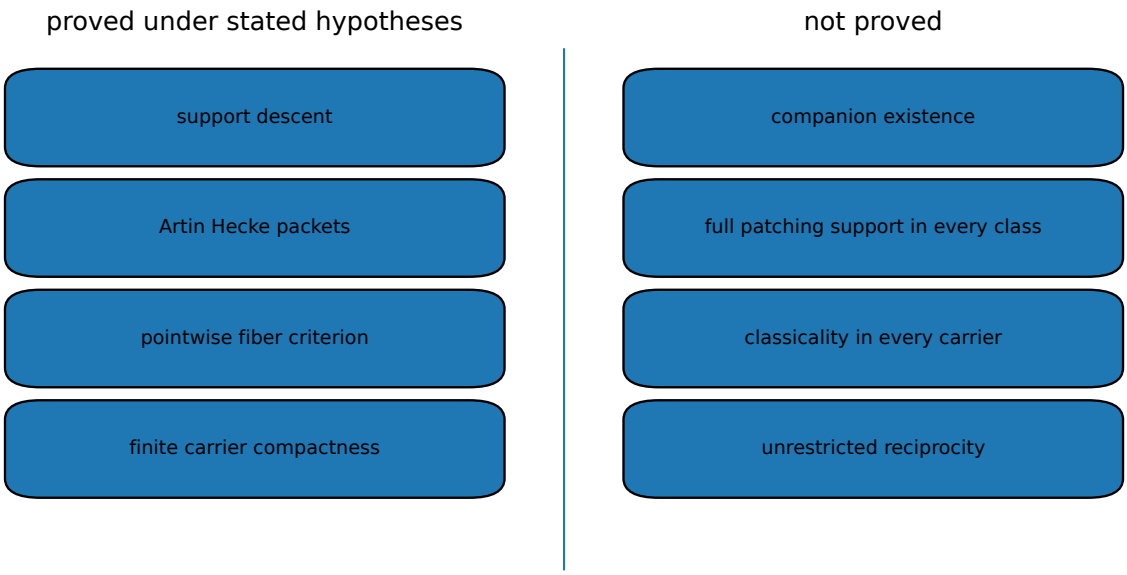

Figure 2. The chapter proves formal support and occupancy theorems. It does not prove the universal existence statements shown on the right.

3 Local conditions are quotient packets

The completed tensor product combines the local deformation conditions. The first theorem records the exact quotient law.

Theorem 3.1 (Completed tensor quotient)**.** *Let $R_1, \dots, R_s$ be complete Noetherian local $\mathcal{O}$ algebras with common residue field k. Let $I_i \subseteq R_i$ be closed ideals. Put*

$$R^{\mathrm{loc}} = R_1 \mathbin{\widehat{\otimes}}_{\mathcal{O}} \cdots \mathbin{\widehat{\otimes}}_{\mathcal{O}} R_s$$

and let J be the closed ideal generated by the images of the I_i. Then there is a canonical isomorphism

$$\boxed{(R_1/I_1) \mathbin{\widehat{\otimes}}_{\mathcal{O}} \cdots \mathbin{\widehat{\otimes}}_{\mathcal{O}} (R_s/I_s) \cong R^{\mathrm{loc}}/J.}$$

Proof. Write $S = \bigotimes_{i=1}^{s} R_i$ for the ordinary tensor product. Its ideal of definition is

$$\mathfrak{a} = \mathfrak{m}_{\mathcal{O}} S + \sum_i \mathfrak{m}_{R_i} S, \qquad L = \sum_i I_i S.$$

The scalar term retains the base adic topology when the family is empty. The ordinary quotient theorem gives a canonical algebra isomorphism

$$S/L \cong \bigotimes_{i=1}^{s} (R_i/I_i),$$

carrying the image of $\mathfrak{a}$ to the defining ideal on the right. The quotient topology on S/L is precisely this image ideal topology.

Here completion means the actual Hausdorff completion for the additive uniformity of the indicated adic topology. For every adic ring S and ideal L, there is a canonical bicontinuous ring isomorphism

$$\widehat{S}\big/\overline{L\widehat{S}} \cong \widehat{S/L}.$$

Indeed, the completed quotient map kills the closed extended ideal. In the other direction, the quotient map from S/L to $\widehat{S}/\overline{L\widehat{S}}$ extends to its completion. The latter quotient is complete: the adic uniformity has a countable base, and the quotient of a complete countably based additive group is complete. Its closed defining subgroup makes it Hausdorff. The two composites agree with the identity on dense quotient representatives, so continuity proves both inverse laws.

Applying this comparison to the displayed ordinary tensor isomorphism proves the claim. The closed extended ideal is exactly J, since extension commutes with the finite sum of the factor ideals. The maps preserve coefficients and each canonical factor map. The common residue field identifies $S/\mathfrak{a}$ with k. Finite generation of $\mathfrak{a}$, supplied by the Noetherian factor hypotheses, identifies the completed topology with its maximal ideal topology. Proper quotients retain locality. If a condition is the unit ideal, the ring comparison remains valid with the zero ring, without treating it as a local ring with residue field k. □

Corollary 3.2 (Simultaneous local conditions)**.** *A continuous point of R^{loc} with Hausdorff target factors continuously through R^{loc}/J if and only if its restriction to every R_i factors continuously through R_i/I_i. Each factor is unique. If the original point is local, its quotient factor is local.*

Proof. Let $f : R^{\mathrm{loc}} \to A$ be the point. Since A is Hausdorff and f is continuous, $\ker f$ is closed. Thus it contains the closed ideal J if and only if it contains the algebraic ideal generated by the images of the I_i. This is equivalent to every local restriction killing I_i. The universal property of the actual ideal quotient gives the factors, and the quotient topology gives their continuity. Surjectivity of the quotient map gives uniqueness. If f reflects units, lift an element of the quotient to the original ring to see that its factor also reflects units. □

Proposition 3.3 (Global base change for local conditions)**.** *In the global deformation datum of definition 2.1, let $R^{\square}$ be a complete Noetherian local $\mathcal{O}$ algebra receiving a continuous local $\mathcal{O}$ algebra map from R^{loc}. Then*

$$R^{\tau} = R^{\square} \mathbin{\widehat{\otimes}}_{R^{\mathrm{loc}}} R^{\mathrm{loc},\tau}$$

represents the base change of the global deformation problem to the simultaneous local conditions. A continuous local $\mathcal{O}$ algebra point of $R^{\square}$ with complete Hausdorff coefficient target factors uniquely and continuously through R^{τ} exactly when all of its local restrictions satisfy the declared quotient conditions.

Proof. Put $A = R^{\mathrm{loc}}$, $B = R^{\square}$, and let $J \subseteq A$ be the closed local condition ideal. By theorem 3.1, the independently constructed ring $R^{\mathrm{loc},\tau}$ is canonically A/J. The ordinary tensor identity

$$B \otimes_A (A/J) \cong B/JB$$

carries the defining ideal of the tensor to the image of $\mathfrak{m}_B$. Here the structural map is local by the stated global deformation datum, so it carries $\mathfrak{m}_A$ into $\mathfrak{m}_B$. Completing, and applying the completion and quotient comparison from the preceding proof, gives a bicontinuous isomorphism

$$R^{\tau} \cong B/\overline{JB}.$$

The construction commutes with the canonical map from B, which is therefore surjective. It is also unchanged by transporting the tensor factor from A/J to the actual completed tensor of the local quotients. The transported ideal is exactly its natural defining ideal.

For a continuous algebra point $x : B \to C$ with complete Hausdorff target, the kernel of x is closed. Consequently x has a unique continuous factor through R^{τ} if and only if it kills JB, equivalently if its restriction to A kills J. By corollary 3.2, this is exactly the requirement that all local restrictions satisfy their quotient conditions. The factor is an algebra map because its composite with the canonical global map is x. If x is local, surjectivity of that map shows that its factor reflects units and is local. Uniqueness also proves naturality under coefficient preserving maps of targets. This identifies the represented base change. It does not supply representability of a new arithmetic deformation problem. □

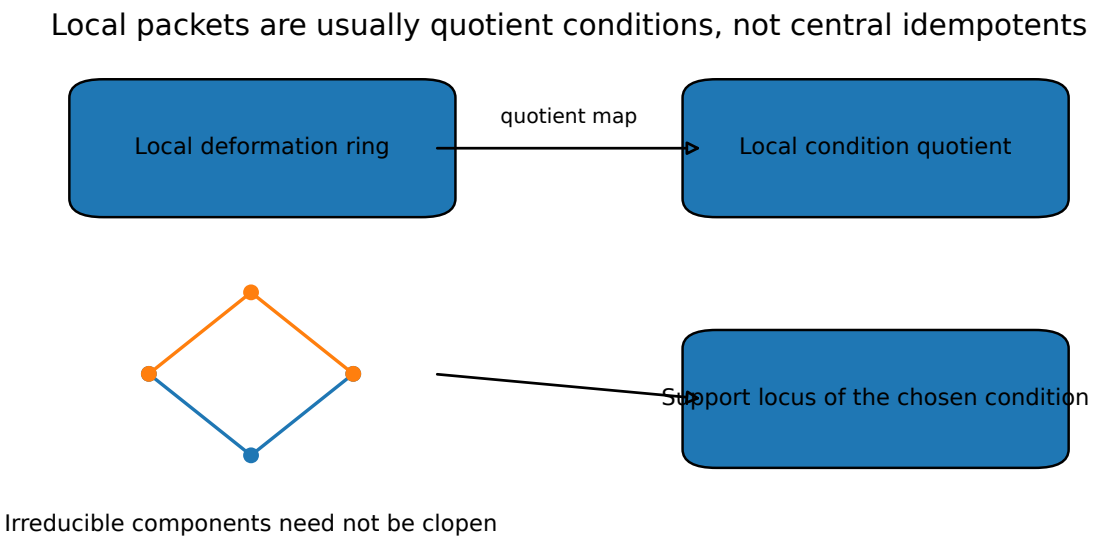

Figure 3. Local conditions are imposed by quotient rings. Components are support loci unless a genuine product decomposition exists.

The local coefficient points in proposition 3.3 are test rings in the represented deformation category. Later field valued points $x : R \to E'$ are algebraic or generic specializations, and continuity of ρ_x is imposed separately. Such a field specialization need not be a local ring map: under $\mathcal{O} \to E$, a uniformizer becomes a unit.

Proposition 3.4 (Idempotents in a local ring)**.** *If R is a commutative local ring, then its only idempotents are zero and one.*

Proof. Let $e^2 = e$. Since $e + (1 - e) = 1$, at least one of e and $1 - e$ is a unit. If e is a unit, then $e = 1$. If $1 - e$ is a unit, then $e = 0$. □

Remark 3.5. An irreducible component of $\operatorname{Spec} R$ for a local deformation ring need not be open and closed. It therefore need not be selected by an idempotent. Components and local conditions should be described by quotient ideals and module support. Idempotent packet formulas are reserved for finite Artin algebras or other settings with an actual product decomposition.

4 Adequacy and the residual input

Adequacy is one of the residual image hypotheses used in several automorphy lifting theorems. The definition and its role are external to the support arguments below [13, 25, 17].

Standard Fact 4.1 (Adequate image)**.** Let $G \subseteq \mathrm{GL}(V)$ act absolutely irreducibly over a finite field k of characteristic p. Under the standard definition, adequacy imposes vanishing conditions on $H^1(G, k)$ and $H^1(G, \mathrm{ad}^0 V)$, a scalar condition, and a generalized eigenspace detection condition for every irreducible submodule of $\mathrm{ad}^0 V$.

The following small example makes the projector detection condition explicit. It is a certificate for one finite representation, not a new adequacy criterion.

Let $G = S_3$, let $k = \mathbb{F}_7$, and let V be the standard two dimensional representation. In the basis

$$v_1 = (1, -1, 0), \qquad v_2 = (0, 1, -1),$$

a transposition and a three cycle act by

$$s = \begin{pmatrix} 6 & 1 \\ 0 & 1 \end{pmatrix}, \qquad t = \begin{pmatrix} 0 & 6 \\ 1 & 6 \end{pmatrix}.$$

Theorem 4.2 (Finite adequacy certificate)**.** *The standard representation of S_3 over $\mathbb{F}_7$ is adequate. More precisely,*

$$H^0(S_3, \mathrm{ad}^0 V) = 0, \qquad H^1(S_3, \mathbb{F}_7) = 0, \qquad H^1(S_3, \mathrm{ad}^0 V) = 0,$$

and

$$\mathrm{ad}^0 V \cong \mathrm{sgn} \oplus V.$$

The sign summand is detected by an eigenprojector of a three cycle, and the standard summand is detected by an eigenprojector of a transposition.

Proof. The coordinate map

$$(a, b) \longmapsto (a, -a + b, -b)$$

identifies the displayed matrices with the permutation action on the sum zero subspace of $\mathbb{F}_7^3$. This action is faithful. The four matrices $1, s, t, st$ span M_2 over every field of characteristic seven: the determinant of their coordinate matrix is $4 \neq 0$. A subspace stable under the group is therefore stable under every endomorphism, so the representation is absolutely irreducible. The characteristic polynomials of the identity, transpositions, and three cycles are respectively

$$(X - 1)^2, \qquad (X - 1)(X + 1), \qquad (X - 2)(X - 4).$$

Thus all eigenvalues already lie in $\mathbb{F}_7$.

A trace zero matrix fixed by conjugation by both s and t is zero, as follows by comparing its four entries. This proves $H^0(S_3, \mathrm{ad}^0 V) = 0$. For any $\mathbb{F}_7[S_3]$ module M and one cocycle f, put

$$u = -6^{-1} \sum_{h \in S_3} f(h).$$

Summing $f(gh) = gf(h) + f(g)$ over h gives $gu - u = f(g)$. Hence every one cocycle is a coboundary and $H^1(S_3, M) = 0$, giving both asserted first cohomology vanishings.

Write

$$W(a, b, c) = \begin{pmatrix} a & b \\ c & -a \end{pmatrix}, \qquad Z = W(2, 3, 4), \quad A = W(1, 1, 2), \quad B = W(1, 5, 6).$$

The three coordinate columns have determinant $3 \neq 0$. Under conjugation,

$$sZ = -Z, \quad tZ = Z, \qquad sA = -A, \quad sB = A + B, \quad tA = B, \quad tB = -A - B.$$

Consequently $(z, (a, b)) \mapsto zZ + aA + bB$ is an equivariant isomorphism from $\mathrm{sgn} \oplus V$ to $\mathrm{ad}^0 V$.

The sign witness is $W_{\mathrm{sgn}} = Z$, while $W_{\mathrm{std}} = W(6, 4, 3) = 3A + 3B$ belongs to the standard summand. The corresponding projectors and trace pairings are

$$P_{t,2} = \begin{pmatrix} 2 & 4 \\ 3 & 6 \end{pmatrix}, \qquad \mathrm{Tr}(P_{t,2} W_{\mathrm{sgn}}) = 3 \neq 0,$$

$$P_{s,1} = \begin{pmatrix} 0 & 4 \\ 0 & 1 \end{pmatrix}, \qquad \mathrm{Tr}(P_{s,1} W_{\mathrm{std}}) = 6 \neq 0.$$

For an operator D with $(D - \alpha I)(D - \beta I) = 0$ and $\alpha \neq \beta$, the canonical projector is

$$P_{D,\alpha} = (\alpha - \beta)^{-1} (D - \beta I).$$

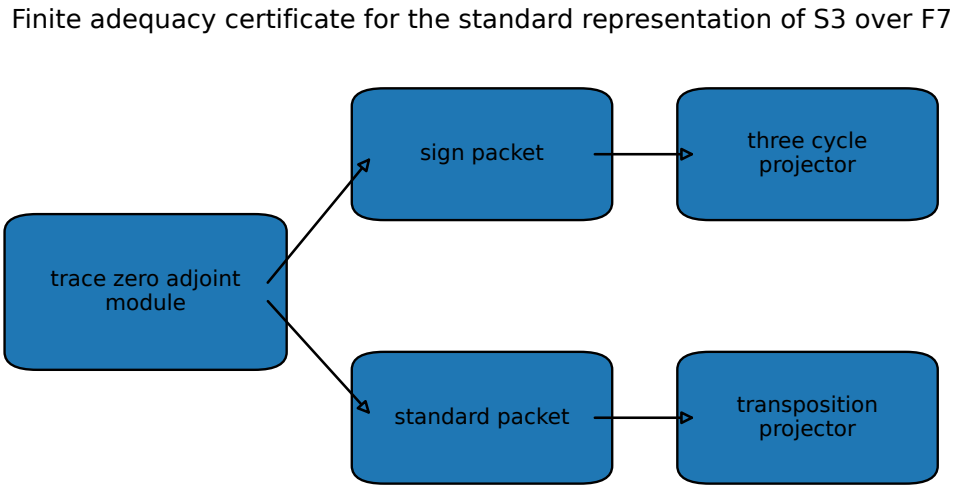

Figure 4. The two irreducible adjoint packets are detected by different generalized eigenspace projectors.

Its image equals $\ker((D-\alpha I)^n)$ for every $n \geq 1$, and it kills $\ker((D-\beta I)^n)$. This identifies the displayed matrices with the generalized eigenspace projectors required in the adequacy definition.

For detection on every irreducible submodule, one can check the stronger assertion that canonical projectors detect every nonzero matrix. In addition to the two projectors above, use

$$P_{s,-1} = \begin{pmatrix} 1 & 3 \\ 0 & 0 \end{pmatrix}, \qquad P_{tst^{-1},1} = \begin{pmatrix} 1 & 0 \\ 4 & 0 \end{pmatrix}.$$

The four trace pairings with these matrices have trivial common kernel in $M_2(\mathbb{F}_7)$, by row reduction. Every irreducible adjoint submodule contains a nonzero matrix, so some canonical projector has nonzero trace pairing on that submodule. This verifies the last adequacy clause and completes the certificate. □

Remark 4.3. The theorem verifies adequacy for one finite image. A global automorphy lifting argument must verify the published residual image hypothesis for its actual representation. The calculation does not replace that step, and it does not provide a uniform coefficient prime two theorem.

5 Auxiliary group algebras and augmentation

Let Δ be a finite abelian p group and let

$$\Lambda = \mathcal{O}[\Delta].$$

The augmentation map is

$$\epsilon : \Lambda \longrightarrow \mathcal{O}, \qquad \sum_{g \in \Delta} a_g g \longmapsto \sum_{g \in \Delta} a_g.$$

Its kernel is the augmentation ideal $\mathfrak{a}$.

Proposition 5.1 (Functorial group algebra transfer)**.** *A group homomorphism $q : \Delta' \to \Delta$ induces an $\mathcal{O}$ algebra homomorphism*

$$q_* : \mathcal{O}[\Delta'] \longrightarrow \mathcal{O}[\Delta].$$

If q is surjective, then q_* is surjective. Augmentation commutes with the transfer:

$$\epsilon_\Delta q_* = \epsilon_{\Delta'}.$$

Proof. Extend q linearly from the group basis. Multiplicativity follows from $q(gh) = q(g)q(h)$. Surjectivity follows because every basis element of $\mathcal{O}[\Delta]$ has a preimage. Both augmentation maps send every group element to one, which gives the final identity. □

Theorem 5.2 (Residual augmentation algebra)**.** *Suppose*

$$\Delta \cong \prod_{i=1}^{r} C_{p^{n_i}}.$$

Choose generators γ_i, and let $X_i = \gamma_i - 1$. Then

$$\boxed{k[\Delta] \cong k[X_1, \dots, X_r]/(X_1^{p^{n_1}}, \dots, X_r^{p^{n_r}}).}$$

The augmentation ideal is generated by the X_i, and $k[\Delta]$ is local.

Proof. In characteristic p,

$$(1 + X_i)^{p^{n_i}} - 1 = X_i^{p^{n_i}}.$$

Thus the assignment $X_i \mapsto \gamma_i - 1$ gives a surjective homomorphism from the displayed truncated polynomial ring to $k[\Delta]$. Both sides have dimension $\prod_i p^{n_i} = |\Delta|$ over k, so the map is an isomorphism. The quotient by the ideal generated by the X_i is k. Since each X_i is nilpotent, that ideal is the unique maximal ideal. □

Corollary 5.3 (No residual character splitting)**.** *The residual group algebra $k[\Delta]$ has no nontrivial idempotents. In particular, character projectors do not split a finite p group algebra in residue characteristic p.*

Proof. The first assertion follows from locality in theorem 5.2. For the general finite p group assertion, let $e \in k[G]$ be idempotent and write $\epsilon : k[G] \to k$ for augmentation. Suppose $\epsilon(e) = 0$ and $e \neq 0$. The $\mathbb{F}_p$ span W of the left translates ge is a nonzero finite dimensional $\mathbb{F}_p$ vector space, stable under G. Its cardinality is divisible by p. The orbit counting formula implies that its fixed point set also has cardinality divisible by p. Since zero is fixed, there is a nonzero fixed vector $v \in W$.

A vector in the regular representation fixed by all left translations has constant coefficients. Consequently $ve = \epsilon(e)v = 0$. On the other hand, $e^2 = e$ implies $we = w$ for every $w \in W$, hence $ve = v$, a contradiction. Thus every idempotent of augmentation zero is zero. Since $\epsilon(e)^2 = \epsilon(e)$ in the field k, either $\epsilon(e) = 0$ or $\epsilon(e) = 1$. In the latter case, apply the preceding argument to $1 - e$. □

For $M \otimes_{\Lambda,\epsilon} \mathcal{O}$, we use a right Λ module M. The left module convention is $\mathcal{O} \otimes_{\Lambda,\epsilon} M$. Throughout, $\mathfrak{a}M$ denotes the augmentation relation submodule: it is generated by ma for right modules and by am for left modules, with $a \in \mathfrak{a}$. This convention also applies to nonabelian groups in corollary 11.2. For abelian groups, both tensor orders agree over the commutative group algebra.

Theorem 5.4 (Coinvariant recovery)**.** *Let M be a free Λ module of rank d. Then*

$$\boxed{M/\mathfrak{a}M \cong M \otimes_{\Lambda,\epsilon} \mathcal{O} \cong \mathcal{O}^d.}$$

The statement is valid for every coefficient prime, including two.

Proof. Choose a Λ basis of M. Tensoring the resulting isomorphism $M \cong \Lambda^d$ along augmentation gives $\mathcal{O}^d$. Tensoring by $\Lambda/\mathfrak{a}$ is the same as quotienting by $\mathfrak{a}M$. □

Standard Fact 5.5 (Iwasawa limit)**.** For $\Delta_m = (\mathbb{Z}/p^m\mathbb{Z})^r$, the inverse limit of $\mathcal{O}[\Delta_m]$ is the Iwasawa algebra

$$\mathcal{O}[[\mathbb{Z}_p^r]] \cong \mathcal{O}[[X_1, \dots, X_r]],$$

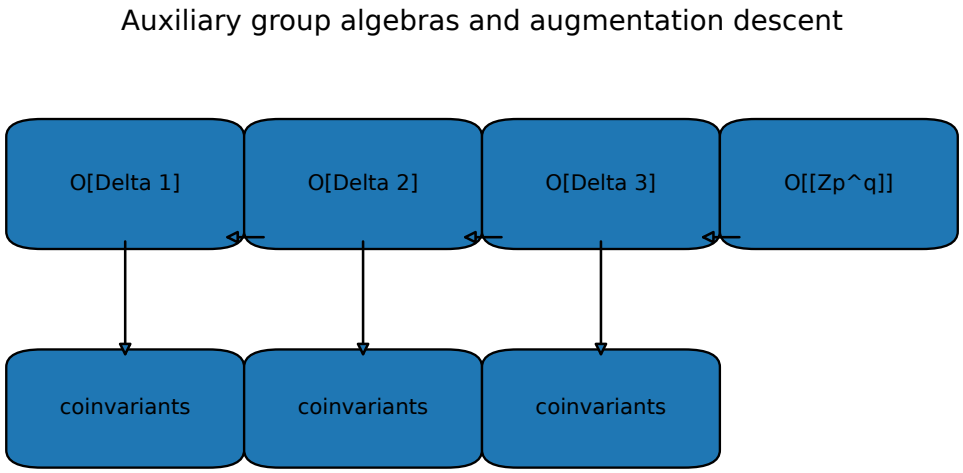

Figure 5. Auxiliary group algebras refine through quotient maps, while augmentation recovers the coarse level.

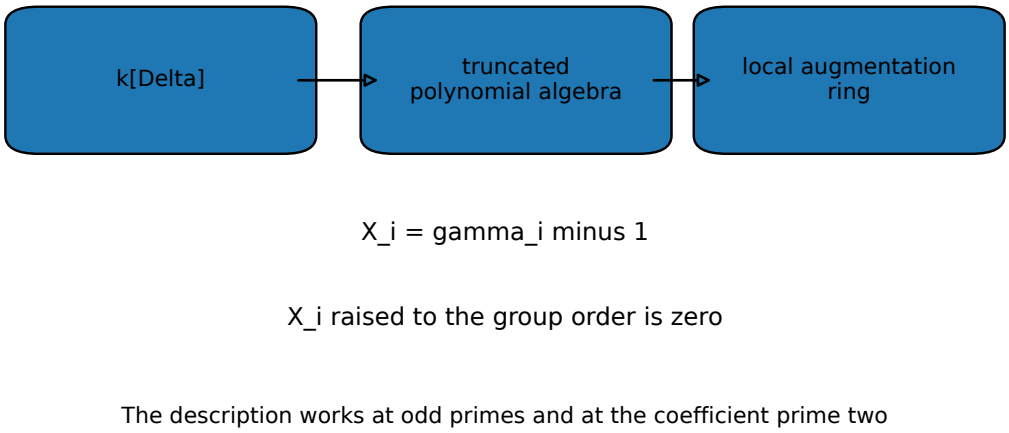

Figure 6. The residual auxiliary algebra is a local truncated polynomial algebra at every coefficient prime.

where X_i corresponds to a chosen topological generator minus one [20].

The augmentation formalism is uniform in p. The difficult coefficient two questions lie elsewhere. Residual image hypotheses, local deformation geometry, and classicality may change at two even though coinvariant recovery remains exact.

6 Ordinary and derived patching support

The algebraic conclusion supplied by a patching argument is most naturally stated through support. This section isolates the commutative algebra needed to descend that conclusion from a patched object to finite level.

Definition 6.1 (Support and near faithfulness)**.** Let R be a commutative ring and let M be an R module. Its support is

$$\operatorname{Supp}_R(M) = \{\mathfrak{p} \in \operatorname{Spec} R : M_{\mathfrak{p}} \neq 0\}.$$

If R is Noetherian and M is finite, then M is *nearly faithful* when $\operatorname{Ann}_R(M)$ is a nilpotent ideal.

Theorem 6.2 (Finite module support)**.** *Let R be a commutative ring and let M be a finite R module. Then*

$$\boxed{\operatorname{Supp}_R(M) = V\big(\operatorname{Ann}_R(M)\big).}$$

Proof. Let $\mathfrak{p} \in \operatorname{Spec} R$. If $\operatorname{Ann}_R(M) \not\subseteq \mathfrak{p}$, choose $a \in \operatorname{Ann}_R(M) \setminus \mathfrak{p}$. The element a becomes a unit in $R_{\mathfrak{p}}$, so $M_{\mathfrak{p}} = 0$.

Conversely, suppose $M_{\mathfrak{p}} = 0$. Choose generators $m_1, \dots, m_d$ of M. For each i, there is an element $s_i \notin \mathfrak{p}$ such that $s_i m_i = 0$. The product $s = s_1 \cdots s_d$ lies outside $\mathfrak{p}$ and annihilates every generator. Thus $s \in \operatorname{Ann}_R(M) \setminus \mathfrak{p}$. This proves the equality. □

Theorem 6.3 (Fitting support criterion)**.** *Let R be Noetherian and let M be a finite R module. Then*

$$\boxed{\operatorname{Supp}_R(M) = V\big(\operatorname{Fitt}_0^R(M)\big).}$$

Proof. If $M = 0$, the statement follows from the usual convention $\operatorname{Fitt}_0(0) = R$. Assume $M \neq 0$, and choose a finite presentation

$$R^m \xrightarrow{A} R^n \longrightarrow M \longrightarrow 0$$

with $n \geq 1$. The zeroth Fitting ideal is generated by the n by n minors of A. After localization at a prime $\mathfrak{p}$, the module $M_{\mathfrak{p}}$ vanishes exactly when $A_{\mathfrak{p}}$ is surjective. A map onto the free module $R_{\mathfrak{p}}^n$ is surjective exactly when one maximal minor is a unit. Thus $M_{\mathfrak{p}} = 0$ exactly when $\operatorname{Fitt}_0^R(M) \not\subseteq \mathfrak{p}$. □

Theorem 6.4 (Higher Fitting strata)**.** *Let R be Noetherian and let M be finite. For $r \geq 1$, put*

$$\mu_{\mathfrak{p}}(M) = \dim_{\kappa(\mathfrak{p})} \left(M \otimes_R \kappa(\mathfrak{p})\right).$$

Then

$$\boxed{\{\mathfrak{p} \in \operatorname{Spec} R : \mu_{\mathfrak{p}}(M) \geq r\} = V\big(\operatorname{Fitt}_{r-1}^R(M)\big).}$$

Proof. Use a finite presentation with target rank n. If $r > n$, every fiber has dimension at most n, so the left-hand locus is empty. The convention $\operatorname{Fitt}_{r-1}(M) = R$ for $r - 1 \geq n$ makes the right-hand locus empty as well. It remains to consider $1 \leq r \leq n$. At $\mathfrak{p}$, the fiber dimension is

$$n - \operatorname{rank} A(\mathfrak{p}).$$

It is at least r exactly when the rank is at most $n - r$, which is equivalent to the vanishing of every minor of size $n - r + 1$. Those minors generate $\operatorname{Fitt}_{r-1}^R(M)$. □

Proposition 6.5 (Fitting ideals and base change)**.** *Let $R \to S$ be a ring map and let M be a finitely presented R module. Then for every $j \geq 0$,*

$$\boxed{\operatorname{Fitt}_j^S(M \otimes_R S) = \operatorname{Fitt}_j^R(M)S.}$$

Proof. Base change carries a finite presentation matrix for M to a presentation matrix for $M \otimes_R S$. Every defining minor is carried to the corresponding minor over S. □

Remark 6.6. Support records nonvanishing. The higher Fitting strata record lower bounds on the number of generators in each fiber. They should not be confused with automorphic multiplicity formulas, which require additional representation theoretic input.

Theorem 6.7 (Near faithfulness is full support)**.** *Let R be Noetherian and let M be a finite R module. The following conditions are equivalent.*

(1) M is nearly faithful.
(2) $\operatorname{Supp}_R(M) = \operatorname{Spec} R$.
(3) $\operatorname{Ann}_R(M) \subseteq \operatorname{Nil}(R)$.

If R is reduced, these conditions are equivalent to faithfulness.

Proof. By theorem 6.2, full support is equivalent to

$$V\big(\operatorname{Ann}_R(M)\big) = \operatorname{Spec} R.$$

This holds exactly when $\operatorname{Ann}_R(M)$ is contained in every prime ideal, hence in the nilradical. Because R is Noetherian, the ideal $\operatorname{Ann}_R(M)$ is finitely generated. An ideal generated by finitely many nilpotent elements is nilpotent. This proves the equivalence of the first three conditions. If R is reduced, its nilradical is zero. □

Corollary 6.8 (Support on every irreducible component)**.** *Under the hypotheses of theorem 6.7, a nearly faithful module is nonzero at the generic point of every irreducible component of* $\operatorname{Spec} R$.

Proof. Every generic point is a prime of R, and full support contains every prime. □

Theorem 6.9 (Support after a quotient)**.** *Let R be Noetherian, let $I \subseteq R$ be an ideal, and let M be a finite R module. Under the canonical identification*

$$\operatorname{Spec}(R/I) \cong V(I) \subseteq \operatorname{Spec} R,$$

one has

$$\boxed{\operatorname{Supp}_{R/I}(M/IM) = \operatorname{Supp}_R(M) \cap V(I).}$$

Proof. Let $\mathfrak{p} \supseteq I$. Localizing gives

$$(M/IM)_{\mathfrak{p}} \cong M_{\mathfrak{p}}/I_{\mathfrak{p}}M_{\mathfrak{p}}.$$

If $M_{\mathfrak{p}} = 0$, the quotient is zero. If $M_{\mathfrak{p}} \neq 0$, then $I_{\mathfrak{p}}$ lies in the maximal ideal of the local ring $R_{\mathfrak{p}}$. Nakayama's lemma shows that $M_{\mathfrak{p}}/I_{\mathfrak{p}}M_{\mathfrak{p}} \neq 0$. The stated equality follows. □

Definition 6.10 (Ordinary patching datum)**.** An ordinary patching datum consists of a Noetherian ring R_∞, an ideal $\mathfrak{a} \subseteq R_\infty$, a finite R_∞ module M_∞, and identifications

$$R \cong R_\infty/\mathfrak{a}, \qquad M \cong M_\infty/\mathfrak{a}M_\infty.$$

In automorphy lifting applications, R_∞ is a patched deformation ring and M_∞ is a patched automorphic module. The definition itself contains no automorphy assertion.

Theorem 6.11 (Ordinary patching support descent)**.** *Let $(R_\infty, \mathfrak{a}, M_\infty, R, M)$ be an ordinary patching datum. If*

$$\operatorname{Supp}_{R_\infty}(M_\infty) = \operatorname{Spec} R_\infty,$$

then

$$\boxed{\operatorname{Supp}_R(M) = \operatorname{Spec} R.}$$

Equivalently, if M_∞ is nearly faithful, then M is nearly faithful. If R is reduced, then M is faithful.

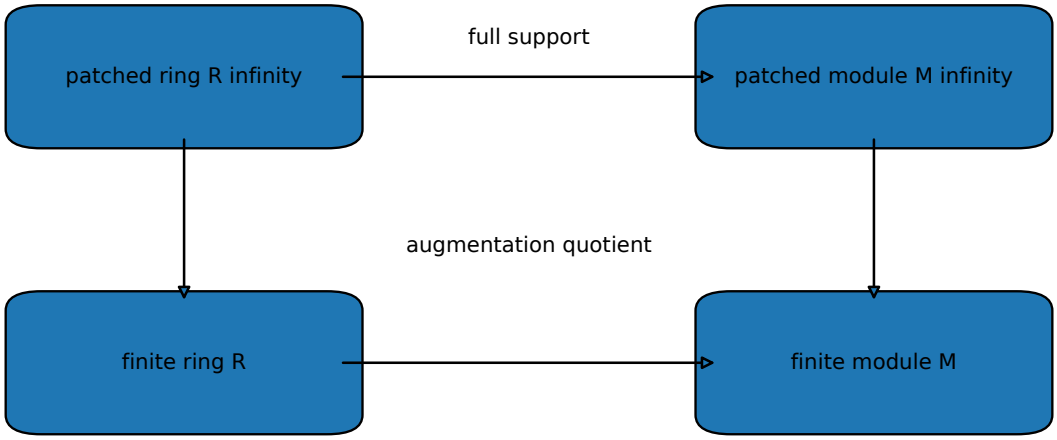

Figure 7. Full support at the patched level descends through the augmentation quotient.

Proof. Apply theorem 6.9 with $I = \mathfrak{a}$. The support of the quotient is

$$\operatorname{Spec} R_\infty \cap V(\mathfrak{a}) = V(\mathfrak{a}),$$

which identifies with $\operatorname{Spec} R$. The remaining statements follow from theorem 6.7. □

Corollary 6.12 (Componentwise finite level occupancy)**.** *In the setting of theorem 6.11, every irreducible component of* $\operatorname{Spec} R$ *is contained in the support of* M*. In particular, no component of the finite level deformation ring is erased by the quotient from the patched level.*

Proof. The module M has full support by theorem 6.11. □

Example 6.13 (Freeness over auxiliary variables is not enough)**.** Let k be a field, let $S = k[[t]]$, and put

$$R = S[[x]]/(x(x - t)).$$

The ring R is reduced and has two irreducible components. Let

$$M = R/(x) \cong S.$$

Then M is free of rank one over S, but

$$\operatorname{Supp}_R(M) = V(x)$$

is only one component of $\operatorname{Spec} R$. Thus freeness over the auxiliary power series ring does not imply full support over the deformation ring.

Proof. The two nonassociate prime factors x and $x - t$ occur with multiplicity one, so the principal quotient is reduced. The displayed isomorphism makes M free over S. Its annihilator as an R module is (x), hence

$$\operatorname{Supp}_R(M) = V(x)$$

by theorem 6.2. The generic point $(x - t)$ of the other component does not contain x, so it is not in the support. □

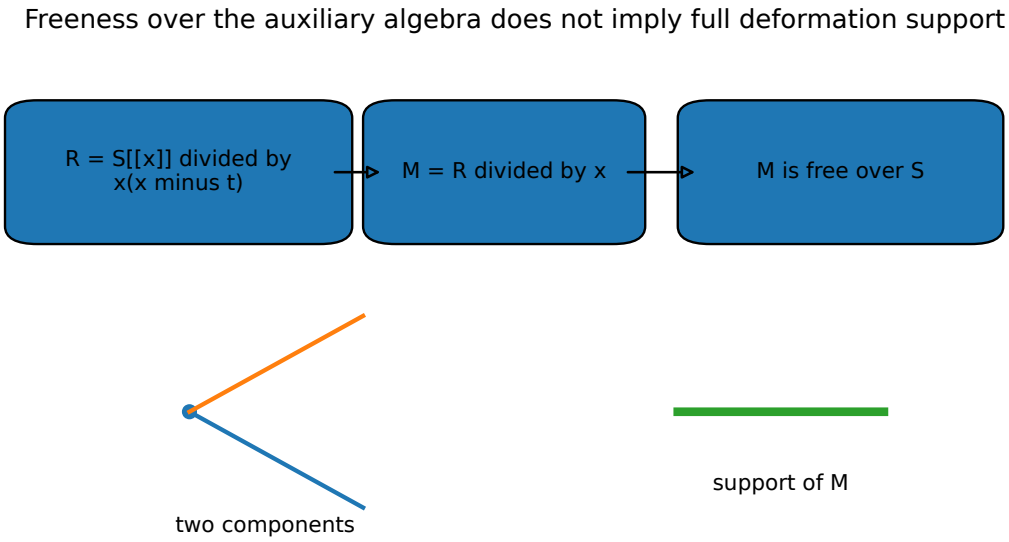

Figure 8. A module can be free over the auxiliary ring while occupying only one deformation component.

Derived patching replaces one module by a perfect complex. The correct support is detected after derived specialization.

Definition 6.14 (Derived support)**.** Let R be a commutative ring and let C be a perfect complex of R modules. Its derived support is

$$\operatorname{Supp}_R(C) = \left\{ \mathfrak{p} \in \operatorname{Spec} R : C \overset{\mathbf{L}}{\otimes}_R \kappa(\mathfrak{p}) \not\simeq 0 \right\}.$$

Standard Fact 6.15 (Cohomological description of derived support)**.** If R is Noetherian and C is perfect, then

$$\operatorname{Supp}_R(C) = \bigcup_i \operatorname{Supp}_R H^i(C).$$

In particular, derived support is closed and is empty exactly when $C \simeq 0$ [26, 11].

Theorem 6.16 (Derived quotient support)**.** *Let R be a commutative ring, let $I \subseteq R$ be an ideal, and let C be a perfect complex over R. Under $\operatorname{Spec}(R/I) \cong V(I)$, one has*

$$\boxed{\operatorname{Supp}_{R/I}\left(C \overset{\mathbf{L}}{\otimes}_R R/I \right) = \operatorname{Supp}_R(C) \cap V(I).}$$

Proof. Choose a bounded complex P of finite projective R modules representing C. Scalar extension to a commutative R algebra S is computed degree by degree as $S \otimes_R P$. The canonical symmetry of tensor products gives the displayed order $C \otimes^{\mathbf{L}}_R S$. Scalar extension preserves the bounds, finite generation, and projectivity of the terms. A derived isomorphism between two such projective models lifts to a homotopy equivalence, which scalar extension preserves. The resulting derived object and its residue field fibers are therefore independent of the chosen model.

Let $q \in \operatorname{Spec}(R/I)$, and let $\mathfrak{p}$ be its inverse image in R. The composite point $R \to R/I \to \kappa(q)$ has kernel $\mathfrak{p}$, so it factors through a field embedding $\kappa(\mathfrak{p}) \to \kappa(q)$. The ordinary tensor associator in every degree gives an isomorphism of complexes

$$\kappa(q) \otimes_{R/I} \left((R/I) \otimes_R P \right) \cong \kappa(q) \otimes_R P \cong \kappa(q) \otimes_{\kappa(\mathfrak{p})} \left(\kappa(\mathfrak{p}) \otimes_R P \right).$$

Extension of fields is faithfully flat. It preserves and reflects exactness in each degree, hence also acyclicity. The left-hand complex is thus nonzero in the derived category exactly when the residue field fiber of C at $\mathfrak{p}$ is nonzero. This proves the support identity on corresponding primes. The image of $\operatorname{Spec}(R/I) \to \operatorname{Spec} R$ is exactly $V(I)$, giving the stated ambient spectrum equality, including the case $I = R$. □

Definition 6.17 (Derived patching datum)**.** A derived patching datum consists of a Noetherian ring R_∞, an ideal $\mathfrak{a}$, a perfect complex C_∞ over R_∞, and identifications

$$R \cong R_\infty/\mathfrak{a}, \qquad C \simeq C_\infty \overset{\mathbf{L}}{\underset{R_\infty}{\otimes}} R.$$

Theorem 6.18 (Derived patching support descent)**.** *Let $(R_\infty, \mathfrak{a}, C_\infty, R, C)$ be a derived patching datum. If*

$$\operatorname{Supp}_{R_\infty}(C_\infty) = \operatorname{Spec} R_\infty,$$

then

$$\boxed{\operatorname{Supp}_R(C) = \operatorname{Spec} R.}$$

For every point $x : R \to E'$ to a field, the derived fiber

$$C \overset{\mathbf{L}}{\underset{R,x}{\otimes}} E'$$

is nonzero.

Proof. Apply theorem 6.16 to the patched complex and use the actual ring identification $R \cong R_\infty/\mathfrak{a}$. Full patched support restricts to $V(\mathfrak{a})$, which corresponds to all of $\operatorname{Spec} R$. The supplied derived isomorphism with C preserves this support by the projective model argument in that theorem.

For a field valued point $x : R \to E'$, put $\mathfrak{p} = \ker x$. The point factors as $R \to \kappa(\mathfrak{p}) \to E'$, where the second map is a field embedding. Tensor association on a projective model identifies the fiber at x with the extension to E' of the fiber at $\mathfrak{p}$. The latter is nonzero by full support. Faithful flatness of the field extension reflects exactness in every degree, so the fiber at x is nonzero as well. This applies to every field valued point, with no closed point restriction. □

Corollary 6.19 (A nonzero cohomological degree survives)**.** *Under the hypotheses of theorem 6.18, for every field valued point $x : R \to E'$, there is an integer i such that*

$$H^i\left(C \overset{\mathbf{L}}{\underset{R,x}{\otimes}} E'\right) \neq 0.$$

Proof. The derived fiber is nonzero by theorem 6.18. If every cohomology object vanished, a cochain model of that fiber would be acyclic. Its image in the derived category would then be zero, a contradiction. Hence some integer degree has nonzero cohomology. □

Remark 6.20. The support theorem does not decide the cohomological degree in which the point occurs. It also does not prove that the surviving class is classical. Those are separate arithmetic inputs.

7 Transport through an isomorphism $R \cong \mathbb{T}$

An isomorphism between a deformation ring and a Hecke algebra is an exact coordinate change. It transports support and finite presentation data, but it does not create a supported module.

Theorem 7.1 (Support and Fitting transport)**.** *Let $\varphi : R \to \mathbb{T}$ be an isomorphism of Noetherian rings. Let M be a finite $\mathbb{T}$ module, viewed as an R module through φ. Then the homeomorphism*

$$\varphi^* : \operatorname{Spec} \mathbb{T} \longrightarrow \operatorname{Spec} R$$

satisfies

$$\boxed{\varphi^*\big(\operatorname{Supp}_{\mathbb{T}}(M)\big) = \operatorname{Supp}_R(M).}$$

For every $j \geq 0$,

$$\boxed{\varphi\left(\operatorname{Fitt}_j^R(M)\right) = \operatorname{Fitt}_j^{\mathbb{T}}(M).}$$

Proof. Localization commutes with transport along an isomorphism, so a localization of M vanishes on one side exactly when the corresponding localization vanishes on the other. This proves the support identity. A finite presentation matrix over R is carried entry by entry to a presentation matrix over $\mathbb{T}$. The minors generating each Fitting ideal are therefore carried to the corresponding minors. □

Corollary 7.2 (Full support is invariant under $R \cong \mathbb{T}$)**.** *In the setting of theorem 7.1, M has full R support if and only if it has full $\mathbb{T}$ support.*

Proof. Apply the support homeomorphism in theorem 7.1. □

Proposition 7.3 (A quotient can erase a component)**.** *Let*

$$R = k[[x, y]]/(xy)$$

and let

$$\mathbb{T} = R/(x) \cong k[[y]].$$

Viewed as an R module, $\mathbb{T}$ has support $V(x)$, which misses the generic point (y) of the other irreducible component. Thus a surjection $R \twoheadrightarrow \mathbb{T}$ does not by itself imply full component occupancy.

Proof. The annihilator of the R module $\mathbb{T}$ is (x). Hence its support is $V(x)$ by theorem 6.2. The prime (y) does not contain x, so it is not in this support. □

Theorem 7.4 (Field fiber criterion)**.** *Let R be a commutative ring, let M be a finite R module, and let $x : R \to E'$ be a homomorphism to a field. Put $\mathfrak{p} = \ker x$. Then*

$$\boxed{M \otimes_{R,x} E' \neq 0 \quad \Longleftrightarrow \quad \mathfrak{p} \in \operatorname{Supp}_R(M).}$$

Proof. The map x factors through the local ring $R_{\mathfrak{p}}$ and then through an embedding of the residue field $\kappa(\mathfrak{p})$ into E'. Since M is finite, Nakayama's lemma gives

$$M_{\mathfrak{p}} \neq 0 \quad \Longleftrightarrow \quad M \otimes_R \kappa(\mathfrak{p}) \neq 0.$$

Extension of scalars from $\kappa(\mathfrak{p})$ to E' preserves nonzero vector spaces. □

Corollary 7.5 (Supported deformation points give nonzero Hecke fibers)**.** *Let $R \cong \mathbb{T}$, and let M be a finite Hecke module. If a point $x : R \to E'$ lies in $\operatorname{Supp}_R(M)$, then the corresponding Hecke fiber*

$$M \otimes_{\mathbb{T},x} E'$$

is nonzero.

Proof. Transport the support through theorem 7.1, then apply theorem 7.4. □

8 Finite Hecke packets and infinite occupancy

Finite Hecke carriers admit canonical packets even when the Hecke action is not semisimple. The packets come from the Artin local factors of the finite commutative Hecke algebra.

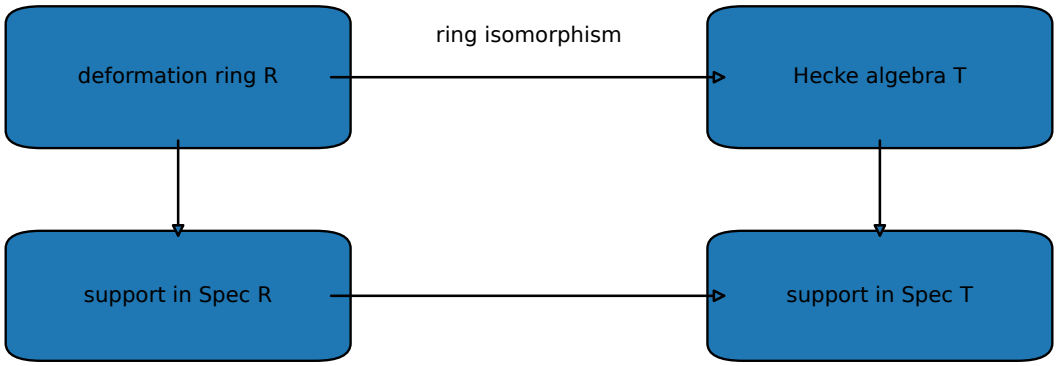

Figure 9. An isomorphism transports occupied support exactly. A quotient can remove a component.

Standard Fact 8.1 (Artin decomposition)**.** Let E' be a field and let $\mathbb{T}$ be a finite dimensional commutative E' algebra. Then

$$\boxed{\mathbb{T} \cong \prod_{\mathfrak{m} \in \operatorname{Max} \mathbb{T}} \mathbb{T}_{\mathfrak{m}}.}$$

Each factor is an Artin local algebra. Equivalently, there is a unique complete family of central idempotents $(e_{\mathfrak{m}})$ such that

$$e_{\mathfrak{m}} e_{\mathfrak{n}} = 0 \quad (\mathfrak{m} \neq \mathfrak{n}), \qquad \sum_{\mathfrak{m}} e_{\mathfrak{m}} = 1,$$

and $e_{\mathfrak{m}} \mathbb{T} \cong \mathbb{T}_{\mathfrak{m}}$ [2, 15].

Theorem 8.2 (Canonical Hecke packet decomposition)**.** *Let $\mathbb{T}$ be a finite dimensional commutative algebra over a field E', and let V be a finite $\mathbb{T}$ module. Then*

$$\boxed{V = \bigoplus_{\mathfrak{m} \in \operatorname{Max} \mathbb{T}} e_{\mathfrak{m}} V.}$$

For every maximal ideal $\mathfrak{m}$, the canonical map gives

$$\boxed{e_{\mathfrak{m}} V \cong V_{\mathfrak{m}}.}$$

The packet $e_{\mathfrak{m}} V$ is nonzero exactly when $\mathfrak{m} \in \operatorname{Supp}_{\mathbb{T}}(V)$.

Proof. The idempotent relations in standard fact 8.1 give the direct sum decomposition. Localization at $\mathfrak{m}$ kills every factor except the $\mathfrak{m}$ factor, where $e_{\mathfrak{m}}$ becomes one. Thus the localization map identifies $e_{\mathfrak{m}} V$ with $V_{\mathfrak{m}}$. The final statement is the definition of support. □

Corollary 8.3 (Simultaneous generalized eigenspaces)**.** *Assume that E' is algebraically closed and that $\mathbb{T}$ is generated by commuting operators $T_1, \dots, T_d$ on V. For a maximal ideal*

$$\mathfrak{m} = (T_1 - \lambda_1, \dots, T_d - \lambda_d),$$

there is an integer $N \geq 1$ such that

$$\boxed{e_{\mathfrak{m}} V = \left\{ v \in V : (T_i - \lambda_i)^N v = 0 \text{ for every } i \right\}.}$$

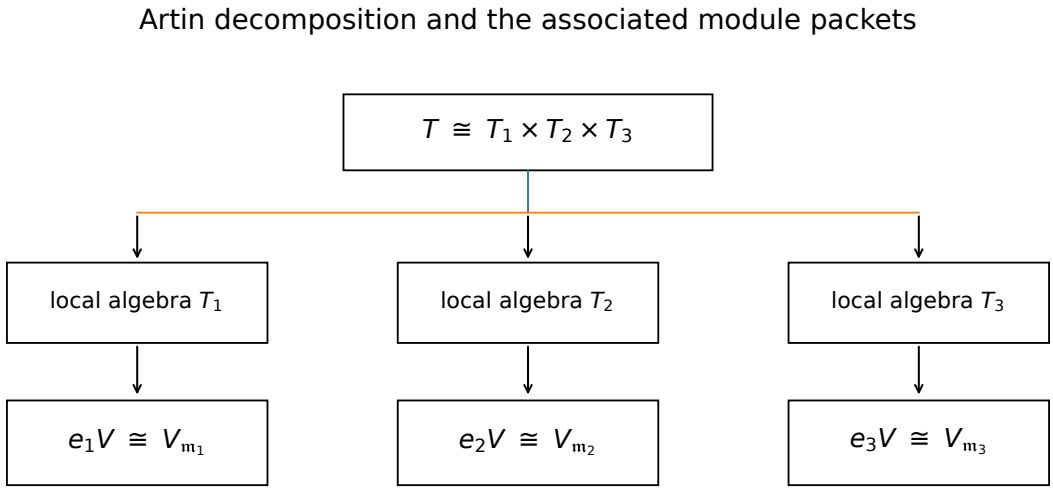

Figure 10. A finite commutative Hecke algebra splits into canonical Artin local packets.

Thus the canonical Artin packet is the simultaneous generalized eigenspace.

Proof. The maximal ideal of the Artin local algebra $\mathbb{T}_{\mathfrak{m}}$ is nilpotent. Hence a common power of every $T_i - \lambda_i$ kills the local packet. On every other local factor, at least one $T_i - \lambda_i$ is a unit, so no nonzero vector can satisfy all the displayed nilpotence conditions.

Conversely, suppose every $(T_i - \lambda_i)^N$ kills v. Every monomial of total degree greater than $d(N-1)$ contains one factor to exponent at least N. Therefore a power of $\mathfrak{m}$ kills v, which places v in the $\mathfrak{m}$ primary packet. □

Corollary 8.4 (Rank and trace detection in characteristic zero)**.** *Assume that E' has characteristic zero. For every maximal Hecke packet,*

$$\boxed{\operatorname{Tr}_{E'}(e_{\mathfrak{m}}|V) = \operatorname{rank}_{E'}(e_{\mathfrak{m}}|V) = \dim_{E'} e_{\mathfrak{m}}V.}$$

In particular, the packet is occupied exactly when its projector has positive rank, equivalently nonzero trace.

Proof. An idempotent linear map has minimal polynomial dividing $X(X-1)$, which has distinct roots. It is diagonalizable with eigenvalues zero and one. Its trace and rank both equal the multiplicity of the eigenvalue one. A positive integer is nonzero in characteristic zero. □

Remark 8.5. The trace criterion can fail in positive characteristic when the packet dimension is divisible by the characteristic. The rank and localization criteria remain valid.

Example 8.6 (A nonsemisimple Hecke packet)**.** Let

$$\mathbb{T} = E'[u]/(u^2) \times E'[v]/(v^3)$$

and let $V = \mathbb{T}$ be the regular module. The two canonical central idempotents split

$$V = V_u \oplus V_v$$

with dimensions two and three. Multiplication by u is nilpotent on V_u, and multiplication by v is nilpotent on V_v. Neither local factor is semisimple, but the two maximal Hecke packets are isolated exactly by the Artin idempotents.

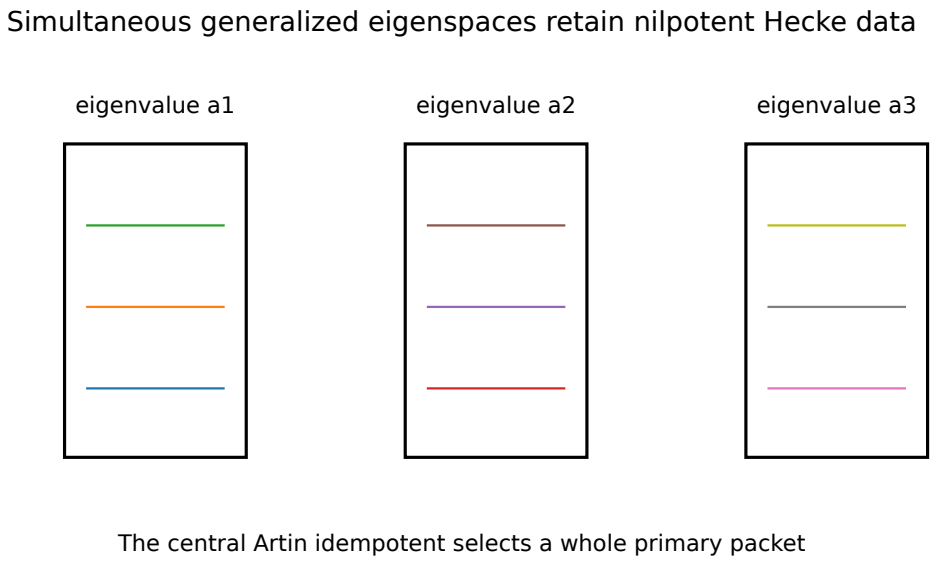

Figure 11. An Artin packet is a simultaneous generalized eigenspace, not necessarily an ordinary eigenspace.

Proof. The product decomposition gives the two central idempotents $(1,0)$ and $(0,1)$. Their ranges are the two local factors. The classes of u and v are nilpotent of orders two and three, respectively. □

The next two theorems distinguish a fixed finite carrier from a sequence of changing carriers.

Theorem 8.7 (Nested packets in one finite carrier)**.** *Let V be a finite dimensional vector space. Let $e_1, e_2, \dots$ be idempotents such that*

$$e_{m+1}e_m = e_m e_{m+1} = e_{m+1}$$

for every m. If $e_m V \neq 0$ for every m, then the descending chain stabilizes and

$$\boxed{\bigcap_{m\geq 1} e_m V \neq 0.}$$

Proof. The displayed relations give

$$e_{m+1}V \subseteq e_m V.$$

The nonnegative dimensions form a nonincreasing sequence of positive integers, so they eventually become constant. Once two consecutive dimensions agree, the corresponding inclusion is equality. Thus the ranges stabilize at a nonzero subspace, which is their intersection. □

Corollary 8.8 (Finite witness of incompatibility)**.** *Under the hypotheses of theorem 8.7, if*

$$\bigcap_{m\geq 1} e_m V = 0,$$

then $e_m V = 0$ for some finite m.

Proof. This is the contrapositive of theorem 8.7. □

Definition 8.9 (Stable core)**.** Let

$$V_1 \longleftarrow V_2 \longleftarrow V_3 \longleftarrow \cdots$$

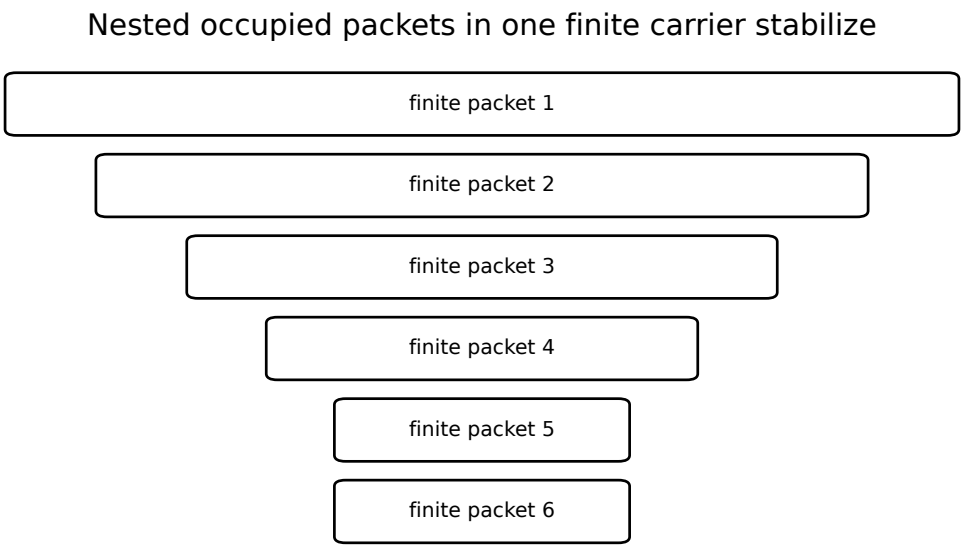

Figure 12. Nested nonzero packets in one finite carrier stabilize after finitely many steps.

be an inverse system of finite dimensional vector spaces. For $n \geq m$, write $f_{n,m} : V_n \to V_m$. The stable core at level m is

$$Y_m = \bigcap_{n \geq m} \operatorname{im}(f_{n,m}).$$

Lemma 8.10 (Surjectivity on stable cores)**.** *For every m, the transition map $V_{m+1} \to V_m$ induces a surjection*

$$\boxed{Y_{m+1} \twoheadrightarrow Y_m.}$$

Proof. Fix $y \in Y_m$. For $n \geq m+1$, let

$$A_n = \{z \in \operatorname{im}(f_{n,m+1}) : f_{m+1,m}(z) = y\}.$$

Each A_n is a nonempty affine subspace of V_{m+1}, and the sequence (A_n) is descending. A descending sequence of affine subspaces in a finite dimensional vector space stabilizes whenever every term is nonempty. Choose an element in its stable value. It lies in Y_{m+1} and maps to y. □

Theorem 8.11 (Nonzero stable core criterion)**.** *Let (V_m) be an inverse system of finite dimensional vector spaces. If*

$$Y_m \neq 0$$

for every m, then

$$\boxed{\varprojlim_m V_m \neq 0.}$$

More precisely, the inverse limit contains a compatible sequence whose first coordinate is any prescribed nonzero element of Y_1.

Proof. Choose $0 \neq y_1 \in Y_1$. By lemma 8.10, choose recursively $y_{m+1} \in Y_{m+1}$ mapping to y_m. Every y_m is nonzero because it maps to the nonzero vector y_1. The sequence (y_m) is a nonzero element of the inverse limit. □

Corollary 8.12 (Surjective systems)**.** *If every transition map $V_{m+1} \to V_m$ is surjective and every V_m is nonzero, then the inverse limit is nonzero.*

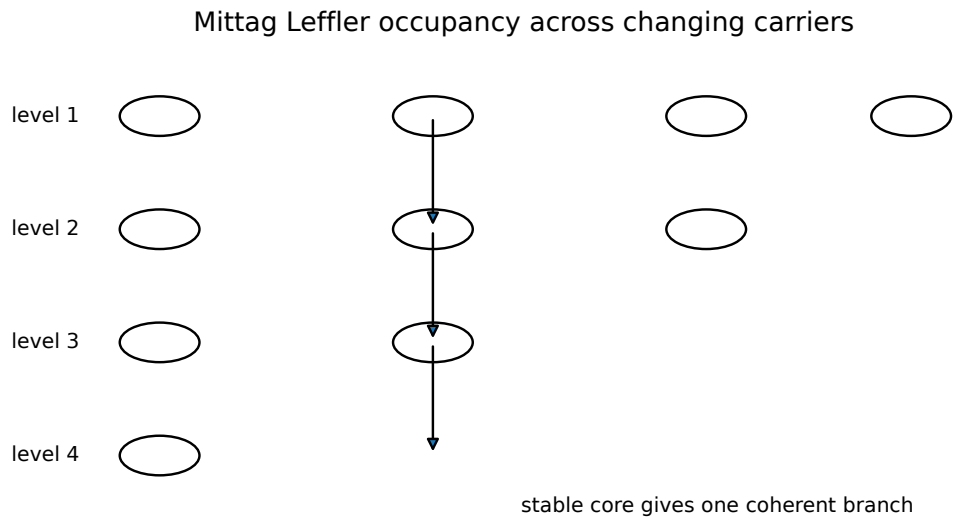

Figure 13. Changing finite carriers require a nonzero stable core, not only nonzero individual levels.

Proof. Surjectivity gives $Y_m = V_m$. Apply theorem 8.11. □

Example 8.13 (Tail escape in an infinite carrier)**.** Let $V = \ell^2(\mathbb{N})$, and let P_m be the orthogonal projection onto the closed span of

$$e_m, e_{m+1}, e_{m+2}, \dots.$$

Every range $P_m V$ is nonzero and the ranges are nested, but

$$\boxed{\bigcap_{m \geq 1} P_m V = 0.}$$

Thus the finite carrier hypothesis in theorem 8.7 cannot be removed.

Proof. A vector in every tail range has its first $m-1$ coordinates equal to zero for every m. All of its coordinates vanish. □

9 Pointwise automorphy from support

Support produces a nonzero Hecke fiber. A realization theorem is still required to turn that fiber into a classical automorphic representation and to identify its Galois representation.

Definition 9.1 (Automorphic Hecke datum)**.** An automorphic Hecke datum consists of the following objects.

(1) A commutative $\mathcal{O}$ algebra $\mathbb{T}$.
(2) A finite $\mathbb{T}$ module H, or a perfect $\mathbb{T}$ complex C, obtained from an automorphic or cohomological carrier.
(3) For every unramified place v outside a finite set, a polynomial
$$P_v(X) \in \mathbb{T}[X].$$
(4) A declared characteristic zero locus on which a nonzero field fiber is known to be classical and is known to carry an attached Galois representation whose Frobenius polynomial at v is the specialization of $P_v(X)$.

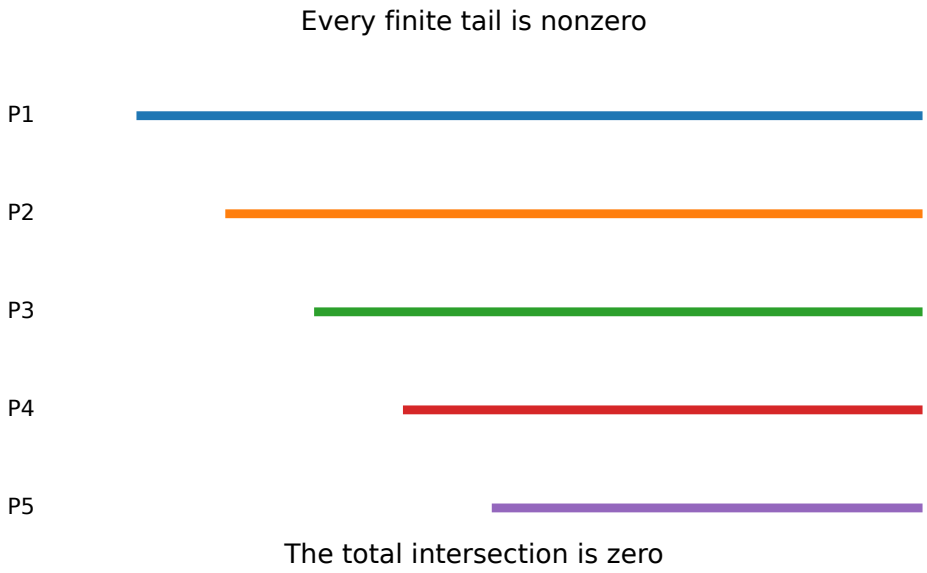

Figure 14. Nested nonzero ranges can escape to infinity in an infinite dimensional carrier.

Standard Fact 9.2 (Chebotarev and Brauer Nesbitt identification)**.** Let E' be a Hausdorff topological field of characteristic zero, with continuous ring operations. Let

$$\rho_1, \rho_2 : G_{F,S} \longrightarrow \mathrm{GL}_n(E')$$

be continuous semisimple representations. If their characteristic polynomials agree at every Frobenius element outside a density zero exceptional set, then

$$\boxed{\rho_1 \cong \rho_2.}$$

This follows from Chebotarev density and the Brauer Nesbitt theorem [5, 18, 12].

Theorem 9.3 (Support gives a Hecke eigensystem)**.** *Let $R \cong \mathbb{T}$, let H be a finite $\mathbb{T}$ module, and let $x : R \to E'$ be a field valued point. If*

$$\ker x \in \mathrm{Supp}_R(H),$$

then

$$\boxed{H_x := H \otimes_{\mathbb{T},x} E' \neq 0.}$$

Every element of $\mathbb{T}$ acts on H_x through the scalar prescribed by x.

Proof. Nonvanishing follows from corollary 7.5. The tensor product relation

$$th \otimes 1 = h \otimes x(t)$$

shows that $t \in \mathbb{T}$ acts through $x(t)$. □

Theorem 9.4 (Pointwise Galois realization)**.** *Let E' be a Hausdorff topological field of characteristic zero, with continuous ring operations. Require both $\rho_x = x \circ \rho_R$ and the attached representation below to be continuous. Assume the following data.*

(1) A represented deformation ring R with universal representation

$$\rho_R : G_{F,S} \longrightarrow \mathrm{GL}_n(R).$$

(2) An isomorphism $R \cong \mathbb{T}$.

(3) An automorphic Hecke datum $(\mathbb{T}, H, (P_v))$.

(4) *A characteristic zero point* $x : R \to E'$ *lying in* $\operatorname{Supp}_R(H)$.

(5) *A classical automorphic representation* π_x *occurring in the fiber* H_x*, together with a semisimple attached representation*

$$\rho_{\pi_x} : G_{F,S} \longrightarrow \mathrm{GL}_n(E')$$

whose unramified characteristic polynomial is $x(P_v(X))$.

(6) *Equality*

$$\det\left(X - \rho_x(\mathrm{Frob}_v)\right) = x(P_v(X))$$

for $\rho_x = x \circ \rho_R$ *at every unramified place in a Chebotarev dense set.*

Then

$$\boxed{\rho_x^{\mathrm{ss}} \cong \rho_{\pi_x}.}$$

If ρ_x *is irreducible, then* $\rho_x \cong \rho_{\pi_x}$.

Proof. The coefficients of the characteristic polynomials of ρ_x and ρ_{π_x} are continuous and constant on conjugacy classes. Their equality on the declared dense union of Frobenius conjugacy classes therefore extends to every element of $G_{F,S}$, by Hausdorffness. A semisimplification has the same characteristic polynomials as the original representation. The algebraic Brauer Nesbitt input in standard fact 9.2 thus gives $\rho_x^{\mathrm{ss}} \cong \rho_{\pi_x}$. If ρ_x is irreducible, it is already semisimple. □

Corollary 9.5 (Full support gives pointwise automorphy on the realized locus)**.** *In the setting of theorem 9.4, suppose*

$$\operatorname{Supp}_R(H) = \operatorname{Spec} R.$$

For every characteristic zero point $x : R \to E'$ *with* $\ker x \in U \subseteq \operatorname{Spec} R$*, assume the coefficient topology and continuity hypotheses of theorem 9.4 and the declared classicality and Galois realization input. Then every such point is automorphic in the precise sense of theorem 9.4.*

Proof. Every point of U lies in the support, so theorem 9.3 gives a nonzero Hecke fiber. Apply the declared realization input and then theorem 9.4. □

Theorem 9.6 (Derived pointwise realization)**.** *Let* $e : R \cong \mathbb{T}$*, and let* C *be a perfect automorphic Hecke complex with full derived support. Choose a bounded finite projective model for* C*, supported in degrees* $[a, b]$*. For every characteristic zero point* $x : R \to E'$*, write* $y = x \circ e^{-1}$*. Then some integer* $i \in [a, b]$ *has*

$$H^i\left(C \overset{\mathbf{L}}{\underset{\mathbb{T},y}{\otimes}} E'\right) \neq 0.$$

Every $t \in \mathbb{T}$ *acts on this cohomology through* $y(t)$.

For the realization conclusion, give E' *a Hausdorff topological field structure. Supply a universal representation* ρ_R*, a continuous specialization* $\rho_x = x \circ \rho_R$*, and a semisimplification of* ρ_x*. Suppose its characteristic polynomials on a Chebotarev dense set are* $y(P_v(X))$*. Let the declared classicality range contain* $[a, b]$*. Assume that every nonzero Hecke eigensystem in that range is realized by a classical automorphic representation occurring in that degree, with a continuous semisimple attached representation whose characteristic polynomials on the same dense set are* $y(P_v(X))$*. With the standard Chebotarev density and Brauer Nesbitt inputs of standard fact 9.2, the specialization* ρ_x *is automorphic after semisimplification. If* ρ_x *is irreducible, it is itself isomorphic to the attached representation.*

Proof. Full derived support gives a nonzero fiber at y. Scalar extension of the chosen projective model preserves its degree bounds. Its cohomology therefore vanishes below a and above b. Since vanishing in every degree is equivalent to being zero in the derived category, some degree $i \in [a, b]$ has nonzero cohomology. Choose a nonzero vector in that cohomology module.

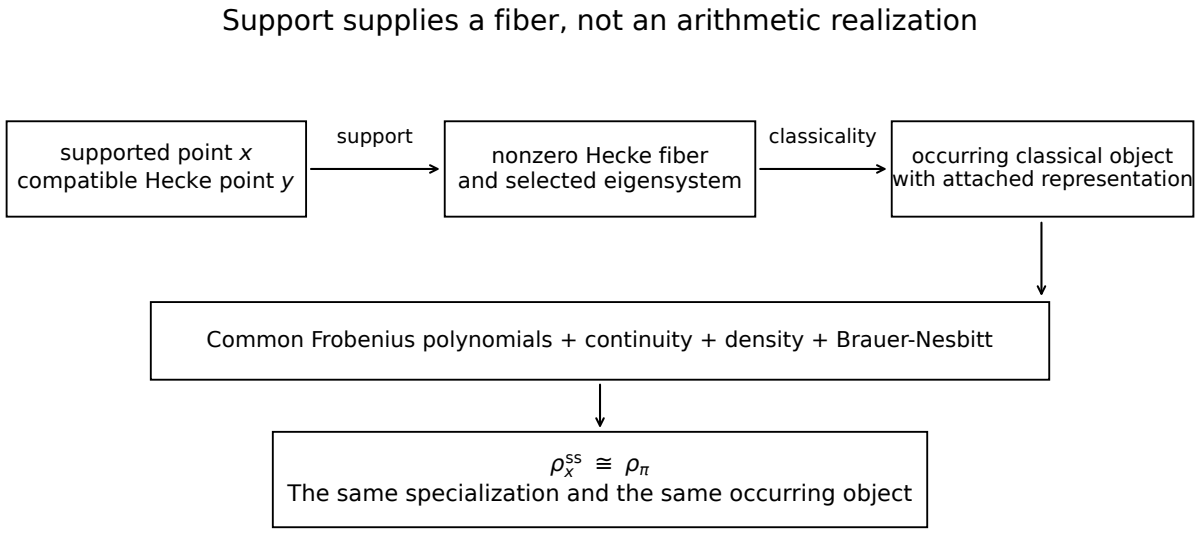

Figure 15. Support gives a nonzero Hecke fiber. Classicality and Galois realization complete the pointwise argument.

Multiplication by $t \in \mathbb{T}$ is a cochain endomorphism of the original model. In the scalar extension the tensor relation identifies this endomorphism with $y(t)$ times the identity. Passing to the derived category and then to cohomology preserves this equality. Thus the chosen vector is a common Hecke eigenvector with character y.

The interval inclusion puts this eigensystem in the declared classicality range. Apply the realization input to obtain an occurring automorphic representation and its continuous semisimple attached representation. Its Frobenius characteristic polynomials agree with those of ρ_x on the prescribed dense set. Continuity extends the equality to every group element. The supplied semisimplification preserves these polynomials, so the general Brauer Nesbitt input gives an invertible linear intertwiner. If ρ_x is irreducible, it is already semisimple and the same comparison applies directly. □

Remark 9.7. Derived support does not identify the cohomological degree, Hodge type, or classical weight of the surviving eigensystem. Those properties must come from the external local and global realization theorem.

10 Compatible systems and companion completion

Pointwise automorphy at one coefficient place and existence of companions at other coefficient places are different statements. They meet only after a common algebraic Frobenius spine has been fixed.

Definition 10.1 (Algebraic Frobenius spine)**.** An algebraic Frobenius spine consists of a number field L, a finite set of places S of F, and polynomials

$$P_v(X) \in L[X]$$

for every finite place $v \notin S$, together with any additional local labels required by the declared compatibility problem.

Definition 10.2 (Finite companion forest)**.** Fix a coefficient place λ of L. A finite companion forest for the spine is an inverse system of finite sets

$$X_{\lambda,1} \longleftarrow X_{\lambda,2} \longleftarrow X_{\lambda,3} \longleftarrow \cdots$$

whose points are admissible realizations modulo λ^m, with edges given by reduction. A complete realization is admissible for this forest when all its finite reductions belong to the displayed levels; the empty level obstruction below concerns this declared admissibility problem.

Theorem 10.3 (Companion branch criterion)**.** *Suppose every level $X_{\lambda,m}$ is finite and nonempty, and every point reduces along the displayed forest to the fixed residual root. Then*

$$\boxed{\varprojlim_m X_{\lambda,m} \neq \varnothing.}$$

Proof. The disjoint union of the levels is an infinite rooted tree. It is locally finite because every level is finite. It contains a vertex at every depth. König's infinity lemma gives an infinite branch [10]. That branch is a point of the inverse limit. □

Corollary 10.4 (Empty finite companion obstruction)**.** *If $X_{\lambda,m} = \varnothing$ for some m, then no complete λ adic realization admissible for this forest exists.*

Proof. A complete realization would reduce to a point at every finite level. □

Finite forests alone give compatible classes. To obtain actual continuous representations, we use the following explicit coefficient and admissibility data. They also delimit the meaning of completion in the next theorem.

Fix a topological group Γ, a finite matrix index set D, and a set Λ of coefficient indices. For each λ, let $\mathcal{O}_\lambda$ be a commutative ring, complete and separated for a finitely generated ideal I_λ, with finite residue ring $\mathcal{O}_\lambda/I_\lambda$. Give $\mathcal{O}_\lambda$ its ideal adic topology and every quotient its discrete topology. Let

$$i_\lambda : \mathcal{O}_\lambda \longrightarrow K_\lambda, \qquad e_\lambda : L \longrightarrow K_\lambda$$

be supplied ring homomorphisms, where L and K_λ are fields, K_λ has a declared topology, and i_λ is continuous.

For every positive integer n, let $X_{\lambda,n}$ be a finite nonempty set of conjugacy classes of actual continuous representations

$$\Gamma \longrightarrow \mathrm{GL}_D(\mathcal{O}_\lambda/I_\lambda^n).$$

Conjugacy means change of basis by an invertible matrix over that quotient. Assume reduction preserves these sets and that $X_{\lambda,1}$ consists of the declared residual class. Each admissible class must have a continuous representative. The auxiliary level zero is the unique class over the trivial quotient and imposes no extra occupancy hypothesis.

Choose elements $\gamma_v \in \Gamma$ on a sample set Ω, with declared good subsets $\Omega_\lambda \subseteq \Omega$. In the arithmetic application these are the chosen Frobenius elements at the permitted places. For each $v \in \Omega_\lambda$, supply an integral polynomial $P_{\lambda,v} \in \mathcal{O}_\lambda[X]$ such that

$$i_\lambda(P_{\lambda,v}) = e_\lambda(P_v) \quad \text{in } K_\lambda[X].$$

Here and below a ring homomorphism applied to a polynomial acts on its coefficients. Assume every representative of every class in $X_{\lambda,n}$ has characteristic polynomial $P_{\lambda,v}$ mod I_λ^n at γ_v. Also supply a subgroup $H_\lambda \leq \Gamma$ on which all these finite representations are trivial. This is an inertia condition when H_λ is the specified inertia subgroup.

Finally, put

$$B_\lambda = \mathcal{O}_\lambda[x_{g,a,b} : g \in \Gamma,\ a, b \in D].$$

For each declared local condition index u, supply an ideal $J_{\lambda,u} \subseteq B_\lambda$. Evaluation at a representation sends $x_{g,a,b}$ to its (a,b) matrix entry at g. Assume that evaluation at every admissible finite representative kills $J_{\lambda,u}$, with polynomial coefficients reduced modulo I_λ^n. For this class based theorem, the equations must hold in every admissible frame. A condition imposed only in one chosen frame needs a separate compatible frame argument. No arbitrary arithmetic condition is identified with such an ideal without a separate argument.

Theorem 10.5 (Conditional simultaneous companion completion)**.** *Under the coefficient and finite admissibility hypotheses above, one can choose continuous representations*

$$\rho_\lambda : \Gamma \longrightarrow \mathrm{GL}_D(\mathcal{O}_\lambda) \qquad (\lambda \in \Lambda)$$

whose reduction class belongs to $X_{\lambda,n}$ for every positive n. They retain the declared residual class. After applying i_λ, they are continuous, trivial on H_λ, and satisfy

$$\det(X - i_\lambda(\rho_\lambda(\gamma_v))) = e_\lambda(P_v), \qquad v \in \Omega_\lambda.$$

Their integral evaluation points factor through every actual quotient $B_\lambda / J_{\lambda,u}$.

Proof. The finitely generated ideal and finite residue ring give finite coefficient quotients at every precision. An individual conjugacy class has finitely many frames because the group of invertible basis matrices over each quotient is finite. Thus the finitely many admissible classes give a finite nonempty set of actual continuous representations at each positive level. Continuity is invariant under conjugation. Reduction gives total maps between these sets. Compactness, as in theorem 10.3, selects strictly compatible representatives. This step neither assumes transition surjectivity nor lifts a prescribed conjugating matrix.

Completeness and separatedness identify $\mathrm{GL}_D(\mathcal{O}_\lambda)$ with the compatible inverse limit of the quotient matrix groups. Lift entries and inverse entries to construct this identification. The two reduction and reconstruction identities hold entrywise. Finite quotient continuity implies continuity for the ideal adic topology, including the matrix inverse, so the reconstructed representation is continuous.

Each coefficient of its characteristic polynomial agrees with the prescribed integral coefficient modulo every positive power of I_λ. Separatedness gives equality of the full polynomials. The same argument applied to the matrix entries of $\rho_\lambda(g) - 1$ gives triviality on H_λ. Continuous coefficient change and the matching equations for $P_{\lambda,v}$ give the asserted common spine over the local fields.

For $p \in J_{\lambda,u}$, evaluation commutes with reduction. Its value is zero modulo every positive power of I_λ, hence is zero integrally by separatedness. Therefore the evaluation homomorphism kills the whole ideal and factors uniquely through $B_\lambda / J_{\lambda,u}$. Choose a realization for each λ. □

The quotient conclusion is a proved effectivity statement for the declared polynomial relations. For local conditions presented by continuous maps from represented local rings, corollary 3.2 also accounts for the closed ideal generated by their defining ideals. Neither statement constructs a deformation ring for a condition that has not been shown representable. Hodge conditions, Weil–Deligne conditions, integral lifts of arbitrary Frobenius polynomials, and the finite occupancy hypotheses still require their own arithmetic inputs. The theorem retains a residual conjugacy class, not a prescribed residual matrix frame, and asserts no uniqueness up to integral conjugacy.

Standard Fact 10.6 (Strict compatibility and one member determination)**.** A strictly compatible semisimple system is determined at every coefficient place by its common unramified characteristic polynomials. If an automorphic representation gives a compatible system with the same polynomials, then Chebotarev density and Brauer Nesbitt identify the two systems member by member after semisimplification [23, 3].

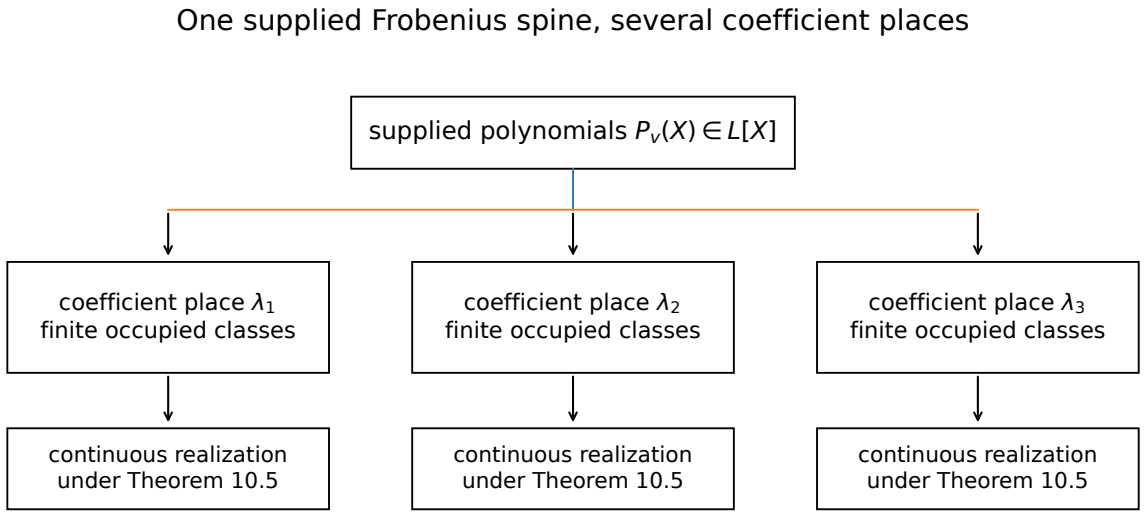

Figure 16. Under the coefficient and effectivity hypotheses of theorem 10.5, local companion branches realize the Frobenius spine fixed in advance.

Theorem 10.7 (One member propagation in a fixed system)**.** *Let*

$$\{\rho_\lambda\}_{\lambda\in\Lambda}$$

be a semisimple strictly compatible system with Frobenius spine (P_v). Suppose that for one coefficient place λ_0, the representation ρ_{λ_0} is identified with the Galois representation attached to an automorphic representation π. Assume that the compatible system attached to π has the same polynomials $P_v(X)$. Then for every $\lambda \in \Lambda$,

$$\boxed{\rho_\lambda \cong \rho_{\pi,\lambda}^{\mathrm{ss}}.}$$

Proof. For every λ, the two semisimple representations have the same unramified characteristic polynomials at all places outside one finite set. Apply standard fact 9.2. □

Remark 10.8. The theorem propagates automorphy inside a compatible system that already exists. It does not construct a missing coefficient place member and does not prove universal companion existence.

Proposition 10.9 (Finite Frobenius separator)**.** *Let $t_1, \dots, t_r$ be linearly independent functions on a set Ω with values in a field E'. Then there are points $\omega_1, \dots, \omega_r \in \Omega$ such that the matrix*

$$\big(t_i(\omega_j)\big)_{j,i}$$

is invertible. In particular, when the trace functions of finitely many compatible constituents are linearly independent on the unramified Frobenius set, finitely many Frobenius traces recover their multiplicities in any known semisimple carrier.

Proof. Let

$$W = \operatorname{span}\{(t_1(\omega), \dots, t_r(\omega)) : \omega \in \Omega\} \subseteq E'^r.$$

If $W \neq E'^r$, a nonzero linear functional on E'^r would vanish on every evaluation vector, giving a nontrivial linear relation among the functions. Thus $W = E'^r$. Choose r evaluation vectors forming a basis. □

11 The coefficient prime two

The auxiliary augmentation algebra works at every coefficient prime. What changes at two is the availability of integral character projectors and, in many applications, the residual image and local deformation hypotheses.

Proposition 11.1 (Failure of integral sign projectors)**.** *Let $C_2 = \langle g \rangle$. Over $\mathbb{Q}_2$, the two sign projectors are*

$$\boxed{e_+ = \frac{1+g}{2}, \qquad e_- = \frac{1-g}{2}.}$$

Neither belongs to $\mathbb{Z}_2[C_2]$. After reduction modulo two,

$$\boxed{\mathbb{F}_2[C_2] \cong \mathbb{F}_2[X]/(X^2), \qquad X = g - 1.}$$

This ring is local and has no nontrivial idempotents.

Proof. The displayed rational elements are the unique primitive idempotents because they project to the two characters of C_2. Their coefficients contain $1/2$, so they are not integral. In characteristic two,

$$(g-1)^2 = g^2 - 2g + 1 = 0.$$

The map $X \mapsto g - 1$ gives the displayed isomorphism. The quotient by (X) is $\mathbb{F}_2$, and (X) is nilpotent. Thus the ring is local. □

Corollary 11.2 (Dyadic coinvariant recovery)**.** *Let Δ be a finite two group, let $\Lambda = \mathcal{O}[\Delta]$ with $\mathcal{O}$ a finite extension of $\mathbb{Z}_2$, and let M be finite free over Λ. Then*

$$\boxed{M \otimes_{\Lambda,\epsilon} \mathcal{O} \cong M/\mathfrak{a}M}$$

is free over $\mathcal{O}$ of the same Λ rank. No semisimple character decomposition is required.

Proof. Use the right module convention fixed in section 5. Quotienting by all balancing relations identifies $M \otimes_{\Lambda,\epsilon} \mathcal{O}$ with $M/\mathfrak{a}M$, without any commutativity assumption on Δ. Applying ϵ to the coordinates of a finite Λ basis gives an $\mathcal{O}$ basis with the same index set. □

Remark 11.3. The corollary is an algebraic statement about augmentation and coinvariants. It does not supply a coefficient two adequacy theorem, a local deformation ring with the desired geometry, or a classicality theorem. Those inputs must be checked in the automorphy lifting theorem being used.

12 Conditional automorphic completion

The following theorem assembles the preceding statements as a chain of gates. Each gate has a distinct mathematical source.

Definition 12.1 (Ordinary completion datum at a point)**.** An ordinary completion datum at a characteristic zero point $x : R \to E'$ consists of the following objects.

(1) A represented global deformation ring R with declared local quotient conditions and universal representation ρ_R.

(2) An ordinary patching datum
$$(R_\infty, \mathfrak{a}, M_\infty, R, H)$$
whose finite level module H is an automorphic Hecke carrier.

(3) Full patched support
$$\operatorname{Supp}_{R_\infty}(M_\infty) = \operatorname{Spec} R_\infty.$$

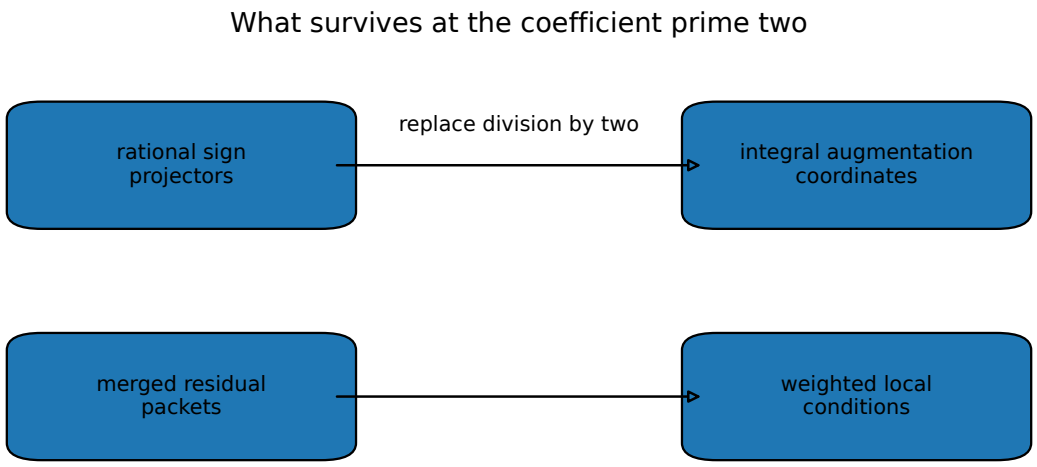

Figure 17. Augmentation survives at two, while semisimple character projectors and arithmetic hypotheses require separate treatment.

(4) An isomorphism
$$R \cong \mathbb{T}$$
with the Hecke algebra acting on H. The R action on H supplied by the patched control isomorphism is the restriction of this $\mathbb{T}$ action along the displayed isomorphism.

(5) An automorphic Hecke datum $(\mathbb{T}, H, (P_v))$ and a pointwise classicality and Galois realization theorem satisfying all the inputs of theorem 9.4 for the nonzero fiber at x: an occurring classical automorphic representation with a continuous semisimple attached representation; equality of the characteristic polynomials of both that representation and $\rho_x = x \circ \rho_R$ with $x(P_v(X))$ on the same declared Chebotarev dense union of Frobenius conjugacy classes; and the standard semisimplification, density, and general Brauer Nesbitt inputs. The coefficient topology and continuity requirements are retained in theorem 12.2.

Theorem 12.2 (Ordinary conditional automorphic completion)**.** *Let $x : R \to E'$ admit an ordinary completion datum. Assume E' is a Hausdorff topological field of characteristic zero with continuous ring operations, and that both $\rho_x = x \circ \rho_R$ and its attached comparison representation are continuous. Then*
$$\boxed{H \otimes_{\mathbb{T},x} E' \neq 0.}$$
The specialization
$$\rho_x = x \circ \rho_R$$
is identified after semisimplification with the Galois representation attached to a classical automorphic representation in that fiber. If ρ_x is irreducible, it is itself automorphic.

Proof. Full patched support descends to full support of H over R by theorem 6.11. The isomorphism $R \cong \mathbb{T}$ transports that support by theorem 7.1. The field fiber is nonzero by theorem 9.3. The declared classicality and realization theorem supplies an automorphic representation in the fiber and an attached Galois representation. The comparison with ρ_x follows from theorem 9.4. □

Definition 12.3 (Derived completion datum at a point)**.** A derived completion datum is defined in the same way, with a perfect patched complex C_∞ of full derived support and a finite level automorphic complex

$$C \simeq C_\infty \overset{\mathbf{L}}{\underset{R_\infty}{\otimes}} R$$

in place of the ordinary modules. Under the Hecke ring isomorphism $e : R \cong \mathbb{T}$, require an actual derived carrier identification between the scalar transport of this finite level complex and the automorphic Hecke complex. This identification retains the R action induced by patched control as the restriction of the $\mathbb{T}$ action along e.

Theorem 12.4 (Derived conditional automorphic completion)**.** *Let $x : R \to E'$ admit a derived completion datum, with Hecke identification $e : R \cong \mathbb{T}$, and put $y = x \circ e^{-1}$. Then*

$$\boxed{C \overset{\mathbf{L}}{\underset{\mathbb{T},y}{\otimes}} E' \not\simeq 0.}$$

Some integer cohomological degree contains a nonzero Hecke eigensystem with character y. Its degree lies between the bounds of any chosen finite projective model for C.

For the conditional conclusion, retain the Hausdorff coefficient topology, continuous specialization, supplied semisimplification, and common Frobenius polynomial hypotheses in theorem 9.6. If the declared classicality and Galois realization theorem applies to this eigensystem and supplies an occurring classical automorphic representation with a continuous semisimple attached representation and those Frobenius polynomials, then ρ_x is automorphic after semisimplification. If ρ_x is irreducible, it is itself isomorphic to the attached representation. This pointwise applicability condition does not require a uniform classicality assertion in other degrees.

Proof. Full support descends from the patched perfect complex by theorem 6.18. Scalar transport through e, followed by the actual derived isomorphism with the automorphic Hecke complex, gives full support for C. Its fiber at y is therefore nonzero. The bounded model and induced Hecke action argument in theorem 9.6 supplies a nonzero cohomology eigenvector in an integer degree within the model's bounds.

If realization applies to this eigensystem, it supplies the occurring automorphic object and a continuous semisimple attached representation with the declared Frobenius polynomials. The representation comparison in theorem 9.6 then identifies the supplied semisimplification of ρ_x with that attached representation. Only applicability to this eigensystem is used. A classicality theorem for every degree in a prescribed interval is unnecessary. □

Theorem 12.5 (Compatible system completion from one automorphic member)**.** *Let*

$$\{\rho_\lambda\}_{\lambda \in \Lambda}$$

be a semisimple strictly compatible system with common Frobenius spine. Suppose the member at λ_0 admits an ordinary or derived completion datum and is identified with the Galois representation attached to an automorphic representation π. Assume that the compatible system attached to π has the same Frobenius spine. Then

$$\boxed{\rho_\lambda \cong \rho^{\mathrm{ss}}_{\pi,\lambda} \quad \text{for every } \lambda \in \Lambda.}$$

Proof. The completion theorem at λ_0 gives the automorphic representation π. Apply theorem 10.7 to the two compatible systems. □

Theorem 12.6 (Five gate formulation)**.** *Fix a characteristic zero deformation point $x : R \to E'$. Give E' a Hausdorff topological field structure. The conditional argument uses the following five gates.*

(1) ***Residual gate.*** *Residual occupancy in the declared automorphic carrier and representability of the chosen deformation problem are supplied arithmetic inputs. In particular, the deformation ring R and its universal representation ρ_R are available.*

(2) ***Patching gate.*** *An applicable patching theorem supplies an ordinary finite module or a perfect complex with full patched support, together with the coefficient quotient and the module or derived control isomorphism. Write M for the resulting finite level carrier over R.*

(3) ***Comparison gate.*** *Let H be a finite ordinary Hecke module or a perfect Hecke complex over $\mathbb{T}$. Supply a ring map $f : R \to \mathbb{T}$ satisfying*

$$(f^*)^{-1}\big(\mathrm{Supp}_R(M)\big) \subseteq \mathrm{Supp}_{\mathbb{T}}(H).$$

Use ordinary or derived support according to the carrier. Actual scalar extension satisfies this inclusion, as does transport through a ring isomorphism with the corresponding carrier identification.

(4) ***Fiber gate.*** *Supply a Hecke point $y : \mathbb{T} \to E'$ with $y \circ f = x$. Then the fiber of H at y is nonzero. It contains a nonzero Hecke eigenvector, in some integer cohomological degree in the derived case, with character y.*

(5) ***Realization gate.*** *The declared classicality theorem applies to the resulting eigensystem and supplies an occurring classical automorphic representation π, with a continuous semisimple attached representation. Require the specialization $\rho_x = x \circ \rho_R$ to be continuous and supply its semisimplification. On the same Chebotarev dense set, assume that the characteristic polynomials of both ρ_x and the attached representation are $y(P_v(X))$. Retain the standard density and general Brauer Nesbitt inputs of standard fact 9.2.*

Then ρ_x^{ss} is isomorphic to the representation attached to π. If ρ_x is irreducible, the same conclusion holds for ρ_x itself.

For propagation, suppose both a semisimple compatible family $\{\rho_\lambda\}$ containing ρ_x and a family $\{\rho_{\pi,\lambda}\}$ attached to this same π already exist. Require the distinguished members to be ρ_x and its attached representation, respectively. Assume the coefficient, continuity, density, semisimplification and common algebraic Frobenius spine hypotheses of theorem 10.7, with that spine agreeing with the specialized Hecke polynomials at the distinguished place. Then

$$\rho_\lambda \cong \rho_{\pi,\lambda}^{\mathrm{ss}} \qquad \text{for every } \lambda.$$

Proof. The residual and representability inputs specify the setting in which the supplied patching theorem applies. The formal deduction begins with its actual rings, carriers and comparison maps. In the ordinary branch, finite generation and full support at finite level follow from the coefficient quotient and module control isomorphism. In the derived branch, the derived control isomorphism gives a perfect finite level model, and theorem 6.18 gives full support.

The comparison inclusion transports this full support to H. More specifically, $y \circ f = x$ identifies the contraction of $\ker y$ with $\ker x$, so support at the source point gives support at the Hecke point. In the ordinary case, theorem 7.4 gives a nonzero actual tensor fiber. In the derived case, the support criterion gives a nonzero actual derived fiber and hence a nonzero cohomology vector. Its integer degree lies within the bounds of the chosen finite projective model. In both cases, multiplication on the original carrier induces the scalar $y(t)$ on the specialized vector for every $t \in \mathbb{T}$.

Choose this nonzero eigensystem and apply the declared realization theorem to it. No realization statement in other degrees is needed. The two continuous representations have the same characteristic polynomials on the declared dense Frobenius conjugacy classes. Continuity extends their equality to the whole group. The supplied semisimplification preserves those polynomials, and the general Brauer Nesbitt input gives the required invertible linear intertwiner. The irreducible conclusion follows as in theorem 9.4.

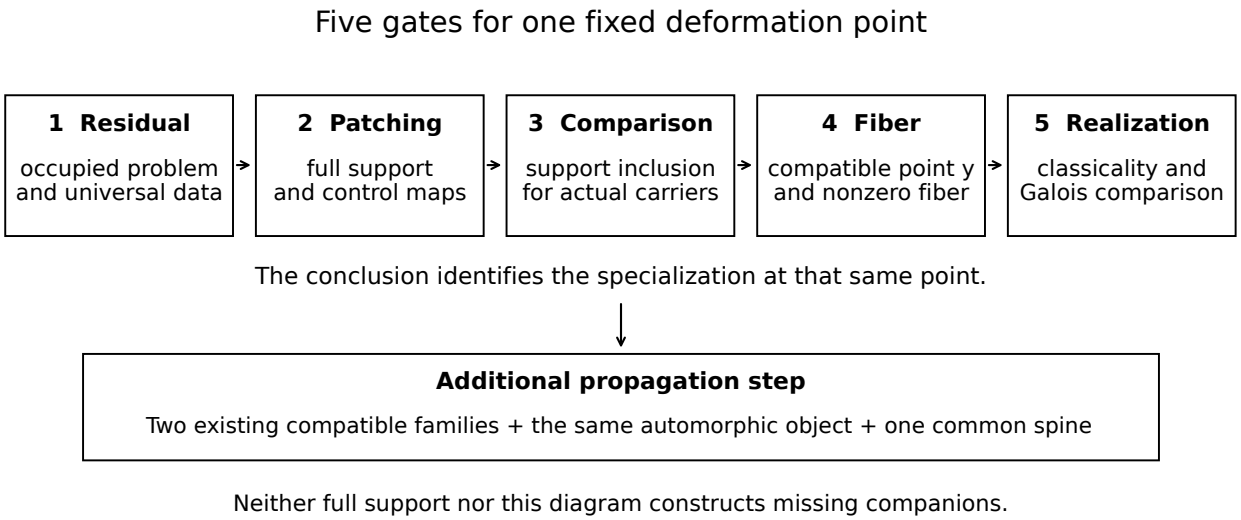

Figure 18. The final theorem is a composition of separate residual, support, comparison, fiber, and realization gates.

Table 1. Proved formal statements and arithmetic inputs that remain external.

Proved in this chapter	Not proved in this chapter
Local conditions combine through completed quotient rings	Representability of every desired local deformation condition
Full ordinary and derived support descends through the patching quotient	Near faithfulness or full support for every global deformation problem
An isomorphism $R \cong \mathbb{T}$ transports support and Fitting data	An $R \cong \mathbb{T}$ theorem outside published hypotheses
Finite Hecke algebras split into Artin packets	Positive automorphic occupancy of every residual or characteristic zero packet
Nonzero stable cores produce compatible inverse limit points	Universal residual companion existence
One automorphic member determines a fixed compatible system	Existence of a compatible system for every geometric representation
Augmentation and coinvariant recovery work at coefficient prime two	A universal coefficient two replacement for residual image, local geometry, and classicality hypotheses

Finally, retain the same π in its attached family. The distinguished member identities connect both families to the pointwise construction, while the common algebraic spine gives the required Frobenius polynomials at every coefficient place. Apply theorem 10.7 to these two existing families. The construction does not produce a missing companion or an attached compatible family. □

13 Exact boundary of the chapter

The formal results above sharpen the logical role of patching support, Hecke packets, and compatible systems. They do not replace the arithmetic theorems that supply the gates.

Remark 13.1. The strongest global conclusion is conditional automorphic realization inside a declared class for which the five gates have been verified. The chapter does not prove unrestricted global Langlands reciprocity.

Remark 13.2. A numerical certificate can check the finite algebra appearing in an example. It cannot verify a published automorphy lifting theorem, a classicality theorem, or a universal existence statement.

Formal verification scope

The formal records report 748 named theorem
declarations written for Paper XII, including supporting lemmas and interface results. A further 81 theorem declarations are reused unchanged from Paper X and counted separately. The cumulative verification rebuilds all 96 registered project modules with Lean 4.34.0-rc2 and warnings treated as errors. The transitive axiom audit covers 1,229 named declarations and permits only `propext`, `Classical.choice`, and `Quot.sound`. Three deliberately invalid controls test rejection of a false proof, a placeholder, and an incorrect empty family normalization. The pinned Mathlib dependency cache is not itself rebuilt. Exact compiler results, source hashes, and the verification scope are recorded with the archive.

The formal sources map all 49 amended internal numbered
claims. The mathematical text retains those proof bodies and exposes
the hypotheses on the local map and coefficient target in proposition 3.3, makes the $r > n$ convention explicit in the proof of theorem 6.4, states all the pointwise comparison inputs in definition 12.1, and declares a finite ramification set and coherent geometric Frobenius normalization. These editorial clarifications are recorded separately from the inherited eight amendments. They are not counted as newly compiled Lean certificates. No new statement amendment was needed for the completion and tensor results. The eight inherited amendments remain explicitly separate from the original wording, and the cited arithmetic inputs remain outside the internal claim census. Formal proof coverage is recorded claim by claim in the roadmap. These checks certify the formal statements under their explicit hypotheses, not every prose claim, novelty assertion, or external arithmetic result.

The completion block proves theorem 3.1 and proposition 3.3 using actual algebraic tensor products, actual Hausdorff completions, and the actual closed generated ideals. Both inverse laws, continuity in both directions, and the canonical factor maps are checked. An independent comparison with the algebraic inverse limit completion identifies the topology and local ring structure. The global theorem retains continuous local algebra points and their naturality, rather than only an unstructured point existence statement. The empty family retains the scalar adic topology. The zero condition and unit ideal boundaries are checked separately.

The preceding Fitting block proves theorems 6.3, 6.4 and 7.1 and proposition 6.5. Its intrinsic Fitting ideals are independent of the chosen finite presentation, including the number of generators and relations. Arbitrary base change, all higher fiber dimension strata, and the complete support and Fitting transport statement are checked. The Noetherian and finite module hypotheses of the manuscript provide the finite presentation needed by the general construction.

The new checks for proposition 5.1, theorem 5.4, and corollary 11.2 include actual group algebra transfer and augmentation. Coinvariant recovery uses the quotient by all balancing relations, with its universal property proved. In the commutative case, this construction is identified with the ordinary tensor product. The augmentation relations generate exactly the augmentation ideal acting on the module. Applying augmentation to the coordinates of a supplied free basis gives a coefficient basis

with the same index set. The right module argument applies to arbitrary groups, including nonabelian two groups, and includes rank zero.

The new checks for theorem 5.2, corollaries 5.3 and 8.4, and proposition 11.1 construct the full multivariable truncated polynomial algebra isomorphism and identify its augmentation generators. The residual group algebra is local for abelian p groups in characteristic p. For each supplied Hecke idempotent, the trace is the image dimension cast into the coefficient field. For that idempotent, occupancy is equivalent to positive rank and, in characteristic zero, nonzero trace. The dyadic calculation gives the two rational sign projectors, proves that neither lies in the integral group algebra, and identifies the residual algebra with $\mathbb{F}_2[X]/(X^2)$.

Corollary 5.3 is now checked for every finite p group, including nonabelian groups, over every field of characteristic p. The proof uses a finite prime field orbit span and a nonzero fixed vector. The original unrestricted statement is restored, and the earlier explicit abelian restriction is no longer needed.

The checks for proposition 7.3, theorem 8.2, and corollary 8.3 now include the actual formal power series quotient and the canonical Hecke packet maps. In the node $k[[x,y]]/(xy)$, quotienting by (x) gives $k[[y]]$, with support $V(x)$. Lean verifies both irreducible components and the exclusion of the generic point (y). The components can still meet, so this is not a claim that their supports are disjoint.

For the Hecke results, the canonical ring decomposition in standard fact 8.1 remains a declared external input. Its coordinates are the actual localization maps. The module direct sum, the packet identification with the localized module, and the formula $v \mapsto v/1$ are constructed in Lean. Nilpotence in the selected Artin local factor, together with invertibility of a generator on each other factor, gives a single positive exponent for the simultaneous generalized eigenspace. The result includes the explicit generators $T_i - \lambda_i$, agrees with the packet used in the trace theorem, and does not assume semisimplicity.

The revised five gate statement in theorem 12.6 is now checked for both ordinary and derived carriers and for a general support comparison. The comparison is an actual inclusion of subsets of prime spectra, and scalar extension is proved to satisfy it. The coefficient quotient and ordinary or derived control maps yield finite level support. That conclusion is not supplied as a separate patching assumption. The specialized tensor module or derived cohomology supplies an actual nonzero eigenvector. The declared realization theorem is applied to this particular eigensystem, and the resulting representation comparison is an actual invertible linear intertwiner. The system conclusion uses the family attached to the very same automorphic object, with distinguished member identities and a common algebraic polynomial spine.

The original comparison wording did not explicitly supply a compatible Hecke point over the fixed coefficient field. Support preservation alone is insufficient: extension from $\mathbb{Q}$ to $\mathbb{Q}(i)$ preserves full support, but there is no ring map $\mathbb{Q}(i) \to \mathbb{Q}$ extending the identity. The statement imposes $y \circ f = x$ and exposes the arithmetic comparison and existing-family inputs. Residual occupancy, representability and the applicable patching theorem remain supplied arithmetic provenance. The original full statement remains partial. The completed tensor quotients and intrinsic Fitting ideals are now checked as described above, including the full Fitting transport clause.

The derived realization checks cover the revised theorems 9.6 and 12.4. They prove vanishing outside the bounds of an actual finite projective model and construct a nonzero cohomology vector inside those bounds. The Hecke action is induced from multiplication on the original cochain model, carried through scalar extension and derived localization, and proved to act by the specialized character on actual cohomology. The conditional arithmetic step gives an actual invertible linear intertwiner from the declared realization input and common Frobenius polynomials.

The original formulation of theorem 9.6 did not ensure that the surviving degree lies in the classicality range. A complex concentrated in degree one has full support over a field, while a classicality condition restricted to degree zero says nothing about its nonzero fiber. The statement needs the

declared range to contain the model interval. The conditional conclusion of theorem 12.4 retains applicability at the selected eigensystem itself. Both statements now expose the topology, continuity, semisimplification, and common polynomial inputs needed for the representation comparison. Their original unconditional cohomological conclusions are checked, but their original complete statements remain partial. The general support comparison and compatible-point formulation is now checked in the revised theorem 12.6, as described above.

The derived support checks prove theorems 6.16 and 6.18 and corollary 6.19 as originally stated. Perfect complexes are actual derived category objects equipped with bounded finite projective models and derived isomorphisms to those models. Scalar extension is constructed on cochain complexes. Its associativity, preservation of homotopy equivalences, and independence under actual derived isomorphisms are checked. The quotient support formula uses the actual map of spectra and its image $V(I)$. Every field valued point factors through the residue field at its kernel, and faithful flatness of field extensions preserves and reflects acyclicity. The surviving integer degree is expressed using the actual derived cohomology functor, with a corresponding witness in the specialized cochain model. These proofs do not require the external cohomological support description in standard fact 6.15. The external classicality theorems remain supplied arithmetic inputs. The conditional derived realization argument is checked as described above.

The adequacy checks prove theorem 4.2 as originally stated. They construct the faithful standard representation from the actual permutation module, prove irreducibility after extension to the algebraic closure, and split every group element's characteristic polynomial over $\mathbb{F}_7$. The trace zero adjoint is the kernel of matrix trace with its conjugation action, and its sign plus standard decomposition is an actual equivariant linear isomorphism. The averaging proof is connected to Mathlib's actual first group cohomology, while the invariant calculation gives actual degree zero vanishing. Canonical projectors are identified with generalized eigenspace projectors for every positive exponent. Their trace pairings detect every nonzero endomorphism and hence every irreducible adjoint submodule. The two printed constituent witnesses and their traces are checked exactly. The adequacy definition remains a cited convention. No external adequacy theorem is assumed in this finite certificate.

The realization checks cover theorems 9.4, 10.7, 12.2 and 12.5 and corollary 9.5. Characteristic polynomial coefficients are continuous by the principal minor formula. Equality on the declared Frobenius conjugacy classes therefore extends to the whole Galois group. The finite dimensional algebra input is explicit: a supplied semisimple representative preserves every characteristic polynomial, and a general Brauer Nesbitt theorem identifies semisimple representations with equal polynomials. Lean proves independence of this representative and the irreducible conclusion. Construction of semisimplification, the general Brauer Nesbitt theorem, and arithmetic Chebotarev density remain external inputs.

The ordinary completion argument derives finite generation, full finite level support, and an actual nonzero Hecke tensor fiber from the patched support and control isomorphisms. The declared classicality input then supplies the occurring automorphic object and its attached representation. Both existing compatible systems, with their common polynomial spine, are retained as hypotheses in the propagation results. These results do not construct missing companions or an attached compatible system.

The pointwise realization and ordinary completion statements now explicitly require Hausdorff coefficient topology and continuity of the compared representations, including the universal specialization. The corresponding locus statement is restricted to such points. These three revised claims are counted as complete. Their original wording remains partial. This clarification also makes the coefficient topology in standard fact 9.2 explicit without claiming a new proof of that external arithmetic fact.

Two statement qualifications are essential. In corollary 6.12, every irreducible component is contained in the full support. The previous sentence reversed that containment. In theorem 10.5, the coefficient, continuity, integrality, class finiteness, and quotient condition hypotheses are now explicit. Finite forests by themselves establish branches, not all arithmetic effectivity assertions. Corollary 3.2 now gives the closed kernel argument and the continuity and uniqueness of its factors. The original wording and its claim records accompany the sources. In that wording census, 41 claims are fully checked, seven are partial, and one is not checked as written. The corrected corollary 6.12 and restricted theorem 10.5 are counted as proved only for their revised statements. The original unrestricted completion wording is not retrospectively marked proved. Source hashes, the exact amendments, compiler logs, and a mathematical self-review accompany the code. Compiler and axiom checks are distinguished from semantic proof review and external arithmetic results.

Plate XII.1 / A STANDALONE READER'S COMPANION

Seeing the objects

Patching Support, Hecke Packets, and Conditional Automorphic Completion Main statement 12.6

Komorebi P.

The chapter repeatedly asks three different questions: does an object exist, where is a supplied object nonzero, and when does that object have the desired arithmetic meaning? This guide makes those distinctions tangible through examples that can be followed by hand.

Existence	Is there a represented deformation problem, a nonzero carrier, or a compatible family to start with?
Support	At which prime ideals does the supplied module or complex survive?
Realization	Does the surviving eigensystem come from a classical automorphic object with the required attached representation?

Three models, rather than one overloaded analogy

Model	What it lets you see	Lessons
A formal thickening	Conditions on power series, infinitesimal points, obstructed lifts, and compatible precision levels.	Plates XII.3–XII.5
A presented module	Matrix rank, support, Fitting ideals, changes of coordinates, and nonreduced structure.	Plates XII.6–XII.8
A finite Artin algebra	Generalized eigenspaces, nilpotent directions, canonical packets, and empty packet modules.	Plates XII.12–XII.14

The models are connected by the chapter's theorems, but they are not the same ring. A polynomial coordinate plane is not a complete local spectrum, and a local branch is not an Artin product factor. Explicitly changing models prevents a picture from silently changing the hypotheses.

A route through the guide

Use the object atlas on Plate XII.2 when a symbol becomes unfamiliar. The local model starts on Plate XII.3, and the matrix model starts on Plate XII.6. Plates XII.9–XII.11 explain what quotients, patching, and derived fibers preserve. Plates XII.15–XII.16 separate finite occupancy from genuine infinite compatibility. The exact arithmetic boundary is on Plate XII.17.

How to read a visual claim

Each lesson gives an explicit object, a calculation, and a source reference. Coordinate sketches display only the stated real points. Coefficient arrays and finite specialization diagrams describe the stated algebraic data exactly. Line thickness never stands for nilpotent multiplicity.

Read this as: These examples explain the mathematical constructions. They add no assumptions or Lean certificates. The accompanying scripts check the explicit finite calculations. They do not establish universal arithmetic existence.

Plate XII.2 / ORIENTATION

An atlas of the objects

Main text: Sections 2, 3, 6, 7, 8 and 12 Main statement 3.3

A *ring* describes possible points. A *module over the ring* describes what is carried at those points. A nonempty space of possibilities does not imply a nonzero carrier at every point.

Symbol	Object and role	Keep separate
$\mathcal{O},\ k$	Complete coefficient ring and its residue field. The formal teaching model uses $\mathcal{O} = \mathbb{Z}_5, k = \mathbb{F}_5$.	Coefficients versus variables.
$R_i,\ I_i$	A supplied local ring and the ideal imposing a declared local condition.	A quotient condition is not an idempotent.
R^{loc}	Completed tensor product of the local rings over $\mathcal{O}$.	Completion uses the declared adic topology.
J	Closed ideal generated by the images of all I_i in R^{loc}.	Closure, not just a finite list of tests.
$R^{\mathrm{loc},\tau}$	Completed tensor of the local quotients, identified with R^{loc}/J.	A constructed comparison, not assumed notation.
$R^{\square}$	Supplied global ring receiving the local structural maps.	Representability is arithmetic input.
R^{τ}	Completed global base change imposing the simultaneous local conditions.	Does not create a missing residual point.
$R_\infty,\ M_\infty$	Patched ring and its module. A perfect complex is used in the derived version.	Freeness over an auxiliary ring is weaker than full support.
$R,\ M$	Finite-level ring and carrier after the specified quotient and control isomorphism.	The module may be zero on a component.
$T,\ H$	Hecke algebra and its ordinary or derived carrier.	Ring comparison does not imply classicality.
$e_{\mathfrak{m}}H$	Packet selected by a canonical Artin idempotent.	A generalized packet need not be an eigenspace.
Y_m	Stable image at level m of an inverse system.	Nonzero levels alone do not give a nonzero limit.

Why arrows reverse when points appear

A ring map $f : R \to T$ sends a prime of T to its inverse image in R:

$$f^* : \operatorname{Spec} T \longrightarrow \operatorname{Spec} R, \qquad \mathfrak{q} \longmapsto f^{-1}(\mathfrak{q}).$$

Similarly, a point $y : T \to E'$ gives the point $y \circ f : R \to E'$. The equality $y \circ f = x$ is an actual requirement in the final theorem, not a consequence of drawing a connecting arrow.

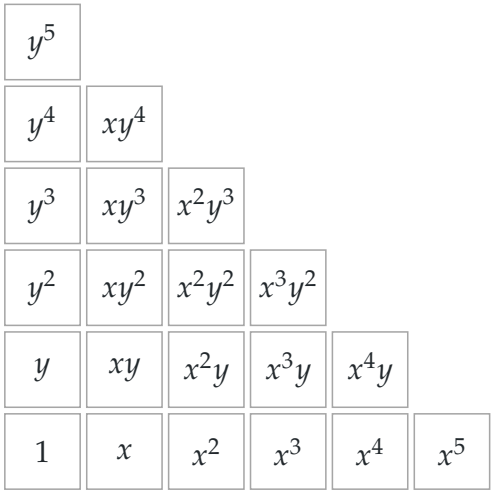
Two kinds of point

Local quotient factorization is stated for continuous local coefficient-algebra maps to deformation test rings. The later field-valued point $x : R \to E'$ uses its kernel and scalar fiber. A characteristic-zero field point is generally not a local ring map: the coefficient uniformizer becomes a unit. These two uses of “point” must retain their own categories.

Plate XII.3 / MODEL A / A FORMAL THICKENING

Local conditions remove directions

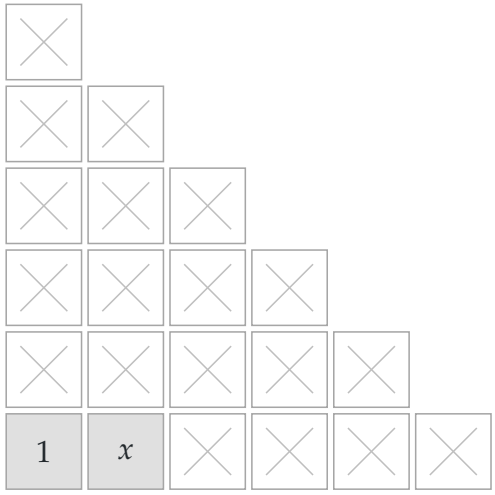
Main text: Theorem 3.1 and Corollary 3.2 Main statement 3.1



Fix $\mathcal{O} = \mathbb{Z}_5$. Take two independent local variables and impose two different kinds of condition:

$$R_1 = \mathcal{O}[[x]], \quad I_1 = (x^2), \qquad R_2 = \mathcal{O}[[y]], \quad I_2 = (y).$$

Their completed local tensor is $A = \mathcal{O}[[x, y]]$. The closed generated ideal is $J = (x^2, y)$, and both routes through Theorem 3.1 give



$$(R_1/I_1) \mathbin{\widehat{\otimes}}_{\mathcal{O}} (R_2/I_2) \cong A/J \cong \mathcal{O}[\varepsilon]/(\varepsilon^2).$$

Before imposing the ideals

$i + j < 6$ shown; coefficients lie in $\mathcal{O}$.

After imposing (x^2, y)

$i + j < 6$ shown; coefficients lie in $\mathcal{O}$.

An exact finite window of monomials over $\mathcal{O}$. Crosses mean that the monomial is zero in the quotient. They do not represent a small numerical coefficient. All terms outside the window satisfy the same divisibility rule.

The calculation behind the image

For $f = \sum_{i,j \geq 0} a_{ij} x^i y^j$, reduction gives

$$f \longmapsto a_{00} + a_{10}\varepsilon.$$

Every term involving y vanishes. Every term involving x^2 vanishes. The class of x does *not* vanish: it becomes a nonzero element whose square is zero. The quotient is a free $\mathcal{O}$-module with basis $1, \varepsilon$.

Why a point picture alone would miss this

After passing to the special fiber, $k[\varepsilon]/(\varepsilon^2)$ has the same underlying one-point spectrum as k. The extra direction is visible in the algebra and in maps from test rings, not as a second point. It is also not a second component or a second Artin packet.

Read this as: The condition $y = 0$ deletes a variable. The condition $x^2 = 0$ retains a first-order nilpotent direction. Both are quotient conditions, but their effects are different.

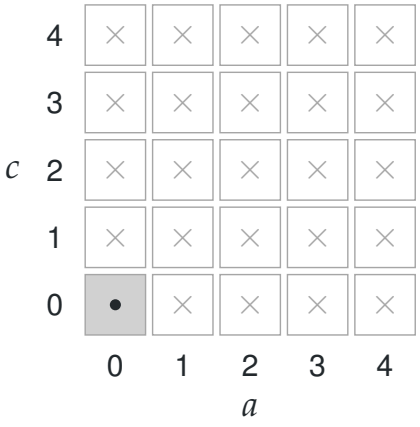
Plate XII.4 / MODEL A / FACTORIZATION AND OBSTRUCTION

A point is a test of the equations

Main text: Proposition 3.3; this explicit example also exhibits a failed infinitesimal lift Main statement 3.3

Let $R^{\square} = \mathcal{O}[[u, v]]$ and send $x \mapsto u$, $y \mapsto v - u$. The local conditions become

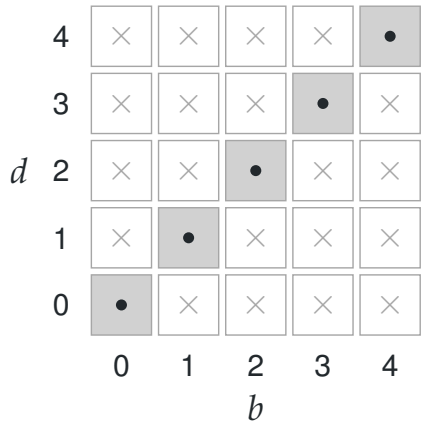
$$u^2 = 0, \qquad v - u = 0, \quad \text{so} \quad R^{\tau} = \mathcal{O}[[u, v]]/(u^2, v - u) \cong \mathcal{O}[\varepsilon]/(\varepsilon^2).$$



Probe this ring using $D_3 = \mathbb{F}_5[\delta]/(\delta^3)$, with the fixed coefficient map $\mathbb{Z}_5 \to \mathbb{F}_5$. A continuous local point is specified by

$$u \longmapsto a\delta + b\delta^2, \qquad v \longmapsto c\delta + d\delta^2, \qquad a, b, c, d \in \mathbb{F}_5.$$

It factors through R^{τ} precisely when



$$a^2 = 0, \quad c = a, \quad d = b \quad \Longleftrightarrow \quad a = c = 0,\ d = b.$$

First-order coefficients

Only the slope pair $(a, c) = (0, 0)$ survives. Each square initially has 25 choices of (b, d).

Remaining second-order coefficients

Once $a = c = 0$, the five diagonal choices $d = b$ give all accepted points.

An obstruction you can calculate

There are $5^4 = 625$ candidate D_3-points and exactly five accepted points. Over $D_2 = \mathbb{F}_5[\delta]/(\delta^2)$, however, the five maps $u = v = a\delta$ all satisfy the equations. Reduction of *every* accepted D_3-point gives the zero D_2-point. The four nonzero tangent directions therefore do not lift to order three.

> **Read this as:** A point satisfies equations in a target ring. A tangent direction can exist while its next-order lift fails. The factorization theorem identifies the condition. It does not promise that every point lifts.

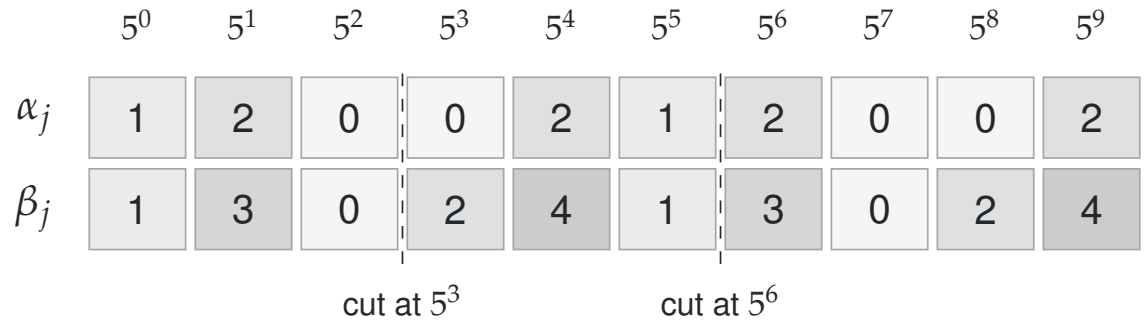
Plate XII.5 / MODEL A / COMPATIBLE COEFFICIENTS

Completion retains every precision

Main text: Theorem 3.1; reconstruction and finite occupancy in Section 10 Main statement 10.5

For $B = \mathbb{Z}_5[\varepsilon]/(\varepsilon^2)$, consider the finite quotient rings

$$B_n = (\mathbb{Z}/5^n\mathbb{Z})[\varepsilon]/(\varepsilon^2), \qquad |B_n| = 5^{2n}, \qquad B \cong \varprojlim_n B_n.$$



A point of the limit is a *single compatible choice* at every level, not unrelated choices from the nonempty finite rings.

Two explicit 5-adic numbers

Choose the canonical digits

$$\alpha_j = (j^2 + 1) \bmod 5, \qquad \beta_j = (2j + 1) \bmod 5,$$

with values in $\{0, 1, 2, 3, 4\}$. Set $a = \sum_{j\geq 0} \alpha_j 5^j$ and $b = \sum_{j\geq 0} \beta_j 5^j$. The element $a + \varepsilon b$ is determined by the following coefficient array.

Cutting before column 5^n produces reduction modulo 5^n. The digit formulas define every column, including those not drawn.

n	1	2	3	4	5
5^n	5	25	125	625	3125
$a \bmod 5^n$	1	11	11	11	1261
$b \bmod 5^n$	1	16	16	266	2766

Every longer prefix reduces to the previous one. The digit formulas specify all later coefficients.

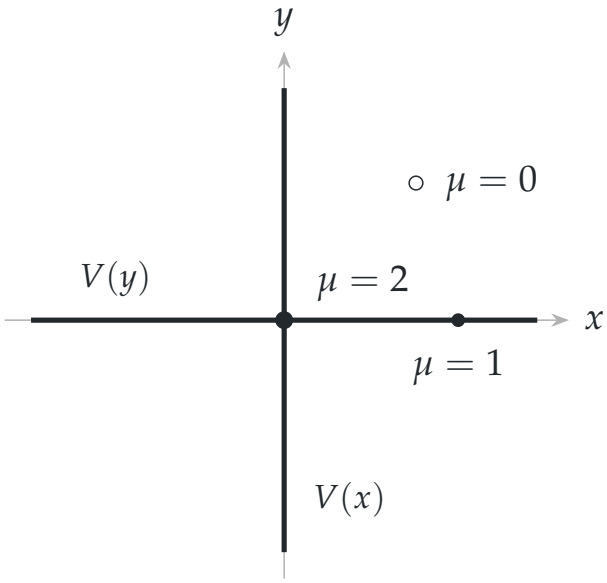
Where the topology enters

The 5-adic and $(5, \varepsilon)$-adic topologies on B agree: for every n,

$$(5, \varepsilon)^{n+1} \subseteq 5^n B \subseteq (5, \varepsilon)^n.$$

For the general quotient theorem, the condition ideal must be closed. A continuous map to a Hausdorff target has closed kernel: vanishing on the original generators therefore kills their closure.

Plate XII.6 / MODEL B / FITTING STRATA



A matrix becomes a support locus

Main text: Theorems 6.2, 6.3 and 6.4 Main statement 6.3

Now change models. Let $R = k[x, y]$ for a field k, and present a module by

$$R^2 \xrightarrow{A} R^2 \longrightarrow M \longrightarrow 0, \qquad A = \begin{pmatrix} x & 0 \\ 0 & y \end{pmatrix}.$$

The relations are $xe_1 = 0$ and $ye_2 = 0$, so $M \cong R/(x) \oplus R/(y)$.

The minor calculation

$$\begin{aligned} \mathrm{Fitt}_0(M) &= (xy), \\ \mathrm{Fitt}_1(M) &= (x, y), \\ \mathrm{Fitt}_j(M) &= R \quad (j \geq 2). \end{aligned}$$

At a prime $\mathfrak{p}$, reduce the matrix to its residue field:

$$\mu_{\mathfrak{p}}(M) = 2 - \operatorname{rank} A(\mathfrak{p}).$$

Two independent relations disappear at the origin. Only one disappears along either punctured axis.

For the drawing, take $k = \mathbb{R}$. It shows real closed points, not every point of $\operatorname{Spec} R$. The displayed ideals and rank criterion describe the full algebraic loci over any field.

Position	Matrix rank	Fiber dimension	What survives
$x \neq 0, y \neq 0$	2	0	neither generator
$x = 0, y \neq 0$	1	1	the e_1 direction
$x \neq 0, y = 0$	1	1	the e_2 direction
$x = y = 0$	0	2	both directions

Thus $\operatorname{Supp}(M) = V(xy) = V(x) \cup V(y)$, whereas the locus where the fiber needs at least two generators is $V(x, y)$. The latter is a *higher* Fitting stratum. For $r > 2$, the locus $\mu_{\mathfrak{p}}(M) \geq r$ is empty, corresponding to the unit Fitting ideal.

> **Read this as:** Support asks whether any direction survives. Higher Fitting strata ask how many generators the residue-field fiber needs. This is not an automorphic multiplicity formula.

Plate XII.7 / MODEL B / NILPOTENT STRUCTURE

The same support can hide more algebra

Main text: Theorems 6.3–6.4; distinguish an ideal from its vanishing set Main statement 6.4

Compare the previous module with a slightly different presentation:

$$M = \operatorname{coker}\begin{pmatrix} x & 0 \\ 0 & y \end{pmatrix}, \qquad M' = \operatorname{coker}\begin{pmatrix} x^2 & 0 \\ 0 & y \end{pmatrix}.$$

Their support sets coincide. Their residue-field fiber dimensions also coincide at every prime. But their Fitting ideals do not.

	M	M'
Zeroth Fitting ideal	(xy)	(x^2y)
First Fitting ideal	(x, y)	(x^2, y)
Support as a set	$V(x) \cup V(y)$	$V(x) \cup V(y)$
Fiber dimension at (x, y)	2	2

Magnify transversely, rather than draw a thicker line

Take the slice $y = 1$. The second summand vanishes because y becomes a unit. What remains is

$$M|_{y=1} \cong k[x]/(x), \qquad M'|_{y=1} \cong k[x]/(x^2).$$

The first has basis 1. The second has basis $1, x$. Multiplication by x distinguishes them exactly:

reduced slice

$$1 \xrightarrow{\times x} 0$$

$$[x] = [0]$$

nilpotent slice

$$1 \xrightarrow{\times x} x \xrightarrow{\times x} 0$$

$$[x] = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$$

A test ring detects the thickening of the higher stratum

Let $D = k[\delta]/(\delta^2)$ and send $x \mapsto \delta$, $y \mapsto 0$. The ideal (x^2, y) maps to zero, but (x, y) does not. Therefore this D-point lies in the scheme defined by the first Fitting ideal of M', but not in the corresponding scheme for M.

No extra ordinary point has appeared. What changed is the behavior on nilpotent test rings. This is the same distinction encountered in the formal model on Plate XII.3.

> **Read this as:** Taking $V(I)$ forgets nilpotent thickness. Fitting *ideals* can retain information that both the support set and the function giving fiber dimensions fail to distinguish.

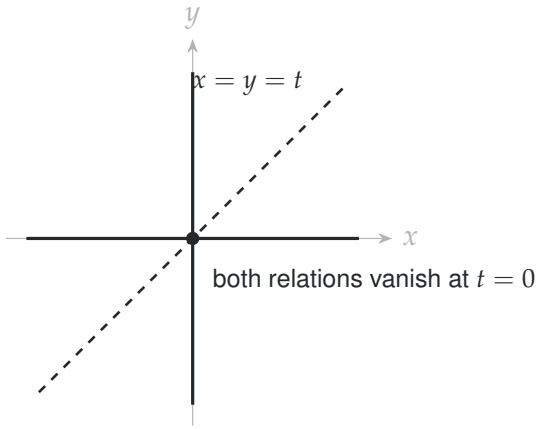


Plate XII.8 / MODEL B / SPECIALIZATION AND TRANSPORT

Base change is an algebraic pullback

Main text: Proposition 6.5 and Theorem 7.1 Main statement 6.5

Return to $M = \operatorname{coker} \operatorname{diag}(x, y)$ over $R = k[x, y]$. Pull back along the diagonal $R \to k[t]$, $x \mapsto t$, $y \mapsto t$. The base-changed presentation is literal:

$$M \otimes_R k[t] \cong \operatorname{coker} \begin{pmatrix} t & 0 \\ 0 & t \end{pmatrix} \cong \big(k[t]/(t)\big)^2.$$

Both relations vanish together

$$(xy) \longmapsto (t^2), \qquad (x, y) \longmapsto (t).$$

The support is the origin, but the origin has fiber dimension two. Replacing (t^2) by its radical (t) would lose the zeroth Fitting ideal.

This map is not flat: it is the quotient by $x - y$. The Fitting base-change theorem still applies. It does not require flatness.

A view of the real points on the diagonal slice. The double algebraic contribution is certified by the minor t^2, not by the visual thickness of the intersection point.

An isomorphism changes coordinates, not occupancy

Over a field of characteristic other than two, the isomorphism

$$k[x, y] \xrightarrow{\sim} k[a, b], \qquad x \mapsto a + b, \quad y \mapsto a - b$$

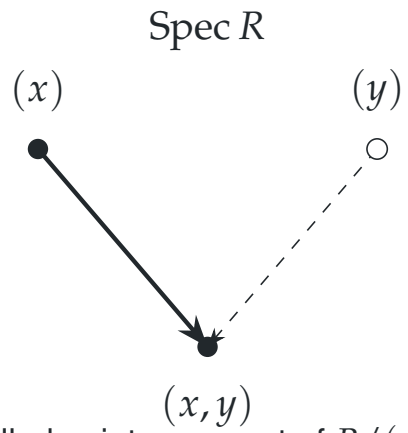
sends the Fitting ideals to $(a^2 - b^2)$ and (a, b). The two axes become the two lines $a = b$ and $a = -b$. No previously missing module vector is created by this relabeling.

An extra presentation generator changes nothing

Replacing $\operatorname{diag}(x, y)$ by $\operatorname{diag}(x, y, 1)$ adds a generator killed by the relation 1. The new maximal minor is xy, and the new next-size minors generate $(xy, x, y) = (x, y)$. The module and its intrinsic Fitting ideals are unchanged. This is a small visible instance of presentation independence of Fitting ideals.

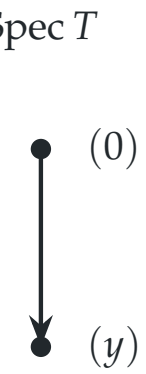
> **Read this as:** Specialization substitutes into the actual relation matrix. An isomorphism transports all the data. Neither operation may be replaced by an informal edit of the support picture.

Plate XII.9 / LOCAL GEOMETRY / AN EXACT FINITE SPECTRUM



A branch is not an Artin packet

Main text: Proposition 3.4 and Proposition 7.3 Main statement 7.3



Consider the complete local node

$$R = k[[x,y]]/(xy), \qquad T = R/(x) \cong k[[y]].$$

Every prime of R contains x or y. Since $k[[x]]$ and $k[[y]]$ are discrete valuation rings, the following diagram lists *all three* prime ideals of R and their specialization relations.

Filled points: support of $R/(x)$.
Arrows: specialization of prime ideals.

The quotient retains one generic point and the common closed point.

What the quotient removes

As an R-module, T has annihilator (x), hence

$$\mathrm{Supp}_R(T) = V(x) = \{(x), (x,y)\}.$$

The other generic point (y) is missing because it does not contain x. The quotient has not created a disconnected projector summand inside the original local ring. It has changed the ring by imposing an equation.

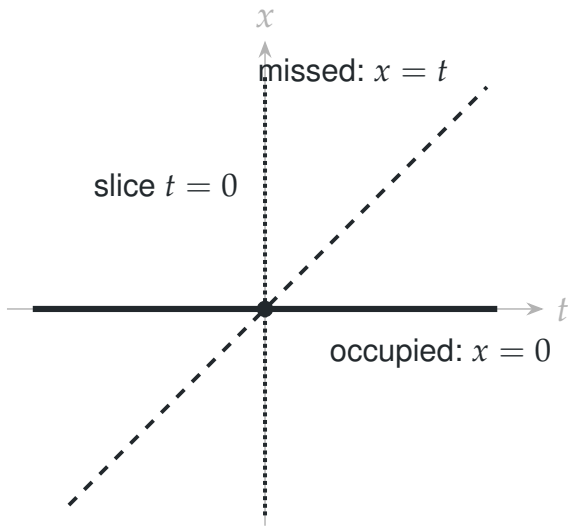
Why no idempotent selects just this branch

In a commutative local ring, $e^2 = e$ implies $e = 0$ or $e = 1$. Indeed, $e + (1-e) = 1$ forces at least one of $e, 1-e$ to be a unit. Canceling in $e(1-e) = 0$ gives the conclusion. Thus this node has no nontrivial idempotent even though it has two irreducible components.

By contrast, a product of two Artin local rings has two disjoint maximal points, with canonical idempotents $(1,0)$ and $(0,1)$. Those idempotents act on *any supplied module over the product*. Their two ranges are the packets studied on Plate XII.12.

> **Read this as:** Intersecting local components are not product factors. Use quotient ideals and support for the node. Use canonical idempotents only where an actual product decomposition exists.

Plate XII.10 / PATCHING / A COUNTEREXAMPLE WITH A VISIBLE SPECIAL FIBER



Free over what? Supported where?

Main text: Theorems 6.7, 6.9 and 6.11; Example 6.13 Main statement 6.11

Let

$$S = k[[t]], \qquad R_\infty = S[[x]]/(x(x-t)), \qquad M_\infty = R_\infty/(x) \cong S.$$

The module is free of rank one over S. Yet over R_∞ its support is only $V(x)$. The generic point $(x-t)$ of the other branch is not occupied.

Remove the auxiliary variable

Set $t = 0$. Then

$$R = R_\infty/(t) \cong k[[x]]/(x^2),$$

$$M = M_\infty/tM_\infty \cong k.$$

The two branches meet in a nonreduced special fiber. The relation becomes $x^2 = 0$, not $x = 0$.

The drawing is a real algebraic shadow of $x(x-t) = 0$. It is not the complete local spectrum. The special fiber's nilpotent structure is recorded by its quotient algebra, not by the point drawn at the intersection.

Full support need not mean faithful action

The ring R has one prime, (x). The nonzero module $M = k$ therefore has full support. But x annihilates M, so the action is not faithful. It is *nearly faithful*: the annihilator (x) is nilpotent. This distinction disappears over a reduced ring.

The actual descent theorem is one-way

For a finite module over a Noetherian ring,

$$\operatorname{Supp}_{R_\infty/(t)}(M_\infty/tM_\infty) = \operatorname{Supp}_{R_\infty}(M_\infty) \cap V(t).$$

If the initial support is full, the resulting support is full on the quotient. Our example shows that full support at the quotient can occur even when initial support was not full. It also shows why freeness over S alone is not the required patching hypothesis.

> **Read this as:** A statement about freeness must name the base ring. A statement about occupancy must name the spectrum. Switching between them without a theorem loses the missing component.

Plate XII.11 / DERIVED SUPPORT / AN ACTUAL TWO-TERM COMPLEX

A vanishing differential changes the fiber

Main text: Definition 6.14 and Theorem 6.16 Main statement 6.16

Take $R = k[t]$ and the perfect complex

$$C = \left[R \xrightarrow{t} R\right] \qquad \text{in cohomological degrees } 0, 1.$$

Specialization at $t = a$ gives $C_a = [k \xrightarrow{a} k]$. When $a \neq 0$, the differential is invertible and the complex is acyclic. When $a = 0$, the differential is zero and both cohomology groups survive.

point a	-2	-1	0	1	2
$\dim H^0(C_a)$	0	0	1	0	0
$\dim H^1(C_a)$	0	0	1	0	0

the zero differential creates two cohomology groups

A few fibers over $k = \mathbb{Q}$ are displayed. The statement for every $a \neq 0$ follows from invertibility of the scalar a. It is not inferred from the sample points.

Compute before and after specialization

Before specialization,

$$H^0(C) = 0, \qquad H^1(C) = k[t]/(t).$$

After *derived* specialization at zero,

$$C \otimes^{\mathbf{L}}_R k = [k \xrightarrow{0} k], \quad H^0 \cong k, \quad H^1 \cong k.$$

If one retained only $H^1(C)$ and took its ordinary tensor product with k, one would see a single k and miss the extra cohomology in degree zero. The projective complex keeps the information needed for specialization.

The support is still a precise locus

At any prime not containing t, the residue-field differential is invertible. At the prime (t) it is zero. Therefore

$$\operatorname{Supp}_R(C) = V(t).$$

Theorem 6.16 identifies support after derived quotient with the intersection of original support and the quotient locus.

> **Read this as:** Derived nonvanishing means that some cohomology group survives after derived specialization. It neither specifies a classical automorphic class nor eliminates the need for a realization theorem.

Plate XII.12 / MODEL C / A NONSEMISIMPLE HECKE ALGEBRA

A packet contains an entire Jordan chain

Main text: Theorem 8.2, Corollary 8.3 and Example 8.6 Main statement 8.2

Work over $\mathbb{Q}$ and let

$$T = \mathbb{Q}[z]/\big((z-1)^2(z+1)^3\big), \qquad V = T.$$

The Chinese remainder theorem gives

$$T \cong \underbrace{\mathbb{Q}[\varepsilon]/(\varepsilon^2)}_{T_+,\ z=1+\varepsilon} \times \underbrace{\mathbb{Q}[\eta]/(\eta^3)}_{T_-,\ z=-1+\eta}.$$

Multiplication by z is an operator H. In the ordered local bases $1, \varepsilon$ and $1, \eta, \eta^2$, its matrix is

$$H = \left(\begin{array}{cc|ccc} 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ \hline 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 1 & -1 \end{array}\right).$$

packet at $z = 1$

$$1 \xrightarrow{H-1} \varepsilon \xrightarrow{H-1} 0$$

two independent basis vectors

packet at $z = -1$

$$1 \xrightarrow{H+1} \eta \xrightarrow{H+1} \eta^2 \xrightarrow{H+1} 0$$

three independent basis vectors

These arrows are the actual nilpotent actions $H-1$ and $H+1$. Each nonzero displayed basis vector belongs to the indicated packet. Only the last nonzero vector in each chain is an ordinary eigenvector.

The projectors can be written explicitly

Modulo $(z-1)^2(z+1)^3$, put

$$e_+(z) = \frac{(5-3z)(z+1)^3}{16}, \qquad e_-(z) = 1 - e_+(z).$$

Then $e_+ \equiv 1 \pmod{(z-1)^2}$ and $e_+ \equiv 0 \pmod{(z+1)^3}$. Consequently

$$e_+(H) = \operatorname{diag}(1,1,0,0,0), \qquad e_-(H) = \operatorname{diag}(0,0,1,1,1).$$

The packet dimensions are two and three. The ordinary eigenspaces each have dimension one. The generalized eigenspaces have dimensions two and three.

> **Read this as:** Canonical idempotents isolate the full primary pieces, including their nilpotent structure. Semisimplicity is not required, and replacing a packet by an ordinary eigenspace can discard most of it.

Plate XII.13 / MODEL C / OCCUPANCY IS MODULE DATA

A possible packet can still be empty

Main text: Theorem 7.4, Theorem 8.2 and Corollary 8.4 Main statement 7.4

Keep the algebra $T = T_+ \times T_-$ from Plate XII.12, but compare two different T-modules:

$$V = T, \qquad W = T_+,$$

where T acts on W through projection to its first factor. The algebra still has two maximal ideals, but only one of them is in $\mathrm{Supp}_T(W)$. Here T is a supplied algebra. Its action on W is *not* assumed faithful.

Squares refer to the local bases of the regular module. Crossed reference slots are absent from W. They are not additional basis vectors of W.

	regular module V	first-factor module W
$\dim e_+(-)$	2	2
$\dim e_-(-)$	3	0
Support	both maximal points	only the $+$ point
Trace of e_-	3	0

A generalized packet is not its residue-field fiber

At the point $z = 1$, the full local packet e_+V has dimension two, but its scalar fiber is

$$V \otimes_{T,\, z\mapsto 1} \mathbb{Q} \cong T_+/(\varepsilon) \cong \mathbb{Q}.$$

The packet has the basis $1, \varepsilon$. Its scalar fiber kills ε. The ordinary eigenspace is instead the kernel of multiplication by ε, spanned by ε. In this example the last two spaces have the same dimension, but they are obtained by different operations.

For W, the fiber at $z = -1$ is zero. At $z = 1$ it is nonzero. The field-fiber criterion detects exactly the support of the supplied module.

> **Read this as:** A ring factor describes an available packet location. A nonzero localized module certifies occupancy there. A field fiber then specializes that module. It is not the whole generalized packet.

Plate XII.14 / A COEFFICIENT-PRIME BOUNDARY

At two, division is the obstruction

Main text: Section 5, Remark 8.5 and Section 11 Main statement 11.1

Let $C_2 = \langle g : g^2 = 1 \rangle$. Over $\mathbb{Q}_2$, the two familiar sign projectors are

$$e_+ = \frac{1+g}{2}, \qquad e_- = \frac{1-g}{2}, \qquad \mathbb{Q}_2[C_2] \cong \mathbb{Q}_2 \times \mathbb{Q}_2.$$

They do not belong to $\mathbb{Z}_2[C_2]$. Therefore one cannot first use them integrally and then reduce modulo two.

Compute the actual residual algebra

Over $\mathbb{F}_2$, put $\delta = g - 1 = g + 1$. Then $\delta^2 = g^2 - 2g + 1 = 0$ and

$$\mathbb{F}_2[C_2] \cong \mathbb{F}_2[\delta]/(\delta^2).$$

The two sign eigenvalues have merged. The ring is local and retains a nilpotent direction instead of two residual projector pieces.

Element	Square	Idempotent?
0	0	yes
1	1	yes
δ	0	no
$1+\delta$	1	no

In the basis $1, \delta$, multiplication by $g = 1 + \delta$ is

$$G = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \qquad G^2 = I \quad \text{over } \mathbb{F}_2.$$

It is not the identity: $G - I$ is nonzero and square-zero.

A trace can vanish while a packet is occupied

The identity projector on $\mathbb{F}_2^2$ has rank two and trace $2 = 0$. Hence nonzero rank and nonzero trace are not equivalent in this characteristic. The localization and rank criteria still detect the nonzero space. The characteristic-zero qualification in Corollary 8.4 is essential.

Recovery without averaging

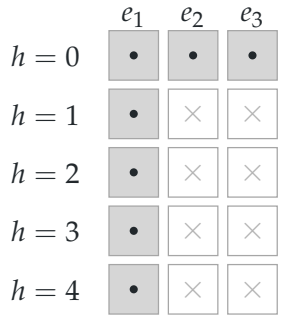
The augmentation map sends g to 1 and has kernel $(g-1)$. Thus

$$\mathbb{Z}_2[C_2]/(g-1) \cong \mathbb{Z}_2, \qquad \big(\mathbb{Z}_2[C_2]^r\big)/(g-1)\mathbb{Z}_2[C_2]^r \cong \mathbb{Z}_2^r.$$

These quotient identities require no division by two. They explain why augmentation and coinvariants remain usable even when sign-projector formulas do not.

> **Read this as:** Use the algebra available at the coefficient prime. Augmentation recovery is valid here. It still does not prove full deformation support or supply a universal automorphy theorem at two.

Plate XII.15 / INVERSE SYSTEMS / THE STABLE CORE



Nonzero at every level is not enough

Main text: Definition 8.9, Lemma 8.10 and Theorem 8.11 Main statement 8.11

Let every level be $V_m = k^3$. For a transition matrix F, compatibility means $v_m = Fv_{m+1}$. The directions visible at level m after looking h levels ahead form $\operatorname{im}(F^h)$.

A surviving direction

$$P = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad P^2 = P.$$

At every positive horizon, precisely the e_1 direction remains visible.

Every direction eventually dies

$$N = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}, \qquad N^3 = 0.$$

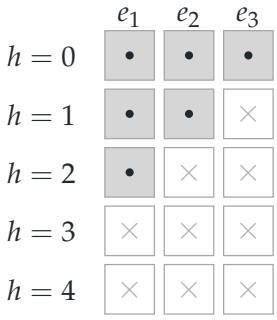


Image dimensions are $3, 2, 1, 0, 0, \ldots$, although every level still has dimension three.

Now compute the limits, not just their level dimensions

For the P-system, the limit consists of the constant compatible sequences $(ae_1, ae_1, \ldots)$, so it is isomorphic to k. For the N-system, every compatible sequence satisfies

$$v_m = N^3 v_{m+3} = 0 \quad \text{for every } m,$$

and the limit is zero. This is an all-level argument from the identity $N^3 = 0$, not a finite experimental guess.

What the stable core measures

In a general inverse system of finite-dimensional spaces,

$$Y_m = \bigcap_{n \geq m} \operatorname{im}(f_{n,m})$$

contains exactly the vectors visible from arbitrarily remote levels. The chapter proves that the transition maps restrict to surjections $Y_{m+1} \twoheadrightarrow Y_m$. A prescribed nonzero vector in Y_1 can then be lifted recursively to a coherent nonzero sequence.

> **Read this as:** The stable core tests persistence through the transition maps. Counting nonzero spaces at separate levels does not test persistence.

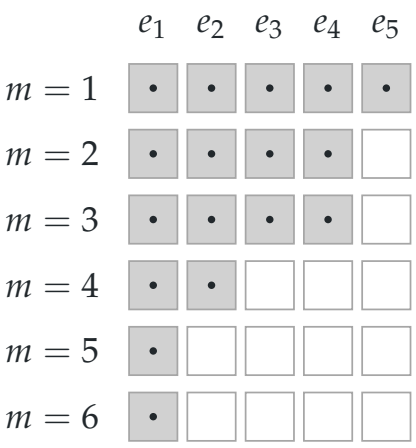

Plate XII.16 / TWO DIFFERENT COMPACTNESS MECHANISMS

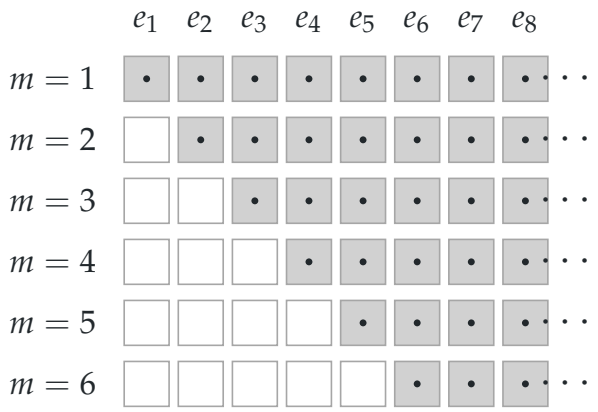
Finite dimension prevents tail escape

Main text: Theorem 8.7, Corollary 8.8 and Example 8.13 Main statement 8.7



Nested nonzero subspaces inside *one fixed finite-dimensional space* behave differently from nested tails inside an infinite-dimensional space.

Fixed carrier k^5

The projectors retain initial basis directions with dimensions $5, 4, 4, 2, 1, 1, \ldots$. In this explicitly defined example the projector is constant from level five onward.

Infinite carrier $\ell^2(\mathbb{N})$

Row m retains all basis vectors e_j with $j \geq m$. Every row continues infinitely to the right. The display is a finite window, not a truncation of the actual carrier.

Why the finite chain eventually stops changing

Suppose idempotents satisfy

$$e_{m+1}e_m = e_m e_{m+1} = e_{m+1}.$$

Their ranges are nested. In dimension d, nonzero ranges allow at most $d - 1$ strict dimension drops. There may be long gaps between drops, but only finitely many drops. The chain therefore becomes constant and has nonzero intersection.

> A single repeated dimension does *not* certify final stabilization. The finite example deliberately has a plateau $4, 4$ before another drop. Finite dimension bounds the number of strict drops, not the time of the last one.

Why every infinite tail can be nonzero while their intersection vanishes

Let P_m project onto the closed span of $e_m, e_{m+1}, \ldots$. Each range is nonzero. But a vector belonging to every range has its j-th coordinate zero once $m > j$. Every coordinate is therefore zero:

$$\bigcap_{m \geq 1} P_m \ell^2(\mathbb{N}) = \{0\}.$$

> **Read this as:** Stabilization in a fixed finite carrier, stable images in an inverse system, and infinite tails in a Hilbert space are different situations. Their hypotheses cannot be exchanged.

Plate XII.17 / THE CONDITIONAL THEOREM / INPUTS AND CONSEQUENCES

Where the arithmetic still enters

Main text: revised Theorem 12.6 and Section 13 Main statement 12.6

The final theorem is a composition of proved implications with explicitly supplied data. Use a single coherent Frobenius normalization in every polynomial comparison. These are not competing labels: an implication may be internally proved while its arithmetic premises remain external.

Gate	What must be supplied	What the formal deduction gives
Residual	Residual automorphic occupancy and a represented deformation problem.	The rings, universal representation, and starting carrier are available as inputs.
Patching	An applicable patching package: full patched support, quotient, and control isomorphism.	Full support descends to the finite-level module or perfect complex.
Comparison	A ring map $f : R \to T$ with the stated support comparison, or the suitable isomorphism and carrier identification.	Support is transported at compatible points.
Fiber	A Hecke point $y : T \to E'$ over the same field, with $y \circ f = x$.	A nonzero scalar fiber and an actual eigensystem. In the derived case, one survives in a cohomological degree.
Realization	Classicality for that eigensystem, an attached representation, continuity, equality of the universal specialization and attached Frobenius polynomials on a dense union of conjugacy classes, and semisimplification/Brauer–Nesbitt inputs.	The specialization is identified after semisimplification with the attached representation.

Support alone does not supply a point over the same field

The inclusion $\mathbb{Q} \to \mathbb{Q}(i)$ preserves full support of the nonzero scalar-extended carrier. But no $\mathbb{Q}$-algebra map $\mathbb{Q}(i) \to \mathbb{Q}$ exists: the image of i would be a rational number a with $a^2 = -1$. Thus one cannot infer the required Hecke point y merely from a support statement.

Propagation needs two existing families and the same automorphic object

After producing an automorphic object π, retain *that same* π. The propagation statement assumes both the original compatible family and the family attached to π already exist, with the common Frobenius polynomial data and the stated comparison hypotheses. It then identifies corresponding members. It does not construct a missing family.

> **Read this as:** The algebra locates and transports supplied nonzero data. Arithmetic inputs establish occurrence, classicality, and attachment. A visualization must not turn one of those inputs into an automatic consequence.

Plate XII.18 / READING ROUTE / SOURCE CROSSWALK / CHECKS

Return to the proofs with a concrete object

Reading guide to Chapter XII and its formal contract Main statement 3.1

Use the example on the left to keep the relevant object in view while reading the exact statement on the right. The guide is explanatory. The main text supplies the theorem hypotheses and the proof contract.

Three short proofreading tests

Can a module have full support but fail to be faithful? Yes. On Plate XII.10, the module k over $k[[x]]/(x^2)$ has a nonzero nilpotent annihilator and full support.

Do equal support sets force equal Fitting ideals? No. On Plate XII.7, (xy) and (x^2y) have the same vanishing set but different infinitesimal behavior.

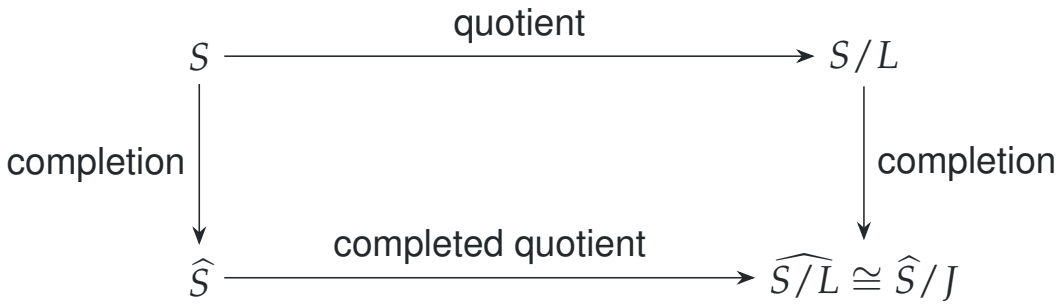
Do nonzero finite levels force a nonzero inverse limit? No. On Plate XII.15, $N^3 = 0$ forces every compatible sequence to vanish, although every level is k^3.

Provenance and reproducibility

The source is Chapter XII, *Patching Support, Hecke Packets, and Conditional Automorphic Completion*. The theorem references above identify statements in that chapter. Its formal companion gives the source and evidence map. The existing 49-claim revised formal contract and its inherited original-wording boundaries are unchanged.

The accompanying Python script performs 46 exact checks: exhaustive finite test-ring enumeration, symbolic minors and CRT identities, exact matrix calculations, and the identities behind the stable-core examples. All drawings are reproducible vector graphics. Further worked details appear on Plates XII.19–XII.25. The inherited revised/original claim boundary is on Plate XII.26. The illustrative examples are not newly certified in Lean by this guide. Its finite checks are recorded separately. Infinite claims are supported by the arguments given here, not by extrapolating a finite image.

Plate XII.19 / TOPOLOGICAL ALGEBRA / THE COMPARISON MAP



Complete the actual topology

Main text: Theorem 3.1, Corollary 3.2 and Proposition 3.3 Main statement 3.1

The hat in $\widehat{\otimes}$ names an actual completion. For the finite family of local rings, start with the ordinary tensor and its ideal of definition:

$$S = \bigotimes_{i=1}^{s} R_i, \qquad \mathfrak{a} = \mathfrak{m}_{\mathcal{O}} S + \sum_i \mathfrak{m}_{R_i} S, \qquad L = \sum_i I_i S.$$

The comparison uses the $\mathfrak{a}$-adic additive uniformity on S, the image ideal topology on S/L, and the closed extended ideal $J = \overline{L\widehat{S}}$.

The square names the actual quotient and completion maps. The lower identification is bicontinuous and preserves the coefficient map and every canonical factor map. The square does not assert that completion leaves S unchanged.

The explicit model revisited

For $R_1 = \mathbb{Z}_5[[x]]$ and $R_2 = \mathbb{Z}_5[[y]]$, the completion of their ordinary tensor in this topology is $\mathbb{Z}_5[[x, y]]$. With L generated by x^2, y, the lower quotient is $\mathbb{Z}_5[\varepsilon]/(\varepsilon^2)$ with its $(5, \varepsilon)$-adic topology. The containment on Plate XII.5 identifies this with its 5-adic topology.

Boundary cases are part of the contract

Case	Actual object and consequence
Empty family	$S = \mathcal{O}$ and $\mathfrak{a} = \mathfrak{m}_{\mathcal{O}}$. The scalar adic topology remains. An empty sum of factor ideals does not erase it.
All $I_i = 0$	$J = 0$; the comparison returns the completed tensor itself.
Some $I_i = R_i$	$J = \widehat{S}$ and both sides are the zero ring. This comparison does not give a local ring with residue field k.

For global base change, the structural map $A \to B$ belongs to the continuous local coefficient-algebra setting. Then $B \widehat{\otimes}_A (A/J) \cong B/\overline{JB}$. For a continuous algebra point to a complete Hausdorff target, closedness of its kernel gives the factorization test. Locality of a point, when supplied, passes to its unique quotient factor.

> **Read this as:** Closure and topology are structural data. A list of equations in a finite model illustrates the quotient but does not replace the actual completed comparison.

Plate XII.20 / RESIDUAL IMAGE / ONE EXPLICIT CERTIFICATE

A finite adequacy calculation

Main text: Theorem 4.2; label `thm:s3_adequacy`. Adequacy convention: external Standard Fact 4.1. Main statement 4.2

Over $k = \mathbb{F}_7$, the standard representation of S_3 has matrices

$$s = \begin{pmatrix} 6 & 1 \\ 0 & 1 \end{pmatrix}, \qquad t = \begin{pmatrix} 0 & 6 \\ 1 & 6 \end{pmatrix}.$$

All entries and calculations on this page are modulo seven. Direct multiplication gives $s^2 = t^3 = I$ and $sts = t^{-1}$. Their eigenvalues are $\{-1, 1\}$ and $\{2, 4\}$. Distinct eigenvalues allow an exact projector formula

$$P_{D,\alpha} = (\alpha - \beta)^{-1}(D - \beta I).$$

sign constituent

$$W = \begin{pmatrix} 2 & 3 \\ 4 & 5 \end{pmatrix} \qquad P_{t,2} = \begin{pmatrix} 2 & 4 \\ 3 & 6 \end{pmatrix} \qquad \operatorname{Tr}(PW) = 3$$

---

standard constituent

$$W = \begin{pmatrix} 6 & 4 \\ 3 & 1 \end{pmatrix} \qquad P_{s,1} = \begin{pmatrix} 0 & 4 \\ 0 & 1 \end{pmatrix} \qquad \operatorname{Tr}(PW) = 6$$

Each row displays the supplied matrix, an actual canonical eigenprojector and its nonzero trace pairing. It detects that stated adjoint constituent. It does not create a global automorphic carrier.

Write $W(a,b,c) = \left(\begin{smallmatrix} a & b \\ c & -a \end{smallmatrix}\right)$. The manuscript exhibits $Z = W(2,3,4)$, $A = W(1,1,2)$ and $B = W(1,5,6)$. Their coordinate determinant is 3. Thus they are a basis of the trace-zero adjoint. Conjugation splits this space as $\mathrm{sgn} \oplus V$. In the drawing the standard witness is $W(6,4,3) = 3A + 3B$.

Why the cohomology argument is uniform in the module

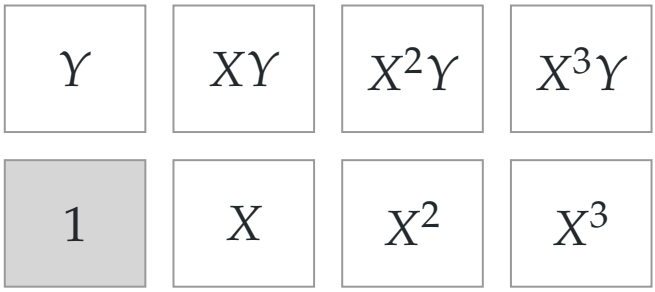
Since $|S_3| = 6$ is a unit in $\mathbb{F}_7$, a cocycle $f : S_3 \to M$ is a coboundary: set $u = -6^{-1} \sum_h f(h)$ and sum $f(gh) = gf(h) + f(g)$ to obtain $gu - u = f(g)$. This proves $H^1(S_3, M) = 0$ for every $\mathbb{F}_7[S_3]$-module M. The printed invariant calculation separately proves $H^0(S_3, \mathrm{ad}^0 V) = 0$.

What makes this a finite certificate

The manuscript also checks absolute irreducibility and projector detection on every irreducible adjoint submodule. In this example $7 \nmid 2$, and every group element's eigenvalues lie in $\mathbb{F}_7$, as required by the stated convention. The two displayed pairings alone are a worked part of that complete certificate.

> **Read this as:** The calculation is exact for $S_3/\mathbb{F}_7$. Applying an automorphy lifting theorem still requires its actual residual image hypotheses and residual occupancy. No adequacy theorem at coefficient prime two follows from this picture.

Plate XII.21 / AUXILIARY ALGEBRA / AN EXACT MONOMIAL BASIS



Augmentation in two variables

Main text: Proposition 5.1, Theorem 5.2 and Theorem 5.4 Main statement 5.2

Take $\Delta = C_4 \times C_2$ in residue characteristic two. If g and h generate its two factors, put $X = g - 1$, $Y = h - 1$. Then

$$\mathbb{F}_2[\Delta] \cong \mathbb{F}_2[X, Y]/(X^4, Y^2).$$

The identity $(1 + X)^4 - 1 = X^4$ and its Y analogue provide the relations. The eight surviving monomials provide the exact dimension $|\Delta| = 8$ and establish the isomorphism after surjectivity.

augmentation: $1 \mapsto 1$; $X, Y \mapsto 0$

All eight basis monomials are displayed. The filled scalar slot survives augmentation. All other displayed monomials lie in the augmentation ideal. This is a basis array, not a spectrum with eight points.

The residual ring is local

The augmentation ideal is (X, Y), its quotient is $\mathbb{F}_2$, and $(X, Y)^5 = 0$: a degree-five monomial has X-exponent at least four or Y-exponent at least two. Every element outside (X, Y) has the form $1 + n$ for nilpotent n, with inverse the finite geometric series. Thus (X, Y) is the unique maximal ideal, and the only idempotents are $0, 1$.

A quotient of groups gives a quotient of algebras

Map $C_4 \times C_2 \to C_2$ by $g \mapsto \bar{g}$, $h \mapsto 1$. The induced algebra map sends X to $\bar{X}$ with $\bar{X}^2 = 0$ and sends Y to zero. It is surjective. Augmentation commutes with this map because every group basis element is sent to another group element of augmentation one.

Recover a free carrier, with its base ring named

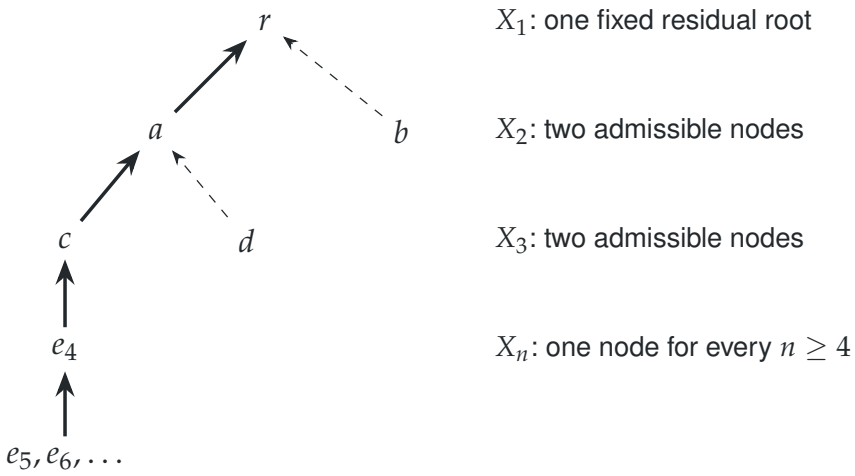
For $\Lambda = \mathbb{Z}_2[\Delta]$ and the right module $M = \Lambda^r$,

$$M \otimes_{\Lambda, \epsilon} \mathbb{Z}_2 \cong M/M \ker \epsilon \cong \mathbb{Z}_2^r.$$

The quotient applies augmentation to each basis coordinate. This remains valid for nonabelian finite two groups with the stated right-module convention. It establishes the rank over the coefficient ring after coinvariants, without establishing full support over a separate deformation ring.

> **Read this as:** The augmentation quotient keeps the scalar coordinate. It needs no averaging denominator and supplies no missing hypothesis on patching support.

Plate XII.22 / FINITE OCCUPANCY / MAPS NEED NOT BE SURJECTIVE



A finite forest selects a branch

Main text: Theorem 10.3 and Corollary 10.4 Main statement 10.3

A finite nonempty set at every precision, with total reduction maps, can select a compatible branch even when some nodes have no deeper lift. Here is an explicit system:

$$X_1 = \{r\}, \quad X_2 = \{a, b\}, \quad X_3 = \{c, d\}, \quad X_n = \{e_n\} \quad (n \geq 4).$$

Both a, b reduce to r; both c, d reduce to a; e_4 reduces to c; and e_{n+1} reduces to e_n for every $n \geq 4$.

Every displayed edge is an actual reduction map. The formula specifies the infinite continuation. The chosen branch is $r, a, c, e_4, e_5, \ldots$. The nodes b, d are admissible at their own precision and have no successor.

What the compactness argument proves

For general finite levels, the reduction forest is a locally finite rooted tree with vertices at every depth. An infinite branch exists. Surjectivity is sufficient but is not necessary: the map $X_3 \to X_2$ above misses b, and $X_4 \to X_3$ misses d.

Finite occupancy does not guarantee a branch through a prescribed node at a higher level. It also does not prove arithmetic occupancy of the finite sets. Those sets must already have been supplied as admissible realizations of the declared spine and residual root.

Why the counterexample with vector spaces is consistent with this

The nilpotent system on Plate XII.15 has a compatible sequence: the zero sequence. Its finite levels are nonempty sets because they contain zero. The question there is whether the inverse limit contains a *nonzero* vector, which needs stable-core data. Here the question is nonemptiness of an inverse limit of admissible finite sets. Different conclusions require different hypotheses.

> **Read this as:** Finite set compactness chooses a branch among existing admissible nodes. It neither extends every node nor produces an arithmetic node absent from the finite forest.

Plate XII.23 / COMPANION COMPLETION / ACTUAL REPRESENTATIVES

Classes are not matrix frames

Main text: revised Theorem 10.5 and its preceding admissibility hypotheses Main statement 10.5

Let $\Gamma = C_2$ with the discrete topology, and represent its generator by $D = \mathrm{diag}(1, -1)$ over $\mathbb{Z}_5$. At precision n, its conjugacy class is an admissible class in $\mathrm{GL}_2(\mathbb{Z}/5^n\mathbb{Z})$. These classes are compatible. Arbitrary representatives need not be.

modulo 25 **modulo** 5

$$\begin{pmatrix} 1 & 23 \\ 0 & 24 \end{pmatrix} \xrightarrow{\text{reduction}} \begin{pmatrix} 1 & 3 \\ 0 & 4 \end{pmatrix} \neq \begin{pmatrix} 1 & 0 \\ 0 & 4 \end{pmatrix}$$

same conjugacy class; incompatible chosen matrices

$$\begin{pmatrix} 1 & 0 \\ 0 & 24 \end{pmatrix} \xrightarrow{\text{reduction}} \begin{pmatrix} 1 & 0 \\ 0 & 4 \end{pmatrix}$$

strictly compatible representatives

The upper representatives are conjugate to the same diagonal involution, but their reductions are unequal matrices. The lower choices use D consistently at both precisions. All entries displayed are canonical residues.

Calculate the mismatch

For $Q = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$,

$$QDQ^{-1} = \begin{pmatrix} 1 & -2 \\ 0 & -1 \end{pmatrix} \equiv \begin{pmatrix} 1 & 23 \\ 0 & 24 \end{pmatrix} \pmod{25}.$$

It reduces to $\left(\begin{smallmatrix} 1 & 3 \\ 0 & 4 \end{smallmatrix}\right)$ modulo five, not the chosen diagonal matrix $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 4 \end{smallmatrix}\right)$. Nevertheless, their residual conjugacy classes agree.

The proof chooses representatives through a finite tree

A finite coefficient quotient has a finite group of invertible basis matrices. Each of the finitely many admissible classes therefore has only finitely many representatives. Take *all* actual continuous representatives of the admissible classes at each level. Reduction is a total map between these finite nonempty sets because admissibility is preserved under reduction. A branch then gives strictly compatible matrices. Completeness reconstructs entries and inverse entries over $\mathcal{O}_\lambda$. Finite-level continuity gives continuity in the ideal-adic topology.

This argument does not assume that a chosen conjugating matrix lifts, nor that every representative has an admissible successor. The theorem retains the declared residual *class*. It specifies neither a prescribed residual frame nor uniqueness up to integral conjugacy.

> **Read this as:** Compatibility of classes is the input. Strictly compatible continuous representatives are a constructed output, obtained with the hypotheses on finite frames and coefficients in the revised statement.

Plate XII.24 / ADIC EFFECTIVITY / DECLARED POLYNOMIAL CONDITIONS

Equations survive every precision

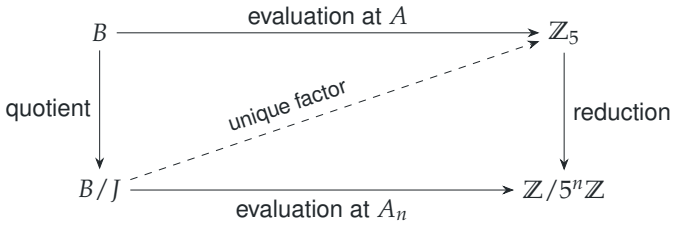
Main text: revised Theorem 10.5 and Corollary 3.2 Main statement 10.5

The preceding involution gives an exact polynomial condition. For a matrix $A = (a_{ij})$, require all entries of $A^2 - I$ to vanish. In

$$B = \mathbb{Z}_5[a_{11}, a_{12}, a_{21}, a_{22}],$$

the ideal J is generated by

$$a_{11}^2 + a_{12}a_{21} - 1, \qquad a_{12}(a_{11} + a_{22}),$$
$$a_{21}(a_{11} + a_{22}), \qquad a_{21}a_{12} + a_{22}^2 - 1.$$



For D and every conjugate QDQ^{-1} these equations vanish. The condition is valid in every admissible frame. By contrast, the equation $a_{12} = 0$ holds for D but fails for the conjugate displayed on Plate XII.23.

The reconstruction argument is coefficientwise

Let A_n be compatible matrices modulo 5^n, each satisfying these four equations. Completeness reconstructs $A \in M_2(\mathbb{Z}_5)$. For each polynomial $f \in J$, evaluation commutes with reduction, so

$$f(A) \in \bigcap_{n \geq 1} 5^n \mathbb{Z}_5 = \{0\}.$$

Separatedness supplies the last equality. Thus the actual evaluation map $B \to \mathbb{Z}_5$ kills J and factors uniquely through B/J. If inverse matrices were reconstructed as well, this is an actual representation in $\mathrm{GL}_2(\mathbb{Z}_5)$.

Every finite evaluation kills the declared ideal. Reduction commutes with evaluation, and separatedness gives integral vanishing. The displayed diagram represents this exact polynomial condition.

The scope of the effectivity conclusion

The companion theorem needs integral Frobenius polynomials, finite admissible continuous classes, reduction closure, finite occupancy, and the declared triviality subgroup. A condition in one frame needs an argument using compatible frames. An arbitrary Hodge or Weil–Deligne condition is not automatically a polynomial ideal in matrix entries.

Represented local quotient conditions use continuous ring maps and the closed-kernel argument on Plate XII.19. These are different supplied objects from the polynomial evaluation model.

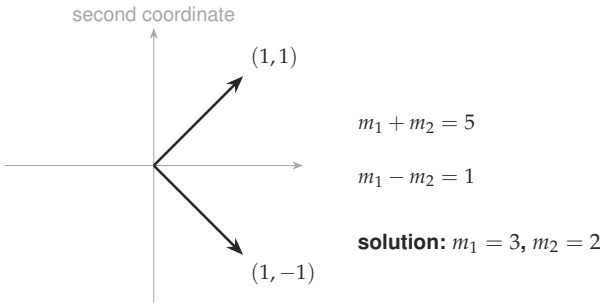
> **Read this as:** The precise coefficient and admissibility hypotheses preserve declared equations. Representability of a desired arithmetic condition remains a separate input.

Plate XII.25 / A FINITE SEPARATOR / A KNOWN SEMISIMPLE CARRIER

Recover multiplicities from traces

Main text: Proposition 10.9 Main statement 10.9

Suppose a known semisimple carrier is a sum of two known constituents with multiplicities m_1, m_2. Consider the independent trace functions



$$t_1(\omega) = 1, \qquad t_2(\omega) = \omega, \qquad \omega \in \mathbb{Q}.$$

At the two sample points $\omega = 1, -1$, their evaluation matrix is

$$A = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \qquad \det A = -2.$$

It is invertible over $\mathbb{Q}$. If the measured trace vector is $(5, 1)$, solve

$$A \begin{pmatrix} m_1 \\ m_2 \end{pmatrix} = \begin{pmatrix} 5 \\ 1 \end{pmatrix} \quad \Longrightarrow \quad \begin{pmatrix} m_1 \\ m_2 \end{pmatrix} = \begin{pmatrix} 3 \\ 2 \end{pmatrix}.$$

The vectors $(1, 1)$ and $(1, -1)$ are the two independent rows of the exact evaluation matrix. The coefficients $3, 2$ are recovered by the displayed linear equations. This illustration uses functions on $\mathbb{Q}$, not a newly constructed arithmetic Frobenius set.

Why finitely many evaluations suffice in general

Independent functions $t_1, \ldots, t_r$ on Ω have evaluation vectors spanning E'^r. Otherwise an annihilating nonzero linear functional would give a forbidden relation among the functions. Choosing r independent evaluations gives an invertible matrix that recovers coefficients in their known sum.

Two checks before using this in arithmetic

The trace functions must be independent on the permitted Frobenius set. The carrier must already be semisimple with the stated constituents. Arbitrary samples supply neither premise. Nonnegative integral multiplicities come from representation data, not every rational solution of a linear system.

The coefficient field matters again

The displayed integer matrix reduces modulo two to a matrix with determinant zero and two coincident rows. Those residual samples cannot recover the two coefficients. This matches the trace caution on Plate XII.14: characteristic-zero trace detection cannot be silently transported to residue characteristic two.

> **Read this as:** A finite separator reconstructs coefficients in supplied independent trace data. It is not a construction of the constituents, their compatible systems, or automorphic realizations.

Plate XII.26 / PROVENANCE / REVISED SCOPE AND ORIGINAL WORDING

Read the exact claim contract

Source: the revised formal contract and original-wording comparison in the formal companion Main statement 12.6

This guide explains the revised manuscript and retains its inherited verification boundaries. There are two censuses, with different statements as their subjects:

Inherited contract	Complete	Partial	Unchecked
Revised 49 internal claims	49	0	0
Original wording of those claims	41	7	1

The eight inherited amendments

Claim	Scope that the revised statement makes explicit
6.12	Each irreducible component is contained in full support. The original containment was reversed.
9.4	Hausdorff coefficient topology and continuity for the compared representations.
9.5	The realized locus consists of points satisfying those topology and continuity hypotheses.
9.6	The surviving cohomological degree belongs to the declared classicality range. Comparison inputs are explicit.
10.5	Complete separated coefficients, finite continuous admissible classes, integrality, and actual quotient equations in every admissible frame.
12.2	Continuous characteristic-zero pointwise comparison under the stated realization input.
12.4	Applicability of realization at the selected derived eigensystem, with the comparison inputs exposed.
12.6	A compatible Hecke point $y \circ f = x$, actual ordinary or derived carriers, and both existing families for the same automorphic object.

In the inherited record, original 6.12 is unchecked. Original 10.5 and the other six amended claims are partial. Revised completeness does not certify the stronger original wording. Claims 3.1 and 3.3 required no additional amendment in the recorded completion.

Scope clarifications

The companions expose finite S, a coherent Frobenius normalization, the local coefficient-test category in 3.3, the $r > n$ Fitting boundary, and both compared Frobenius polynomial identities in ordinary completion. These clarifications are distinct from the eight inherited amendments. No new Lean replay certifies them.

Plate XII.27 / VALIDATION / FOUR DISTINCT KINDS OF EVIDENCE

How to assess the evidence

Inherited source records, current illustrative calculations and final editorial review Main statement 12.6

What this companion adds and what its checks mean

The guide preserves the earlier worked examples. TikZ generates every drawing from exact objects. There are no raster figures. Python checks finite enumerations, minors, projectors and matrices. The text argues uniform conclusions. These checks supply no new Lean certificate or census update. Supporting Markdown (.md) files accompany the source.

> **Read this as:** The source's internal formal implications are distinguished from the arithmetic inputs: representability, residual occupancy, applicable patching, classicality, attached representations and compatible systems, Frobenius density, semisimplification and Brauer–Nesbitt. Universal companions and unrestricted reciprocity remain outside the proved scope.

Inherited labels and current mathematical judgments

The original-status labels record historical verification coverage. The current mathematical audit judges the actual statements. These are different questions:

Original	Inherited label	Current judgment of the statement
6.12	unchecked	The reversed containment is false: in the node of Plate XII.9, $M = R$ has full support, which is not contained in either single component.
10.5	partial	The unrestricted effectivity conclusion lacks the coefficient, continuity, integrality and frame hypotheses made explicit in the statement.

Use each check for its actual subject

Evidence	What its subject is
Inherited Lean record	The mapped revised statements under their supplied hypotheses. This guide neither replays that build nor changes the original-wording record.
Current exact Python checks	Forty-six illustrative assertions: 31 inherited checks and 15 added checks on the printed finite examples and identities.
Mathematical arguments	Uniform quotient, specialization and all-level conclusions, with their hypotheses retained in the text. A finite diagram is not an infinite proof.
PDF and rebuild checks	Topic alignment, bounds, vector-only assets, resolved references, and an isolated byte/text/page comparison. These are document checks.

The source and claim maps identify all 49 internal statements and their exact mathematical labels. Their records separate formal coverage, finite checks and ordinary arguments. Finite calculation does not verify residual automorphic existence, classicality, attached compatible systems or a universal arithmetic theorem.

Further studies

The following studies develop the restricted arithmetic constructions, obstructions and remaining realization questions associated with Chapter XI.

FURTHER STUDY

Arithmetic realization and its obstructions

These studies distinguish finite packet constructions, actual arithmetic candidates, full-character occurrence and comparison for the same candidate.

READING ROUTES

Research companion 1484

Scope

Conjecture 66 remains open. Its unresolved requirements concern general arithmetic realization, H5 for the same candidate, corrected full-character occurrence and actual native data under the stronger contract.

Reading the arithmetic studies

The three parts of this companion develop restricted constructions, compare alternative arithmetic routes, and isolate the remaining conductor and marking obligations.

Part I. Restricted arithmetic constructions. Sections 1–13 develop odd-prime and weighted dyadic recursion, full-character induction, native quotient obstructions, and low-rank enlarged-carrier recovery.

Part II. Monomial routes, Clifford descent and exact obstructions. Sections 14–21 separate admissible induction towers, genuine multiplicities, character occurrence and self-twist failure, compact binders, and exact corner obstructions.

Part III. Conductors, native markings and the equal-capacity boundary. Sections 22–30 examine conductor normalization and candidate filters, separate pair invariants from quotient capacity, and give the fixed-refinement criterion with explicit conditional finite corrections.

Source provenance. Part I remains a preserved reader because its complete editable source archive was not recovered. Parts II and III, the assembly programs, exact suites, source maps, and evidence ledger have editable sources. The retained compact source package contains selected supporting research records, not the entire source archive.

Mathematical boundary. The general realization conjecture, same-candidate H5, and corrected-character occurrence retain their separate open statuses. Host dimension does not supply a canonical native quadratic marking. The finite correction theorems require the stated actions and permitted changes. The recorded conductor and marking audit includes no fresh Lean build or external peer review.

Remaining arithmetic task. The chosen candidate’s actual native marking and phases must still be supplied. The visual studies illustrate this obligation without replacing it.

Reading scope

This study collects the mathematical progress toward the arithmetic realization endpoint of Chapter XI. Its central object is not a numerical completion score. It is the proposed passage from a supplied finite packet, with its character values, phases and transport maps, to an actual supercuspidal representation carrying that same packet.

The general passage remains Conjecture 66. That fact does not erase the constructions obtained along the way. The available record contains finite comparison theorems, arithmetic dictionaries, explicit parameter constructions, full character arguments, exact obstructions to particular hosts, and a low-rank dyadic repair using larger arithmetic inducing groups. The purpose of these studies is to develop these results in their own right, without confusing a restricted construction with a universal realization theorem.

The direct constructions make the parameter recursion, full characters, low-rank recovery, corestriction normalization, native traces, depth endpoints, and noncompact inducing data explicit. The principal Bushnell–Kutzko inputs were checked against the retained book and remain classical inputs. No new Lean compilation or external peer review is claimed. Earlier records described as independent reviews refer to internal reviews.

The evidence record distinguishes manuscript coverage, ordinary proofs, classical inputs, exact computation, inherited formal evidence, and unresolved research obligations. These are separate kinds of evidence. None is treated as a substitute for another.

This research companion develops the arithmetic questions left open in Chapter XI. The retained source archive contains detailed proofs, construction notes, audits, and research records. Its machine-readable source map identifies the files behind each section and distinguishes executed finite checks from inherited evidence.

The monomial, Clifford-descent, and binder branches are developed in Sections 14–21. Conductor and marking questions are examined in Sections 22–30. The synthesis does not claim to incorporate every argument in every retained research record. The formal evidence and source map preserve the remaining provenance boundaries.

1 The realization problem and its quantifiers

1.1 Three different mathematical tasks

Chapter XI separates finite comparison, arithmetic existence and local-factor characterization. These tasks interact, but they have different inputs. A finite Heisenberg representation can be constructed from a nondegenerate alternating pairing. A compatible family of intertwiners can be constructed after its source and target representations are supplied. Neither statement, by itself, constructs the required representation of a general linear group over a local field.

Fix the reciprocity, additive-character, local-factor and phase conventions of Chapter XI. Let $\mathcal{A}$ denote the declared class of irreducible wild Weil atoms. For $\rho \in \mathcal{A}$, write d_ρ for its *supplied* assembled finite datum. The historical names H1–H4 refer to the following data: an intrinsic finite break decomposition, equivariant symplectic bridges to the supplied breakwise type quotients, compatible central-extension and phase data including the declared markings, and a coherent transport system whose matrix holonomy obstruction vanishes. These are assumptions on a specified source, not a theorem that every wild Weil representation already comes equipped with a canonical instance [1, 3].

Definition 1.1 (Arithmetic realization witness)**.** A witness $R(d_\rho, \pi)$ consists of actual arithmetic inducing data for an admissible supercuspidal representation π of $\mathrm{GL}_{\dim \rho}(F)$, together with comparison and recovery maps carrying the prescribed assembled finite packet. Those maps must preserve the declared stabilizer action, supplied character values, central-extension and phase data, and compatible transports. Recovery returns the same π, with the fixed central character and noncompact completion.

An enlarged actual inducing carrier is permitted by this contract. The entire assembled packet need not be the original maximal-simple-type quotient. Conversely, an independently fixed native marking, an original matrix subgroup embedding, or a prescribed numerical depth is not automatically preserved merely because the scalar extension is preserved. Such requirements must be stated and proved separately.

1.2 The conjecture and the surviving comparison theorem

The endpoint is the following statement, with its historical identifier retained:

> **Conjecture 66.** For every $\rho \in \mathcal{A}$ with its supplied H1–H4 datum d_ρ, there exist an actual admissible supercuspidal representation π of $\mathrm{GL}_{\dim \rho}(F)$ and a witness $R(d_\rho, \pi)$.

This is the realization requirement isolated from historical Theorem 16.2, original proof obligation 66, and row 95 of the all-records register. It is not row 66 of that register. It asks for one witness per admitted source. It does not ask that every proposed host work, or that mutually inconsistent noncompact completions be reconciled.

Proposition 1.2 (Comparison of the same realized candidate)**.** *Suppose $R(d_\rho, \pi)$ is supplied for one actual admissible supercuspidal π of the required rank. Suppose H5 holds for this π: its required pair local factors agree with the factors prescribed for ρ on the stipulated characterizing family of twists, in the fixed normalizations. Assume the applicable local-factor characterization for that family and class. Then $\pi \simeq \mathrm{LLC}(\rho)$.*

Proof. The characterization applies to the two actual representations π and the reference representation $\mathrm{LLC}(\rho)$. H5 provides equality of the characterizing factors, so their isomorphism classes agree. The

witness R identifies this same candidate as the carrier of the prescribed packet. The argument neither constructs π nor derives H5 from the finite datum. □

Evidence and scope. This is the pointwise conditional implication in the current paper, not a new local converse theorem. The local-factor characterization is a stated external input.

The distinction can be written as

$$\forall \pi\, [R(d,\pi) \Rightarrow H5(\pi)] \qquad \text{versus} \qquad \exists \pi\, [R(d,\pi) \wedge H5(\pi)].$$

The first statement is true when there are no realizers. The second supplies a realizer. Likewise, a witness of $R(d,\pi_1)$ and a verification of H5 for an unrelated π_2 cannot be combined. This elementary point is important because the general formal interface can quantify over several realizers, while the pointwise comparison uses one fixed candidate.

1.3 What a host obstruction does and does not refute

Let $\mathcal{H}(d)$ be the class of admissible hosts for a datum d. A failed construction establishes that one chosen H does not realize d, or perhaps that no H in a particular subclass does. To refute Conjecture 66 for that datum would require excluding every allowed arithmetic witness. The capacity and inner-normalizer obstructions below are therefore substantive negative results without being counterexamples to the conjecture. They identify constraints a successful construction must avoid.

2 What the formal continuation actually contributes

2.1 The original obligation count is not a measure of distance

The inherited formal record organizes the original paper around 66 obligations. Its retained 65/66 checkpoint means that the final general realization obligation has not been closed under the original scope. It does not mean that one short lemma is left, or that the remaining task is one sixty-sixth of the mathematical work.

2.2 From abstract dictionaries to arithmetic attachments

The continuation sequence matters because it repeatedly strengthens the interpretation of a formal object. A module can prove a theorem about a lattice index without identifying that lattice with the canonical lattice of a supplied arithmetic type. A structure can contain an existence field without constructing an inhabitant of that field. An arbitrary character with the correct values on a tested subgroup need not be the original full character.

Continuation 110 develops Morita-lattice indices, exact one-plus comparisons, and same-carrier dictionaries. Its remaining task is not to rename an abstract parameter as canonical. It is to attach the arithmetic groups, the original character, the canonical extension, and the residue factor to the exact formal data. Continuation 111 moves the character and index attachment further and separates a valid one-break

conditional comparison from the general common-host problem. Separate actual break types do not automatically assemble into one arithmetic type of the total rank [4, 5].

Continuations 112 and 113 make the boundary more concrete. The former supplies complex scalar-cochain transport and honest cyclic-action machinery. Its degree obstruction concerns a whole maximal-type carrier, rather than refuting every permissible assembly carrier. The latter records a cubic non-occurrence test: the first proposed simple character does not occur in the original automorphic-induction candidate. A corrected wild-unit proposal passes the stated self-twist test, but that positive test alone does not prove occurrence [6, 7].

2.3 The retained contract for formal evidence

A Lean theorem certifies its displayed conclusion from its displayed binders and imported declarations. It does not silently instantiate a local field or produce an arithmetic representation that was supplied as a field of a structure. In the general comparison interface, `Realization.exists_atom` is an existence input. The source can still prove nontrivial descent, comparison and uniqueness results using that input. The existence obligation remains distinct.

3 Central products remove one proposed finite obstruction

The finite extension diagnosis [8] isolates a useful positive fact. Once the full factor extensions and their orthogonality are supplied, no further mixed scalar extension class is automatically left over. The following proofs reconstruct the elementary core of that diagnosis.

Proposition 3.1 (Orthogonal factors form a balanced central product)**.** *Let $1 \to Z \to P \to A \to 1$ be a central extension, with $A = \bigoplus_{i=1}^{d} A_i$ with $d \geq 1$. Let P_i be the inverse image of A_i. Assume elements of P_i and P_j commute for $i \neq j$. Then multiplication induces an isomorphism*

$$\Big(\prod_i P_i\Big)\Big/\{(z_i) \in Z^d : \prod_i z_i = 1\} \;\simeq\; P.$$

Proof. Commutation makes multiplication a homomorphism. Given $x \in P$, decompose its image in A as $\sum_i a_i$ and choose a lift $x_i \in P_i$ of each a_i. The difference between x and $\prod_i x_i$ is central and can be absorbed into one factor. Thus multiplication is onto. If $\prod_i x_i = 1$, its image in the direct sum gives $a_i = 0$ for every i. Hence each x_i lies in Z, and the only remaining condition is $\prod_i x_i = 1$. This is exactly the displayed kernel. □

This proposition uses the actual factor extensions, not just a list of dimensions or break labels. Distinct break numbers do not, by themselves, prove the required independence or commutation.

Proposition 3.2 (Same commutator over a divisible scalar center)**.** *Let A be a finite abelian group. Two central extensions of A by $\mathbb{C}^\times$ with the same alternating commutator are isomorphic by a map inducing the identity on A and on $\mathbb{C}^\times$. The isomorphism need not preserve additional independently fixed lifts or finite-center markings.*

Proof. Choose sections and write the two normalized cocycles as a_1, a_2. Their ratio $b = a_2/a_1$ has trivial commutator, so its extension is abelian. Write $A = \bigoplus_j \mathbb{Z}/n_j\mathbb{Z}$ and choose a lift u_j of each cyclic generator

in that abelian extension. Its n_j th power is a scalar. Since $\mathbb{C}^\times$ has n_j th roots, rescale u_j so that $u_j^{n_j} = 1$. The adjusted commuting lifts define a splitting. Thus b is a coboundary and the two original extensions are equivalent. The rescaling choices need not fix any prescribed lift. □

Automorphisms inducing the identity on quotient and center form $\mathrm{Hom}(A, \mathbb{C}^\times)$: they multiply a lift of a by a character value. This residual freedom is exactly why an unmarked scalar-extension equivalence is not a canonical identification of all source data.

3.1 Quadratic information survives only when its marking travels

In characteristic two, let $V = \mathbb{F}_2^2$ and

$$q_+(x,y) = xy, \qquad q_-(x,y) = x + y + xy.$$

They have the same polarization $b((x,y),(x',y')) = xy' + x'y$. Their Gauss sums are different:

$$\sum_{v \in V} (-1)^{q_+(v)} = 2, \qquad \sum_{v \in V} (-1)^{q_-(v)} = -2.$$

The numbers of zeros are three and one. Thus the alternating form alone cannot recover the quadratic refinement.

For a literal representation, put

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

Both pairs (X, Z) and (iX, iZ) have commutator $-I$. In the first pair the generating lifts square to I. In the second they square to $-I$. They generate the usual dihedral and quaternion groups of order eight. After the center is extended to $\mathbb{C}^\times$, the scalar groups generated together with all scalar matrices coincide. Their distinguished finite subgroups and lift-square functions do not coincide.

This example explains the dyadic attachment rule. An extension map F_0 preserves a chosen square relation when the whole marked finite subgroup is carried along, because $F_0(a)^2 = F_0(a^2)$. It does not prove that this transported marking equals an independently fixed native marking of the host [19]. A kernel already killed by the scalar pushout cannot be recovered afterwards by an extension isomorphism.

4 Abstract stabilizer lifting is not an arithmetic normalizer

Two elementary arguments remove finite scalar obstructions under a coprimality hypothesis. They must not be misread as constructing matrices in the required arithmetic normalizer.

Proposition 4.1 (Coprime lifting of an extension action)**.** *Let A be a finite abelian p-group, and let P be a central extension by $\mathbb{C}^\times$. Let a finite group C of order m prime to p act on A, preserving the extension class. Then the action lifts to an action on P fixing the center.*

Proof. Choose a lift q_c for each $c \in C$. The kernel of the group of extension automorphisms over the quotient and center is $M = \mathrm{Hom}(A, \mathbb{C}^\times)$, a finite abelian p-group. Conjugation defines the C-module structure on M. Write the defect of the chosen lifts additively as

$$q_c q_d = f(c,d) q_{cd}, \qquad f(c,d) \in M.$$

Associativity gives

$$f(c,d) + f(cd,e) = cf(d,e) + f(c,de).$$

Let $S(c) = \sum_{e \in C} f(c,e)$. Summing the identity over e gives

$$mf(c,d) = S(c) + cS(d) - S(cd).$$

Multiplication by m is invertible on M. Put $b(c) = m^{-1}S(c)$ and replace q_c by $(-b(c))q_c$. Their new multiplication defect is zero. The adjusted lifts form the required action. □

The hypothesis that each quotient automorphism preserves the extension class supplies the initial individual lifts. Proposition 3.2 supplies that hypothesis when the quotient action preserves the commutator in the finite abelian setting. Neither proposition realizes those lifts by conjugation in $\mathrm{GL}_n(F)$.

Proposition 4.2 (Coprime linearization of projective intertwiners)**.** *Let C be finite of order m. Suppose U_c are invertible operators on a complex vector space of dimension D, with $U_c U_d = a(c,d)U_{cd}$ for a scalar cocycle a. If $\gcd(D,m) = 1$, the operators can be rescaled to a genuine representation of C.*

Proof. Taking determinants shows that a^D is the coboundary of $c \mapsto \det U_c$. Set $A(c) = \prod_{x \in C} a(c,x)$. The cocycle identity, multiplied over x, gives $a(c,d)^m = A(c)A(d)/A(cd)$. Choose integers r,s with $rD + sm = 1$. Then

$$a = \delta\big((\det U)^r A^s\big).$$

Rescaling by the inverse of this cochain eliminates the cocycle. □

For a Heisenberg carrier of dimension p^k and a prime-to-p group C, the coprimality condition holds. Two honest linearizations can still differ by a character. Thus this argument does not select a canonical beta-extension phase. Nor does it cover a stabilizer with p-torsion without further work [8, 23].

5 The compact binder theorem and the missing solvability input

The binder construction asks whether finite compatibility conditions can be joined into one global coefficient choice. The compactness theorem [9] identifies the precise missing input: joint finite solvability within one fixed compact model.

Theorem 5.1 (A fixed compact coefficient binder)**.** *Let F be a nonarchimedean local field, $\mathcal{O}$ its compact ring of integers, and ϖ a uniformizer. Let $X \subseteq \mathcal{O}^m$ be closed and let $f_j : X \to \mathcal{O}$ be continuous for $j \geq 1$. Define*

$$C_n = \{x \in X : f_j(x) \in \varpi^n \mathcal{O} \text{ for every } j \leq n\}.$$

There is an $x \in X$ with $f_j(x) = 0$ for all j if and only if every C_n is nonempty.

Proof. An exact zero belongs to every C_n. Conversely, each C_n is a closed subset of the compact space X, and $C_{n+1} \subseteq C_n$. Nonempty nested closed subsets of a compact space have nonempty intersection. Choose x in that intersection. For any fixed j, one has $f_j(x) \in \varpi^n \mathcal{O}$ for all $n \geq j$. The intersection of these ideals is zero, so $f_j(x) = 0$. □

The theorem does not require surjectivity of a chosen sequence of reduction maps. It does require a single compact coefficient space and simultaneous finite solvability within that space. Allowing the rank, pole order or number of coefficients to grow with precision changes the space and invalidates this argument unless a separate compact model is supplied.

5.1 When a finite empty level is an actual certificate

For polynomial equations with integral coefficients, or rational equations whose denominators remain units, a fixed finite residue template gives a finite test at each precision. If the template exactly describes X modulo ϖ^n, then emptiness of its complete solution set certifies failure of that fixed template. If there is no exact solution in the fixed compact model, Theorem 5.1 guarantees some empty level.

This is a semidecision procedure for nonexistence within that model. It provides neither a uniform bound on the first empty level nor a proof that a partial search was exhaustive. A failed random search, a resource cutoff and an actual empty finite level have different logical meanings.

Example 5.2 (Individual equations are not simultaneous solvability)**.** Over $\mathbb{Z}_2$, the equations $x = 0$ and $x = 1$ are each soluble to every precision. They have no common solution even modulo two. The nonempty sets needed in Theorem 5.1 contain joint solutions to the first n equations, not a separate solution for each equation.

Example 5.3 (A nonclosed admissibility condition can disappear)**.** The elements $x_n = 2^n$ are nonzero in $\mathbb{Z}_2$ and satisfy $x_n \equiv 0 \pmod{2^n}$. Their limit is zero. A requirement such as $x \neq 0$, or an unspecified nonzero determinant, is not automatically a closed condition. A fixed unit leading coefficient or a prescribed nonzero residue class is a different condition and can survive the limit.

5.2 The actual matrix binder obligation

The retained matrix template uses a square-zero variable x and expressions of the form

$$Q(x) = -s(xb_0x), \qquad \beta(x) = \gamma' + [x, b_0] - xb_0x, \qquad x^2 = 0.$$

The purpose is to force desired corestriction and leading-lane behavior inside actual matrix algebras. Compactness can assemble solutions only after the source-to-equation encoding is faithful, the admissibility conditions define a closed fixed template, and every finite collection of equations is jointly soluble. The general H1–H4 assumptions have not been proved to imply those three facts. The binder theorem therefore sharpens the realization problem without closing it.

6 Profiles, twists and the identity of the candidate

6.1 Compact restrictions forget noncompact information

Proposition 6.1 (Unramified twists are invisible on compact subgroups)**.** *Let J be a compact subgroup of $\mathrm{GL}_n(F)$. Then $v_F \circ \det$ vanishes on J. For any $a \in \mathbb{C}^\times$, the unramified character $\nu_a(g) = a^{v_F(\det g)}$ is trivial on J.*

Proof. The continuous image of the compact group J in the discrete group $\mathbb{Z}$ is a finite subgroup. The only finite subgroup of $\mathbb{Z}$ is zero. The character formula now gives the assertion. □

Consequently $\pi|_J$ and $(\pi \otimes \nu_a)|_J$ agree, while the central character on a scalar uniformizer changes by a^n. Choosing $a^n \neq 1$ makes this a visible difference. Compact packet recovery therefore has to retain the noncompact extension, not just its compact restriction.

6.2 Information tests do not replace full pair factors

The inherited rank-nine information test [10] is more specific. Its rank-nine examples, conditional on the pinned source construction used there, have the same recorded determinant, Frobenius matrix, slope, Swan conductor, projective Weil map and self-pair data. They differ in an actual scalar quotient map and are separated by a stated twist test. In the recorded test the Artin conductors are 33 and 45. The source does not claim equality of H5, and these examples are not counterexamples to local-factor characterization [10].

Twist transport has a positive use as well. Once a compatible base realization is genuinely supplied, its character and inducing data can be transported under the stated twist. That transports an existing witness. It does not supply the missing base witness. The distinction is the same one encountered in the formal existence field.

6.3 Equal numerical profiles do not determine quotient capacity

The later dyadic record gives an exact arithmetic comparison of two host patterns. At rank eight with $(h_1, h_2, h_3) = (1, 3, 5)$, the full defining tower has levels $(60, 18, 3)$, Swan conductor 60, torsion number 1 and self-pair conductor 342. Its symplectic type quotient has dimension 6. A skipped-degree pattern $8 \to 2$ can have the same three numerical invariants with quotient dimension 4 [18].

The formula makes the comparison transparent. Put $L = 12h_3$ and $c = h_1 + 4h_2$. For the stated skipped-degree construction,

$$a_{\mathrm{skip}} = 63 + 4L + 3c = 63 + 48h_3 + 12h_2 + 3h_1 = a_{\mathrm{full}}.$$

Yet the two capacity formulas remain different. The recorded exact checks verify the displayed arithmetic identities. The assertion that both patterns arise from actual simple strata remains an ordinary arithmetic claim established in the retained source.

7 The direct odd-prime construction

Evidence and scope. The odd-prime construction [11–14] uses ordinary parameter and character arguments relative to the explicit Bushnell–Kutzko inputs in Section 13. The cited statements and their principal hypotheses were checked in the recorded source audit. This supplies neither Lean proofs of simple-character theory nor a proof of H5.

7.1 Notation and the construction contract

Let p be odd and put $F = \mathbb{F}_p((t))$. Choose

$$0 < h_1 < \cdots < h_d, \qquad p \nmid h_i, \qquad q_i = (p+1)h_i, \qquad N = p^d.$$

The construction produces a literal matrix $\beta \in M_N(F)$, rather than a formal symbol for an unknown arithmetic parameter. Its generated field is maximal and totally ramified, and it normalizes a complete lattice chain. A subsequent, separate argument constructs a full simple character and an extended inducing representation. Only after those steps is there an actual supercuspidal candidate.

At an intermediate local field L, write $\mathcal{O}_L$ for its ring of integers and t_L for its chosen uniformizer. For a hereditary order $\mathfrak{A}$ with radical $\mathfrak{P}$, put $U^r_{\mathfrak{A}} = 1 + \mathfrak{P}^r$ for $r \geq 1$. The valuation $v_{\mathfrak{A}}(x)$ is the largest integer r with $x \in \mathfrak{P}^r$. On a complete period-N chain, scalar valuations satisfy $v_{\mathfrak{A}}(a) = N v_L(a)$. We use ordinary matrix trace over the displayed coefficient field. No trace is divided by a matrix size.

7.2 A separable degree-p step with a native trace identity

Lemma 7.1 (Artin–Schreier parameter and uniformizer)**.** *Let L have characteristic p and residue field $\mathbb{F}_p$, and let $q > 0$ with $p \nmid q$. The equation*

$$\alpha^p - \alpha = t_L^{-q}$$

defines a separable totally ramified extension E/L of degree p. With normalized valuation on E, one has $v_E(\alpha) = -q$. Choose $1 \le b < p$ and $a \in \mathbb{Z}$ with $qb \equiv -1 \pmod{p}$ and $pa = qb + 1$. Then $z = t_L^a \alpha^b$ is a uniformizer and $E = L(z)$. For odd p, $\mathrm{Tr}_{E/L}(\alpha) = 0$.

Proof. If $x \in L$ has negative valuation, then $v_L(x^p - x) = pv_L(x)$ is divisible by p. If its valuation is nonnegative, so is the valuation of $x^p - x$. Thus the right side is not an Artin–Schreier coboundary. All roots differ by constants in $\mathbb{F}_p$. The splitting field obtained by adjoining one root has Galois group a subgroup of the additive group of $\mathbb{F}_p$, so its degree is either one or p. The absence of a root in L forces degree p.

The derivative is -1, which proves separability. If $e = e(E/L)$, the valuation equation gives $pv_E(\alpha) = -eq$. Since $p \nmid q$, one has $p \mid e$. The extension has degree p, hence $e = p$ and $v_E(\alpha) = -q$. The residue degree is one. Finally

$$v_E(z) = pa - qb = 1, \qquad \mathrm{Tr}_{E/L}(\alpha) = \sum_{c \in \mathbb{F}_p} (\alpha + c) = 0$$

for odd p. An element of valuation one cannot belong to L, whose value group in E is $p\mathbb{Z}$, so $L(z) = E$. □

The minimal polynomial $f(X) = \sum_{k=0}^{p} a_k X^k$ of z, with $a_p = 1$, is Eisenstein. It is explicitly computable from

$$f(X) = \prod_{c \in \mathbb{F}_p} \bigl(X - t_L^a (\alpha + c)^b\bigr),$$

reducing by the Artin–Schreier relation. This instruction uses only finite field operations. It does not call an existence oracle for the desired final field.

7.3 The corestriction normalization and its filtered right inverse

In the basis $1, z, \dots, z^{p-1}$ of E/L, let T_{ij} be the coefficient matrix unit. The trace-dual basis is

$$z_j^* = \frac{\sum_{k=j+1}^{p} a_k z^{k-j-1}}{f'(z)}, \qquad 0 \le j < p.$$

The trace corestriction pr satisfies $\mathrm{pr}(T_{ij}) = z^i z_j^*$. Set

$$\kappa = -\frac{f'(z)}{z^{p-1}}, \qquad s = \kappa\,\mathrm{pr}.$$

The leading term of $s(T_{ij})$ is $-z^{i-j}$. Every other term has strictly higher valuation. Indeed $v_E(a_k) \ge p$ for $0 \le k < p$, and the term indexed by $k \ge 1$ has valuation at least k above the leading term. This is the normalization used below, not an arbitrary scalar multiple whose effect on the character is left unspecified.

Let P_0 extract the constant coefficient in each E-coordinate of E^m. The equation $f(z) = 0$ gives

$$z_0^* = -\frac{a_0}{z f'(z)}, \qquad u_0 = s(P_0) = \frac{a_0}{z^p} \in \mathcal{O}_E^\times.$$

For $C \in M_m(E)$ define the L-linear operator

$$\mathrm{Lift}_E(C) = \nu_0^{-1} C P_0. \tag{1}$$

Here the order of composition matters. In a wildly ramified extension, replacing P_0 by an E-linear commuting perturbation would destroy the intended derived contribution.

Proposition 7.2 (Exact corestriction and trace identities)**.** *For the complete interleaved chains on E^m, the operator in* (1) *satisfies*

$$\begin{aligned} s(\mathrm{Lift}_E(C)) &= C, \\ v_{\mathfrak{A}}(\mathrm{Lift}_E(C)) &= v_{\mathfrak{B}}(C) \quad (C \neq 0), \\ \mathrm{tr}_L(\mathrm{Lift}_E(C)) &= \mathrm{Tr}_{E/L}\big(\kappa^{-1} \mathrm{tr}_E(C)\big). \end{aligned}$$

Here $\mathfrak{B}$ is the complete E-order and $\mathfrak{A}$ the corresponding interleaved L-order. In particular $s(\mathfrak{P}^r) = \mathfrak{Q}^r$ at every integer grade.

Proof. The corestriction is an $M_m(E)$-bimodule map. Thus its value on $\nu_0^{-1} C P_0$ is $\nu_0^{-1} C \nu_0 = C$.

For the filtration assertion, take the basis $w_{mi+u} = z^i v_u$, with $0 \le i < p$ and $0 \le u < m$. Multiplication by the unit ν_0^{-1} preserves the E-chain valuation. A term $c_i z^i E_{uv}$ in an entry of $\nu_0^{-1} C$ contributes to a constant-coefficient column of the lift at grade

$$pm\, v_L(c_i) + mi + u - v.$$

This is precisely its E-chain grade. For a fixed entry, the valuations of different powers z^i are distinct modulo p, so a minimum cannot disappear by cancellation. The minimum over all entries proves equality of grades. The leading-term formula for $s(T_{ij})$ gives filtration preservation for s itself, while the explicit lift gives surjectivity on every grade.

Finally the L-trace of the rank-one operator yP_0 is its constant coefficient, namely $\mathrm{Tr}_{E/L}(z_0^* y)$. Apply this entrywise to the diagonal of the lift and use $z_0^* \nu_0^{-1} = \kappa^{-1}$. □

The proposition is not a bimodule splitting of a wildly ramified integral corestriction sequence. The lift is a chosen L-linear coefficient construction. In particular it need not commute with the embedded field. This distinction agrees with the warning following BK 1.4.10 and with BK 2.2.6 [25].

7.4 Recursion, native trace, and literal arithmetic fields

For $d = 1$, let $B(L, t_L; h_1)$ be multiplication by the Artin–Schreier element for q_1. At $d \ge 2$, use the largest q_d for the outer extension E/L, put $m = p^{d-1}$, and set

$$B(L, t_L; h_1, \dots, h_d) = \alpha I_m + \mathrm{Lift}_E\big(B(E, z; h_1, \dots, h_{d-1})\big). \tag{2}$$

Proposition 7.3 (Native trace zero)**.** *Every native matrix in* (2) *has ordinary trace zero over its own coefficient field. Every identity amplification, and every difference of two consecutive compatible native approximations, also has trace zero.*

Proof. The base trace is zero by Lemma 7.1. If C is the inner matrix, induction gives $\mathrm{tr}_E(C) = 0$. Proposition 7.2 then gives

$$\mathrm{tr}_L(B) = m\,\mathrm{Tr}_{E/L}(\alpha) + \mathrm{Tr}_{E/L}(\kappa^{-1}\,\mathrm{tr}_E(C)) = 0.$$

Amplification multiplies a trace by its multiplicity. Both traces in each consecutive difference already vanish at their native ranks, so the difference has trace zero as well. □

This proof is stronger than observing that a multiplicity divisible by p kills a trace. The latter observation says nothing about the native matrix before amplification. Native trace is the datum used when the next full character is constructed.

Theorem 7.4 (Literal parameter field, relative to BK refinement)**.** *Assume the standard simple-stratum definitions and BK Remark 2.2.7. The displayed rank-N matrix $\beta = B(F, t; h_1, \dots, h_d)$ generates a totally ramified maximal field K/F, normalizes the complete chain, and gives a simple stratum $[\mathfrak{A}, n, 0, \beta]$ with*

$$n = p^{d-1}q_d, \qquad k_0(\beta, \mathfrak{A}) = -q_1.$$

The literal approximation fields have degrees $p, p^2, \dots, p^d$, with defining levels

$$n_j = p^{d-j}q_{d-j+1} \qquad (1 \le j \le d).$$

Proof. The degree-p case is minimal because $p \nmid q_1$ and its residue extension is trivial. At the next step write $\gamma = \alpha I_m$, $b = \mathrm{Lift}_E(C)$ and

$$n = p^{d-1}q_d, \qquad R = p^{d-2}q_{d-1}.$$

The outer minimal parameter has $k_0(\gamma, \mathfrak{A}) = -n$. By induction, $E[C]$ is a maximal field in $M_m(E)$, its derived stratum at level R is pure, and $k_0(C, \mathfrak{B}) = -q_1$. The lift supplies $s(b) = C$ and $v_{\mathfrak{A}}(b) = -R$. Since $q_d > q_{d-1}$,

$$n > pR > 2R, \qquad -2R > -n - q_1.$$

These are the actual inequalities required by BK Remark 2.2.7. Its initial stratum is $[\mathfrak{A}, n, R, \gamma]$, its perturbation is $b \in \mathfrak{P}^{-R}$, and its derived field is the supplied maximal $E[C]$. The remark gives the field generated by the actual sum $\gamma + b$, not merely by a conjugate or by a separate model. Its ramification index is p^d, and its critical exponent is $\max(-n, -q_1) = -q_1$. Its valuation remains $-n$ because $n > R$.

For the approximation statement, truncate the same recursion after j native steps and amplify by $I_{p^{d-j}}$. All truncations use the same largest parameters and the same chosen uniformizers at shared outer steps. The lift commutes with identity amplification. Its exact grade preservation gives the level n_j for the corresponding consecutive correction. The shorter native field has degree p^j, completing the defining sequence. □

The derived field $E[C]$ is an input to the refinement theorem. It is not thereby identified with the final field $F[\gamma + b]$. In particular this proof makes no assertion that the approximation fields are nested as literal subfields of K. Likewise, trace zero alone does not prove separability of an arbitrary final field in characteristic p. The source result used here is the maximal, totally ramified field statement. The outer Artin–Schreier fields are separately known to be separable.

7.5 A compatible full character is more than a deep trace calculation

The extension step is elementary once it is placed at the correct maximal parameter field.

Lemma 7.5 (Extension with a fixed trivial subgroup)**.** *Let A be a compact abelian group, $B \subseteq A$ an open subgroup, and $C \subseteq A$ a closed subgroup. A smooth character $\chi : B \to \mathbb{C}^\times$ has a smooth extension to A that is trivial on C if and only if χ is trivial on $B \cap C$.*

Proof. Necessity follows by restriction. For sufficiency, define $\chi'(bc) = \chi(b)$ on BC. Intersection compatibility makes this well defined. Its kernel contains the open subgroup $\ker\chi$ of A, so it factors through a finite subgroup of $A/\ker\chi$. A character of a subgroup of a finite abelian group extends to the whole group: adjoin a generator whose multiple belongs to the subgroup and choose the required root of its prescribed character value in $\mathbb{C}^\times$, then repeat. The resulting character is smooth because it factors through that finite quotient. □

We apply the lemma with $A = U_K^1$, $B = U_K^{m+1}$ and $C = U_F^1$. It does not authorize an arbitrary extension through a nonmaximal matrix centralizer. The determinant condition and the normalization in BK 3.2.5 still have to hold.

For a minimal native parameter α at level q, put $m = \lfloor q/2 \rfloor$. The deep character is ψ_α on $U_{\mathfrak{A}}^{m+1}$. Its restriction to scalar units is trivial because $\mathrm{tr}_F(\alpha) = 0$. Its field-unit restriction therefore extends to U_E^1 trivially on U_F^1 by Lemma 7.5. The minimal simple-character definition, BK 3.2.1, joins these agreeing characters on

$$H^1(\alpha) = U_E^1 U_{\mathfrak{A}}^{m+1}.$$

At a nonminimal native step, the following order of operations is essential.

Transfer the whole preceding character. Let θ_j be the full native character already constructed at rank p^j, trivial on U_F^1. Amplify its parameter by multiplicity p and transfer θ_j to that actual parameter γ. BK 3.6.13(ii) and 3.6.14 preserve the whole beta-determinant unit character χ_j, not just its restriction to deep units. On a scalar $u \in U_F^1$, the transferred value is

$$\Theta_j(uI) = \chi_j\big(\det_{M_p(K_j)}(uI_p)\big) = \chi_j(u^p) = 1. \tag{3}$$

The determinant exponent p cannot be silently dropped. In the transfer theorem the centralizer orders may have different periods, but the full-character transfer uses $m_1 = m_2 = 0$. Thus both normalized indices $\lfloor m_i/e_i \rfloor$ are zero, exactly as required.

Apply the actual correction at the permitted depth. At the next native matrix $\beta = \gamma + \delta$, let $r = q_{d-j}$ and $m = \lfloor r/2 \rfloor$. The two strata are equivalent at level r, and their groups at depth $m+1$ agree. Since

$$\lfloor r/2 \rfloor \le m \le r-1, \qquad r < n,$$

BK 3.3.18 gives the character

$$\vartheta = \Theta_j|_{H^{m+1}(\beta)}\,\psi_\delta \quad \text{in} \quad \mathcal{C}(\mathfrak{A}, m, \beta).$$

The sign is fixed by the source bijection $\theta \mapsto \theta\psi_\delta^{-1}$. Proposition 7.3 makes ψ_δ trivial on scalar units in its domain, so ϑ is trivial on its intersection with U_F^1.

Extend at the new maximal native field. Now $K = F[\beta]$ is maximal at this native rank. Its centralizer is K itself, so the relevant determinant is the identity. The restriction of ϑ to U_K^{m+1} has the intersection compatibility required by Lemma 7.5. Choose its extension χ_K to U_K^1, still trivial on U_F^1. BK 3.2.5, used at full index zero, gives

$$\theta(kh) = \chi_K(k)\vartheta(h), \qquad k \in U_K^1, \quad h \in H^{m+1}(\beta). \tag{4}$$

Agreement on the intersection makes the formula well defined. The normalization and determinant hypotheses are supplied by the simple-character theorem. This proves full shallow-unit triviality inductively, not merely the cancellation of one leading coefficient.

7.6 Central completion without changing the canonical extension

Retain the chosen canonical beta extension κ_θ. The maximal residue factor is a character of $k_K^\times = \mathbb{F}_p^\times$. Where that factor is free to be chosen, it adjusts the compact central character to a prescribed smooth ω trivial on U_F^1. An independently fixed incompatible residue character is not replaced.

The group $\mathcal{N} = K^\times J$ has quotient $\mathcal{N}/J \simeq \mathbb{Z}$. Choose an extension Λ_0 of the fixed compact type. Twisting it by the character that takes a chosen generator to $s \in \mathbb{C}^\times$ changes its value on a scalar uniformizer by s^N. Choose s with

$$s^N = \omega(t)/\omega_{\Lambda_0}(t).$$

This does not assume that a uniformizer of K has literal Nth power t. Their quotient is a unit already handled by the fixed compact data. Once chosen, s becomes part of the candidate and is retained in every recovery argument.

BK 6.2.2 applies to the resulting maximal simple type and its actual extension. It yields

$$\pi = \mathfrak{c}\text{-Ind}_{\mathcal{N}}^{\mathrm{GL}_N(F)} \Lambda$$

as an irreducible supercuspidal representation. The current proof uses this classical theorem. It does not obtain supercuspidality from a finite Heisenberg dimension count.

7.7 Capacity and the precise packet admitted by this construction

The odd-prime profile formulas [11] are

$$t(\pi) = 1, \qquad \mathrm{Sw}(\pi) = p^{d-1}(p+1)h_d,$$
$$\dim_{\mathbb{F}_p}(J^1/H^1) = N-1, \qquad \dim \eta = p^{(N-1)/2},$$
$$a(\pi^\vee \times \pi) = N^2 - 1 + \sum_{i=1}^{d}(p^{2i} - p^{2i-2})h_i.$$

The conductor identities retain their separately pinned arithmetic inputs. They are not consequences of the trace lemmas alone.

There is a useful capacity argument that does not need every lower conductor. Put $n = p^{d-1}q_d$ and $M = n/2$. The leading minimal approximation has degree p. The concrete subgroup $U_{\mathfrak{A}}^M$ survives in $J^1(\beta)$ through all lower corrections. The recursive BK definitions keep it there because every lower critical level is less than $2M$. They also identify

$$H^M(\beta) = H^M(\gamma), \qquad S \simeq \mathfrak{P}^M/(\mathfrak{Q}^M + \mathfrak{P}^{M+1}).$$

The complete-chain grades have dimensions N and N/p, respectively. Therefore $\dim_{\mathbb{F}_p} S = (p-1)p^{d-1}$. On this subgroup, $\beta - \gamma \in \mathfrak{P}^{1-n}$ and commutators lie in $1 + \mathfrak{P}^n$, so the two character commutators agree. BK 3.4.1 makes the resulting form nondegenerate.

Now assume a one-vertex packet with trivial stabilizer and d actually supplied, labeled, full character extensions, each with a whole plane quotient. Their balanced central product has quotient dimension $2d$ and Heisenberg carrier dimension $p^d = N$. Since

$$(p-1)p^{d-1} \geq 2d,$$

a labeled symplectic embedding of the source into S exists. Proposition 3.2 attaches the full scalar extension, including its supplied character values. A line in the complementary Heisenberg factor gives the rank-N sector. The retained induction and idempotent argument recovers the same extended type and the same π [14].

For $p = 3$, the retained native cubic factors provide plane quotients. For $p > 3$, a native minimal rank-p quotient normally has dimension $p - 1$, not two. The plane admission hypothesis must be verified. Neither this capacity proof nor scalar-extension equivalence supplies a nontrivial arithmetic stabilizer action, independently fixed native markings, or literal placement at previously specified numerical depths.

For $p = 3$, $d = 2$ and $(h_1, h_2) = (1, 2)$, the rank is nine, the defining levels are $(24, 4)$, the Swan conductor is 24, the quotient dimension is eight, $\dim \eta = 81$, and the self-pair conductor is 232. The preserved sparse Laurent program has been replayed for this matrix. Its exact identities check the implementation, while the field and character conclusions above use the written proof and its classical inputs.

8 The weighted dyadic construction

Evidence and scope. The dyadic construction uses a different trace mechanism, not a formal substitution $p = 2$ in the odd-prime trace-zero proof. This section reconstructs the native trace, depth, and full-character arguments from [15–17]. The general parameter and simple-character steps remain relative to the classical inputs listed in Section 13.

8.1 Trace one can be invisible at the required depth

Lemma 8.1 (Depth-weighted trace visibility)**.** *Let ψ_F be an additive character trivial on $\mathfrak{p}_F$. Suppose $u \in U_F^s$, with $s \geq 1$, and a matrix δ satisfies*

$$v_F(\operatorname{tr}_F \delta) + s \geq 1.$$

Then $\psi_F((u-1)\operatorname{tr}_F \delta) = 1$.

Proof. The product has valuation at least $s + v_F(\operatorname{tr}_F \delta)$, so it belongs to $\mathfrak{p}_F$, where the character is trivial. □

For $F = \mathbb{F}_2((t))$, choose the additive character reading the constant coefficient. It is trivial on $t\mathcal{O}_F$ and takes the value -1 on 1. A trace of 1 is therefore invisible when multiplied by $u - 1$ for $u \in U_F^1$. A trace of t^{-1} is not: $u = 1 + t$ gives $(u-1)t^{-1} = 1$.

The Euler work motivated replacing literal zero by a weighted visibility condition. It is not an arithmetic input to this proof. The weights here are valuation depths. Multiplication by the integer two in characteristic two would erase the trace for an entirely different reason and would not prove the native assertion.

8.2 The literal quadratic step and exact trace recursion

Take odd integers $0 < h_1 < \cdots < h_d$, put $q_i = 3h_i$ and $N = 2^d$. At a recursive base L, use

$$\alpha^2 - \alpha = t_L^{-q}, \qquad a = (q+1)/2, \qquad z = t_L^a \alpha.$$

The valuation argument of Lemma 7.1 applies with $p = 2$, but the trace is now one. Direct substitution gives

$$f(z) = z^2 + t_L^a z + t_L = 0, \qquad \mathrm{Tr}_{E/L}(\alpha) = 1. \tag{5}$$

The polynomial is Eisenstein and its derivative t_L^a is nonzero. Its corestriction normalization is

$$\kappa = \frac{t_L^a}{z} = \alpha^{-1}, \qquad s(P_0) = \frac{t_L}{z^2}, \qquad \mathrm{Lift}_E(C) = \frac{z^2}{t_L} C P_0.$$

Consequently

$$s(\mathrm{Lift}_E(C)) = C, \qquad \mathrm{tr}_L(\mathrm{Lift}_E(C)) = \mathrm{Tr}_{E/L}(\alpha \,\mathrm{tr}_E(C)). \tag{6}$$

These are the same coefficient and dual-trace computations as Proposition 7.2, with the signs evaluated in characteristic two.

Proposition 8.2 (Three distinct trace statements)**.** *Every native dyadic matrix in the recursion has trace one over its own coefficient field. A preceding parameter amplified by multiplicity two has trace zero. The consecutive correction at the next native rank has trace one.*

Proof. At rank two the trace is $\mathrm{Tr}_{E/L}(\alpha) = 1$. At greater native rank write $B = \alpha I_m + \mathrm{Lift}_E(C)$, with $m = 2^{d-1}$ even. Inductively $\mathrm{tr}_E(C) = 1$. Thus

$$\mathrm{tr}_L(B) = m \,\mathrm{Tr}_{E/L}(\alpha) + \mathrm{Tr}_{E/L}(\alpha) = 0 + 1 = 1.$$

An identity amplification of multiplicity two has trace $2 \cdot 1 = 0$. Subtracting it from the next native matrix gives correction trace one. □

At full rank eight for $(h_1, h_2, h_3) = (1, 3, 5)$, the distinction is visible without any asymptotic notation:

Native rank	Native trace	Multiplicity in rank eight	Ambient trace	Defining level
2	1	4	0	60
4	1	2	0	18
8	1	1	1	3

The ordinary trace used for a new character is the native one. The table does not identify the three trace operations or infer a character from the zeros in its fourth column.

8.3 Refinement, fields, and a separability consequence

For a step of length $d \geq 2$, the outer level and the derived level are

$$n = 2^{d-1} q_d, \qquad R = 2^{d-2} q_{d-1}.$$

Since $q_d > q_{d-1}$, one has $n > 2R$. Hence $-2R > -n - q_1$, the exact inequality in BK Remark 2.2.7. The pure derived maximal field, filtered lift, and critical exponent are supplied as in the odd case. The

theorem gives the actual maximal totally ramified field generated by the displayed sum. It also gives the literal defining levels

$$n_j = 2^{d-j} q_{d-j+1}, \qquad k_0(\beta, \mathfrak{A}) = -q_1.$$

No equality between the final field and its derived centralizer model is used.

Proposition 8.3 (Trace one forces separability after maximality)**.** *Suppose the rank-N dyadic matrix β generates a field K/F of degree $N = 2^d$. Its native trace-one identity implies that K/F is separable.*

Proof. Since the generated field has degree equal to the matrix size, the minimal polynomial of β equals its characteristic polynomial. The coefficient of X^{N-1} is $-\operatorname{tr}_F(\beta) = 1$. Its derivative contains the nonzero term $(N-1)X^{N-2} = X^{N-2}$ in characteristic two. An irreducible polynomial with nonzero derivative is separable. □

This is an elementary consequence of two already explicit hypotheses. Trace one alone does not prove that the matrix generates a field of full degree. The maximality step still uses the refinement theorem. In particular this observation is not an independent replacement for the simple-stratum construction.

8.4 The floor in the correction depth is essential

Every native critical level $r = q_i$ is odd. Put $m = (r-1)/2$, so $r = 2m+1$. For $x, y \in \mathfrak{P}^{m+1}$ and $\delta \in \mathfrak{P}^{-r}$,

$$\delta x y \in \mathfrak{P}^{2(m+1)-r} = \mathfrak{P}. \tag{7}$$

The level-one matrix additive character is trivial there. Thus the error between evaluating the additive expression at $(1+x)(1+y)$ and multiplying its values at $1+x$ and $1+y$ vanishes. This is the depth calculation behind the correction character on the relevant congruence subgroup.

Replacing $m+1$ by m would give $2m - r = -1$, not a positive depth. Writing "approximately half the level" is therefore inadequate here. The endpoint $m = \lfloor r/2 \rfloor$ lies in the closed interval permitted by BK 3.3.18, and the character is evaluated on H^{m+1}.

8.5 The full shallow-character induction

For a minimal rank-two parameter, the deep character ψ_α is trivial on its scalar intersection with U_F^1, since $\operatorname{tr}_F(\alpha) = 1$ and Lemma 8.1 applies. Extend its field-unit character to U_E^1 trivially on U_F^1 using Lemma 7.5. The minimal BK definition then gives the full character on H^1.

Assume a full native character θ_j, trivial on U_F^1, has already been constructed. Transfer it to the multiplicity-two parameter γ. Preservation of the beta-determinant character gives $\Theta_j(uI) = \chi_j(u^2) = 1$ on scalar units. This uses the entire native unit character. It does not transfer a guessed deep approximation and then assume its shallow values.

At the next actual native parameter $\beta = \gamma + \delta$, Proposition 8.2 gives $\operatorname{tr}_F \delta = 1$. Put $r = 2m+1$ as above. The strata and depth range meet BK 3.3.18, so

$$\vartheta = \Theta_j|_{H^{m+1}(\beta)}\, \psi_\delta$$

is a simple character at that depth. Lemma 8.1 gives $\vartheta = 1$ on $U_F^1 \cap H^{m+1}(\beta)$. The actual final field at this native step is maximal. Its forced unit character on U_K^{m+1} and the trivial character on U_F^1 therefore agree on the intersection. Lemma 7.5 extends them to U_K^1, and BK 3.2.5 yields the full formula (4).

The residue field is $\mathbb{F}_2$, so $k_K^\times$ is trivial and $J = J^1$. The compact type is the Heisenberg representation η, with no nontrivial residue character to choose. A prescribed central character trivial on U_F^1 is unramified here. Its remaining value is fixed by the noncompact extension exactly as in the odd case. No division by two takes place in the local coefficient field.

8.6 What the dyadic parameter theorem does and does not realize

The construction supplies a parameter and full character for the stated arbitrary lengths, with

$$t(\pi) = 1, \qquad \mathrm{Sw}(\pi) = 3 \cdot 2^{d-1} h_d,$$
$$\dim_{\mathbb{F}_2}(J^1/H^1) = N - 2, \qquad \dim \eta = 2^{N/2-1},$$
$$a(\pi^\vee \times \pi) = N^2 - 1 + \sum_{i=1}^{d} 3 \cdot 4^{i-1} h_i.$$

The precise conductor inputs remain identified separately. A full source packet of d planes has quotient dimension $2d$ and carrier dimension 2^d. The original maximal-type quotient has enough capacity only for $d \geq 3$. Thus even a valid parameter and full-character construction does not settle attachment at ranks two and four.

Section 9 retains that genuine original-carrier obstruction. Section 10 changes the actual inducing group and proves recovery of the unchanged candidate. Neither operation weakens the dimension theorem for the original quotient. The rank-eight sparse Laurent construction has been replayed, including native and amplified traces and the grades $(60, 18, 3)$. Those finite identities are checks of the displayed matrix algorithm, not substitutes for the full arithmetic proof.

9 Capacity, markings and the low-rank obstruction

9.1 The two dimensions that must not be conflated

For a finite Heisenberg quotient W of dimension $2r$ over $\mathbb{F}_p$, the irreducible carrier with its fixed nontrivial central character has dimension p^r. Quotient dimension and representation dimension measure different objects. A rank-N Weil source assembled from d planes has quotient dimension $2d$ and carrier dimension $N = p^d$. The type carrier can be substantially larger than N.

In the dyadic full tower, the graded contribution at stage j is

$$(2^{d-j+1} - 2^{d-j})\, \mathbf{1}_{n_j \text{ even}}.$$

The last level is odd and the earlier levels are even. Thus

$$\dim W = \sum_{j=1}^{d-1} 2^{d-j} = 2^d - 2.$$

The source quotient fits in this maximal-type quotient precisely when $2^d - 2 \geq 2d$, or $d \geq 3$.

d	N	Host dim W	Host dim η	Source carrier
1	2	0	1	2
2	4	2	2	4
3	8	6	8	8
4	16	14	128	16

These exact values explain why the original rank-two and rank-four maximal-type carriers cannot contain the whole source packet. The later enlargement does not change these numbers. It changes the arithmetic assembly carrier.

9.2 Transported markings versus a fixed native refinement

For $d \geq 3$, the retained scalar-pushout attachment embeds the source symplectic quotient and carries the entire declared marked finite extension. It preserves the squares of those transported lifts and the corresponding refinement data. If an independent native quadratic form q_W is also prescribed, that is an additional compatibility problem [19].

At $d = 3$, source and host have equal dimension six. A native quadratic embedding must be an isometry, so the Arf invariants must agree. For $d \geq 4$, there is at least one complementary hyperbolic-size plane available at the level of quadratic-space classification. When the embedding can be chosen, a complementary Arf contribution permits either source type. For an already fixed embedding f, however, the actual requirement is pointwise:

$$q_W(f(v)) = q_{\mathrm{src}}(v) \quad \text{for every } v.$$

A dimension count or an equality of total Arf invariants does not establish this identity for that fixed map. These assertions about native embeddings remain distinct from preserving the source marking under a constructed extension map.

9.3 Why profile adjustments did not resolve the capacity issue

The capacity record considers changes of parameters and scalar twists while retaining the prescribed numerical profile. Its low-rank negative conclusions concern the original maximal-simple-character carriers in that profile. They do not show that no larger compact subgroup of the same $\mathrm{GL}_N(F)$ can carry the packet. This distinction makes the next construction possible without contradicting the earlier obstruction.

10 Enlarged arithmetic carriers recover the same representation

Evidence and scope. This section expands the rank-two and rank-four ordinary constructions [20–22]. The groups are actual subgroups of the same general linear group. Their character and filtration inputs are retained explicitly. A general finite-index recovery proposition then keeps the full inducing representation, including its noncompact extension. No new candidate is selected through the reference correspondence.

10.1 Rank two: enlarge the group rather than the original quotient

Let $F = \mathbb{F}_2((t))$, $G = \mathrm{GL}_2(F)$ and $[\mathfrak{A}, q, 0, \beta]$ be the actual minimal dyadic stratum, with $q = 2m + 1 \geq 3$ and $K = F[\beta]$. Its complete period-two order has

$$J = J^1 = H^1 = U_K^1 U_{\mathfrak{A}}^{m+1}.$$

The full simple character θ is one-dimensional on J. Fix its actual extension Λ on $\mathcal{N} = K^\times J$ and the candidate $\pi = \mathfrak{c}\text{-}\mathrm{Ind}_{\mathcal{N}}^{G} \Lambda$. The central character and the value of the chosen noncompact generator are fixed data throughout the argument.

Set

$$P = U_K^1 U_{\mathfrak{A}}^m. \tag{8}$$

The field normalizes the complete order, so this product is a compact open group. The filtration commutator estimates give $[P, J] \subseteq U_{\mathfrak{A}}^{m+1}$, and hence $J \triangleleft P$. On the grade $\mathfrak{P}^m/\mathfrak{P}^{m+1}$, the ambient order contributes dimension two over $\mathbb{F}_2$ and the field line contributes dimension one. Thus

$$[P : J] = 2, \qquad P \cap \mathcal{N} = J.$$

For the intersection, an element $kj \in P$ with $k \in K^\times$ has $k \in U_{\mathfrak{A}}^1$, hence $k \in U_K^1 \subseteq J$.

The maximal minimal-character intertwining formula gives $I_G(\theta) = \mathcal{N}$. Choose $g \in P \setminus J$. It does not intertwine θ, so $\theta^g \neq \theta$. Consequently

$$\lambda(j) = \theta(gjg^{-1})/\theta(j)$$

is nontrivial. Its values lie in $\{1, -1\}$ because its commutators lie in the deep subgroup where θ is the additive character of a characteristic-two matrix trace. The entire shallow character θ need not have order two.

Since $g^2 \in J$ and θ is a character, $\lambda^g = \lambda^{-1} = \lambda$. Thus $H_0 = \ker \lambda$ is normal in P, with $[P : H_0] = 4$. Finite-index induction gives

$$\Xi = \mathrm{Ind}_J^P \theta,$$

an irreducible two-dimensional representation. Its restriction to J is the sum of the two distinct characters θ and θ^g, and g exchanges their lines.

10.2 The rank-two quotient and the retained character

In a two-coset model, the represented action has the form

$$j \longmapsto \theta(j) \begin{pmatrix} 1 & 0 \\ 0 & \lambda(j) \end{pmatrix}, \qquad g \longmapsto X = \begin{pmatrix} 0 & 1 \\ a & 0 \end{pmatrix}, \qquad a = \theta(g^2) \neq 0.$$

For an element with $\lambda(j) = -1$, the nonscalar part is $Z = \mathrm{diag}(1, -1)$. One has

$$X^2 = aI, \qquad Z^2 = I, \qquad XZX^{-1} = -Z.$$

The scalar preimage is exactly H_0, so $P/H_0 \simeq \mathbb{F}_2^2$ is the actual projective quotient. Its commutator is nondegenerate. This is more information than the dimension of Ξ alone.

The scalar a remains the value of the original character. It need not equal one, and the matrices do not automatically match an independently prescribed native square marking. A source scalar-pushout identification can carry its marked finite extension, but equality with a fixed native quadratic refinement requires the separate compatibility condition from Section 9.

The carrier occurs in $\pi|_P$ in the functions supported on $\mathcal{N}P$. Explicitly, a function f in $\mathrm{Ind}_J^P \theta$ extends there by $f(np) = \Lambda(n)f(p)$. The equality $\mathcal{N} \cap P = J$ proves that this is well defined. The construction uses the same Λ and does not change its noncompact root [21].

10.3 Rank four: the actual final-field approximation

Use the rank-four dyadic constructor with odd $h_1 < h_2$. Put

$$q_i = 3h_i, \qquad n = 2q_2 = 2a, \qquad r = q_1 = 2m + 1, \qquad m \geq 1.$$

Then $a > r$ and $n > 2r$. Let γ be the degree-two outer minimal approximation, $E = F[\gamma]$, $B = \mathrm{End}_E(F^4) = M_2(E)$, and $\mathfrak{B} = \mathfrak{A} \cap B$. Its radical is $\mathfrak{Q}$. Write $\beta = \gamma + \delta$ and $c = s(\delta)$. The derived parameter c is minimal of degree two over E and has level r. The actual final field is $K = F[\beta]$ of degree four. We do not assume $E \subseteq K$.

The recursive group definitions give

$$H = H^1(\beta) = U_K^1 U_{\mathfrak{B}}^{m+1} U_{\mathfrak{A}}^{a+1},$$
$$J = J^1(\beta) = U_K^1 U_{\mathfrak{B}}^{m+1} U_{\mathfrak{A}}^{a}.$$

Thus J/H has dimension two and its Heisenberg representation η has dimension two. The existing θ on H is not replaced.

Lemma 10.1 (Approximation by the outer centralizer)**.** *For $j \geq 1$ and $k \in K \cap \mathfrak{P}^j$, the minimal corestriction exact sequence gives*

$$k = b + e, \qquad b \in \mathfrak{Q}^j, \qquad e \in \mathfrak{P}^{j+n-r}. \tag{9}$$

These leading $\mathfrak{B}$-grades form precisely the centralizing line of the leading derived parameter c.

Proof. Since k commutes with β, one has $[\gamma, k] = -[\delta, k] \in \mathfrak{P}^{j-r}$. The exact commutator sequence for the minimal parameter γ, BK 1.4.10, removes this commutator by an error in grade $j + n - r$. The remainder centralizes γ and lies in B, proving (9).

Apply s to $[\beta, k] = 0$. The corestriction kills $[\gamma, e]$, and its bimodule property gives $s([\delta, b]) = [c, b]$. The remaining error has grade at least $j + n - 2r$, so

$$[c, b] \in \mathfrak{Q}^{j+n-2r}.$$

Because $n > 2r$, the leading grade of b centralizes that of c. In the complete period-two E-chain, choose the shift R with $R^2 = zI$. The leading parameter is R^{-r}, with r odd. Its centralizer in grade j is the line spanned by R^j. The actual maximal totally ramified field K contributes a one-dimensional grade. Estimate (9) is injective on that grade, so its image is exactly the line. □

This is where a literal arithmetic attachment is needed. A dimension comparison between two abstract graded spaces would not identify the line belonging to the actual final field. The use of the minimal exact sequence is recorded separately in the input audit.

10.4 An actual index-two enlargement and a nontrivial character orbit

Set $P = JU_{\mathfrak{B}}^m$. The field approximation implies

$$[U_{\mathfrak{B}}^m, U_K^1] \subseteq U_{\mathfrak{B}}^{m+1} U_{\mathfrak{A}}^{m+n-r+1} \subseteq H.$$

Together with the ordinary filtration estimates, this proves that P is a compact open group and $J \triangleleft P$. The grade of $U_{\mathfrak{B}}^m$ has dimension two. Its intersection with J has exactly the one-dimensional centralizing

line of Lemma 10.1. The converse containment uses $m + n - r > a$, which puts the approximation error inside $U^a_{\mathfrak{A}} \subseteq J$. Hence $[P : J] = 2$.

Take $D = \operatorname{diag}(1, 0)$ and $u = 1 + R^m D$. Its leading grade is outside that line, so it represents the nontrivial coset. Also $u^2 \in U^{2m}_{\mathfrak{B}} \subseteq H$. The character

$$\lambda(h) = \theta(uhu^{-1})/\theta(h), \qquad h \in H,$$

is J-invariant and has values in $\{1, -1\}$. To see the value rather than guess it, use the defining-sequence formula $\theta = \theta_\gamma \psi_\delta$ on the relevant commutator domain. The outer character is invariant under $U^1_{\mathfrak{B}}$, leaving the actual correction ψ_δ.

Lemma 10.2 (The leading dyadic commutator)**.** *Let $R = \left(\begin{smallmatrix} 0 & z \\ 1 & 0 \end{smallmatrix}\right)$ over $\mathbb{F}_2[z, z^{-1}]$. For $m \geq 1$, $X = R^m \operatorname{diag}(A, B)$ and $Y = R^{m+1} \operatorname{diag}(C, D)$ with $A, B, C, D \in \mathbb{F}_2$, one has*

$$\operatorname{tr}\big(R^{-2m-1}(XY - YX)\big) = (A + B)(C + D).$$

Proof. If $m = 2k$, factor z^k from both matrices and use $R^2 = zI$. After multiplication by R^{-2m-1}, the trace reduces to $D(A + B) + C(A + B)$. If $m = 2k + 1$, the roles of the two diagonal entries are exchanged and the same expression results. In characteristic two the subtraction is addition. Both cases give the displayed product. □

Choose $X = R^m D$ and $Y = R^{m+1} D$. The two sums in the lemma are one. The group-commutator remainder has $\mathfrak{B}$-grade at least $3m + 1$. Multiplication by the leading parameter of grade $-2m - 1$ leaves grade at least $m \geq 1$, so the remainder is invisible. The difference between c and R^{-r} also contributes only positive grade. The normalized character satisfies

$$\psi_E(1) = \psi_F(\operatorname{Tr}_{E/F} \alpha) = \psi_F(1) = -1.$$

Thus $\lambda(1 + Y) = -1$. In particular $\theta^u \neq \theta$ and $\eta^u \not\simeq \eta$. Finite-index induction gives the irreducible four-dimensional carrier $\Xi = \operatorname{Ind}_J^P \eta$.

10.5 The rank-four scalar preimage and quotient

Put $H_0 = \ker \lambda$ inside H. In the two-coset model, $h \in H$ acts by

$$\operatorname{diag}\big(\theta(h) I_2, \theta^u(h) I_2\big).$$

Since $u^2 \in J$ and λ has order two, $\lambda^u = \lambda$, so $H_0 \triangleleft P$. The common character $\theta_0 = \theta|_{H_0}$ is P-invariant.

The depth estimates give $\lambda = 1$ on $U^{a+1}_{\mathfrak{A}}$ because $a + 1 + m - r = a - m > 0$. Write $J = HU^a_{\mathfrak{A}}$. The character λ kills $[H, H]$ and $[H, U^a_{\mathfrak{A}}]$ by J-invariance. It kills $[U^a_{\mathfrak{A}}, U^a_{\mathfrak{A}}]$ and squares from that subgroup because they lie in $U^{2a}_{\mathfrak{A}}$. It kills squares from H because it has order two. Finally $[u, U^a_{\mathfrak{A}}] \subseteq U^{a+m}_{\mathfrak{A}}$ and $\lambda([u, H]) = 1$, while $\lambda(u^2) = 1$ since u commutes with its own square. Consequently

$$[P, P] \subseteq H_0, \qquad g^2 \in H_0 \ (g \in P), \qquad [P : H_0] = 2 \cdot 4 \cdot 2 = 16.$$

An element of J acting scalarly on Ξ must act scalarly on its first η block. Nondegeneracy of the original J/H forces it into H, and then scalar equality of the two blocks forces it into H_0. An element outside J exchanges the two blocks and cannot act scalarly. Therefore H_0 is the entire scalar preimage.

It follows that $P/H_0 \simeq \mathbb{F}_2^4$ with actual commutator form $(gH_0, kH_0) \mapsto \theta_0([g,k])$. If a class belongs to the radical, its represented operator commutes with the irreducible image and is scalar by Schur's lemma. It therefore belongs to H_0. The form is nondegenerate.

The finite scalar center is $\theta_0(H_0)$, which can have order larger than two. The result is an actual Heisenberg central extension with a four-dimensional binary projective quotient. It is not automatically a literal extraspecial group of order 32, nor an identification with an independently marked native quadratic space [22].

10.6 The final field normalizes the enlarged rank-four group

To obtain an inducing datum rather than only compact occurrence, one must prove $kPk^{-1} = P$ for every $k \in K^\times$. Units of K lie in $U_K^1 \subseteq J$ because the residue field is $\mathbb{F}_2$, so they normalize P. Let k be a uniformizer of K. Lemma 10.1 at grade one gives

$$k = b + e, \qquad b = Rv \quad (v \in 1 + \mathfrak{Q}), \qquad e \in \mathfrak{P}^{n-r+1}.$$

Hence $k = b(1+\varepsilon)$ with $\varepsilon \in \mathfrak{P}^{n-r}$. Conjugation by b preserves the two chain filtrations. For $w \in U_{\mathfrak{B}}^m$, the error from $1+\varepsilon$ lies in

$$U_{\mathfrak{A}}^{n-r+m} \subseteq U_{\mathfrak{A}}^a \subseteq J, \qquad n - r + m = 2a - m - 1 > a.$$

Thus $kU_{\mathfrak{B}}^m k^{-1} \subseteq P$. Also $kJk^{-1} = J$ by normalization of the actual simple-character groups. The subgroup kPk^{-1} contains J with the same index two as P, so it equals P. This proof does not insert the unjustified assumption $E \subseteq K$.

10.7 One finite-index recovery theorem for both low ranks

Proposition 10.3 (Enlargement retaining the full inducing representation)**.** *Let $G = \mathrm{GL}_n(F)$, let K/F be a maximal field in $M_n(F)$, and suppose $J \triangleleft P$ are compact open subgroups with $[P : J] = 2$. Assume $K^\times$ normalizes both groups, $K^\times \cap P \subseteq J$, and*

$$\mathcal{N} = K^\times J, \qquad \pi = \mathfrak{c}\text{-}\mathrm{Ind}_{\mathcal{N}}^G \Lambda, \qquad \Lambda|_J = \eta$$

with η irreducible. If $\eta^u \not\simeq \eta$ for $u \in P \setminus J$, then $M = K^\times P$ is open and compact modulo the center,

$$\mathcal{N} \triangleleft M, \quad [M : \mathcal{N}] = 2, \quad \Sigma = \mathrm{Ind}_{\mathcal{N}}^M \Lambda \text{ is irreducible},$$

and

$$\Sigma|_P \simeq \mathrm{Ind}_J^P \eta, \qquad \mathfrak{c}\text{-}\mathrm{Ind}_M^G \Sigma \simeq \pi. \tag{10}$$

The central character and the noncompact extension in Λ are unchanged.

Proof. Normalization makes M a group. The action of $K^\times$ on P/J is trivial because that quotient has order two. Thus $[K^\times, P] \subseteq J$, proving normality of $\mathcal{N}$ in M. The intersection hypothesis gives index two. The group is open because it contains J, and compact modulo $F^\times$ because both $K^\times/F^\times$ and P are compact.

The restriction of Σ to $\mathcal{N}$ is the sum of Λ and Λ^u. They are irreducible and nonisomorphic, since their restrictions to J already differ. Any $\mathcal{N}$-subrepresentation is a sum of these distinct irreducible summands. The element u exchanges them, leaving no nonzero proper M-stable subrepresentation. This proves irreducibility without applying a finite-group semisimplicity assertion to an arbitrary noncompact group.

There is a single $\mathcal{N}$–P double coset in M and $\mathcal{N} \cap P = J$, giving the first isomorphism in (10). Finite-index induction from $\mathcal{N}$ to M is compact induction. Induction in stages proves the second. No character in Λ has been rescaled. □

For rank two, $K^\times$ normalizes $P = U_K^1 U_{\mathfrak{A}}^m$ directly. For rank four the preceding subsection provides the missing arithmetic normalization. The resulting Σ has dimension two or four, respectively, and induces to the original candidate. This consolidates the rank-four induction note and makes the same finite-index argument explicit for rank two.

The word "same" in this result is literal. It refers to the previously fixed Λ, not merely to an unramified-twist class or to a representation with matching conductor. It supplies the enlarged actual inducing data required by this restricted realization contract. It does not prove that their source packet has a nontrivial prescribed stabilizer action or the full same-candidate H5 factors.

10.8 A conditional induction statement with actual groups

Let $G = \mathrm{GL}_n(F)$, and fix

$$\pi = \mathfrak{c}\text{-}\mathrm{Ind}_{\mathcal{N}}^{G} \Lambda, \qquad \eta = \Lambda|_J,$$

where J is compact open and normal in $\mathcal{N}$, η is irreducible and $\mathcal{N}/J$ is infinite cyclic. Suppose P is an actual compact open subgroup containing J, with $P \cap \mathcal{N} = J$, and put $\Xi = \mathrm{Ind}_J^P \eta$.

Proposition 10.4 (Occurrence and compact recovery)**.** *The subspace of $\pi|_P$ supported on $\mathcal{N}P$ is isomorphic to Ξ. Moreover,*

$$\mathfrak{c}\text{-}\mathrm{Ind}_P^G \Xi \simeq \mathfrak{c}\text{-}\mathrm{Ind}_J^G \eta.$$

If the actual intertwining set of η in G is $\mathcal{N}$, then Ξ is irreducible.

Proof. Restriction to the support $\mathcal{N}P$ identifies its functions with induction from $\mathcal{N} \cap P = J$, using $\Lambda|_J = \eta$. The displayed isomorphism is induction in stages. For irreducibility, the finite Mackey endomorphism formula has no contribution from nontrivial double cosets in P, since every intertwiner lies in $\mathcal{N}$ and $P \cap \mathcal{N} = J$. Its endomorphism space is therefore $\mathrm{End}_J(\eta) = \mathbb{C}$. Finite-dimensional smooth representations of compact P factor through finite groups and are semisimple over $\mathbb{C}$. A semisimple representation with scalar endomorphisms is irreducible. □

The original Λ, its central character and its noncompact root are unchanged. The equality above does not yet recover the chosen π from the compact carrier alone. It recovers the larger compactly induced representation from J.

10.9 The noncompact relation is a quotient before central normalization

Choose $u \in \mathcal{N}$ generating $\mathcal{N}/J$. Use left-covariant functions $f(jg) = \eta(j)f(g)$ with right translation by G, and write $X = \mathfrak{c}\text{-}\mathrm{Ind}_J^G \eta$. Define

$$(Tf)(g) = \Lambda(u)^{-1} f(ug).$$

Normality and the actual intertwining identity imply that T preserves covariance. The normalization remembers the chosen noncompact extension.

Proposition 10.5 (Recovery of the fixed noncompact extension)**.** *There is a natural isomorphism*

$$X/(T-1)X \simeq \pi.$$

Proof. Define

$$(Qf)(g) = \sum_{k\in\mathbb{Z}} \Lambda(u)^{-k} f(u^k g).$$

The sum is finite at each argument because f has compact support modulo J, while the cosets indexed by k are discrete. Reindexing shows $Qf(ug) = \Lambda(u)Qf(g)$, and the J-covariance gives full $\mathcal{N}$-covariance. The support is compact modulo $\mathcal{N}$, so $Qf \in \pi$. Choosing representatives of the finitely many relevant $\mathcal{N}$-cosets proves surjectivity.

On each $\mathcal{N}/J$-orbit, the kernel statement is the augmentation identity for finitely supported sequences $(v_k)_{k\in\mathbb{Z}}$. If $\sum_k v_k = 0$, the partial sums are finitely supported and write (v_k) as consecutive differences. These differences are exactly $(T-1)X$ in the normalized coordinates. Finally $Q(Tf) = Qf$, so the induced quotient map is the required isomorphism. □

There need not be a splitting $\pi \to X$ before fixing the center. In this general-linear setting, determinant valuations of the support of a nonzero vector in X form a finite set. A scalar uniformizer shifts that set by n, so such a vector cannot be an eigenvector for the scalar uniformizer. Every vector of π has the fixed central character. Thus a nonzero G-map $\pi \to X$ is impossible in this setting [20].

10.10 After retaining the center, a finite projector is available

Let $Z = F^\times I_n$, $J_Z = ZJ$, and suppose $\mathcal{N}/J_Z$ is cyclic of order ℓ. Retain $\Lambda_0 = \Lambda|_{J_Z}$. On $Y = \mathrm{c\text{-}Ind}_{J_Z}^{G} \Lambda_0$, the same normalized shift satisfies $T^\ell = 1$. Hence

$$e_\Lambda = \frac{1}{\ell} \sum_{j=0}^{\ell-1} T^j$$

is an idempotent. Its image is the space of $\mathcal{N}$-covariant functions, which is precisely the fixed π. Division by ℓ takes place in $\mathbb{C}$, not in the residue field. Choosing another noncompact root changes T and can select another extension.

This projector is a finite Hecke/induction projector after central normalization. It is not the older image-algebra projector onto a sector of the original η. The distinction is part of the result, not a cosmetic change of notation. The low-rank enlargement repairs a particular assembly failure while preserving the obstruction for the original carrier.

11 The native stabilizer obstruction and a scalar positive case

11.1 The obstruction belongs to a specified mechanism

For the totally ramified degree-$n = p^r$ host in the stated residue-rank-one setting, the retained native character-preserving normalizer calculation gives

$$\mathcal{N} = K^\times J^1, \qquad \mathcal{N}/(F^\times J^1) \simeq \mathbb{Z}/n\mathbb{Z}.$$

This is an arithmetic input of the source, not a fact about every possible host. Its immediate finite consequence is decisive [23].

Proposition 11.1 (Prime-to-p inner actions vanish in this host)**.** *If a finite group C of order prime to p acts on the host symplectic quotient through the displayed native-normalizer quotient, its action is trivial. If the action on the full scalar extension fixes the scalar center pointwise and lies over that trivial quotient action, that action is also trivial.*

Proof. The image in the cyclic p-group has order dividing both $|C|$ and p^r, so it is trivial. The remaining automorphisms over quotient and center form $\mathrm{Hom}(W, \mathbb{C}^\times)$, a finite p-group. The same coprimality argument makes the remaining image trivial. □

Honest operators on an irreducible Heisenberg carrier are then scalar by Schur's lemma. Matching the source therefore requires the source extension action to be trivial and its scalar character to equal the host character. A general source with a nontrivial prescribed symplectic action cannot be forced into this native mechanism by adjusting a scalar cochain.

The source record gives a nontrivial prime-to-p symplectic action on separate admitted break targets. That is consistent with the original H2 input and inconsistent with the stronger claim that the current totally ramified host can implement every such action by its own inner normalizer. The obstruction refutes the stronger proposed mechanism, not the original finite hypothesis and not Conjecture 66.

11.2 A genuine scalar inertia phase can descend from a cover

Note [24] also proves a restricted positive extension beyond $C = 1$. Assume C is prime to p, acts trivially on the source scalar extension, and its prescribed honest operators on the entire rank-N Weil carrier are $\chi(c) I_N$ in the actual inertia image. Fix the same-source determinant central character under the specified reciprocity convention.

Let the residue cardinality be q and write $B = \omega(\mathrm{Teich}(k^\times))$. The stated actual-inertia and determinant hypotheses give $\chi(C)^N \subseteq B$. Since N is a power of p and the order of $\chi(C)$ is prime to p, taking N th powers permutes $\chi(C)$, so $\chi(C) \subseteq B$. Choose $k_0 N \equiv 1 \pmod{q-1}$ and set

$$\delta(a) = \omega(\mathrm{Teich}(a))^{k_0}, \qquad \widetilde{C} = \{(c, a) \in C \times k^\times : \chi(c) = \delta(a)\}.$$

The projection $\widetilde{C} \to C$ is onto. The central matrix $\mathrm{Teich}(a^{k_0}) I_N$ acts by $\chi(c)$. Its kernel acts trivially on the entire candidate, so the represented action descends to C [24].

A direct matrix homomorphism from C itself need not exist. An arbitrary scalar phase on a multiplicity subspace is not the required actual-inertia phase on the whole source carrier. The argument also does not rescale a fixed canonical beta extension to manufacture a desired character. These qualifications are essential to the positive result.

12 What has been gained and what remains

12.1 The restricted positive result is substantial

The recovered ordinary constructions now address arbitrary odd-prime and dyadic lengths in their stated families. They build actual parameter fields, control native traces or trace visibility, extend full characters through the required shallow intersections, and retain central and noncompact completion choices. For the one-vertex trivial-stabilizer scalar-pushout contract, the dyadic low-rank repair allows an actual enlarged assembly carrier where the original maximal-type quotient is too small. These are mathematical results with explicit hypotheses, not merely numerical suggestions.

At the same time, these families do not supply an actual witness for every d_ρ admitted by the general conjecture. The same-candidate H5 comparison also remains a separate conditional step. These distinctions keep the restricted results separate from the general realization and comparison obligations.

12.2 The remaining obligations are different kinds of problems

Admission and canonical source data. Broader source classes need intrinsic envelopes, the declared equivariant bridges, and the requisite odd or dyadic phase and marking data. Conjecture 66, as stated, starts after H1–H4 have been supplied. Extending the supply of those inputs is related work, but it is not the same quantified task.

A common arithmetic host. Separate breakwise targets do not yet give one actual inducing system of the total rank. The direct families establish some hosts. Their existence does not prove that the host can realize every admitted source action, transport graph or numerical layer placement.

Nontrivial stabilizer actions. The native inner-normalizer obstruction forces a change of host or a different arithmetic action mechanism for genuinely nontrivial prime-to-p symplectic actions. Abstract cohomological lifting has already removed some finite scalar defects. Repeating that lifting does not solve the missing arithmetic attachment.

Independent native markings and fixed embeddings. Transporting a marked source extension is not the same as matching a separately specified native quadratic refinement. A proposed match must respect the actual fixed embedding, rather than merely an abstract isometry class.

General transport diagrams. A one-vertex packet has no nontrivial global transport constraint. Finite holonomy theorems compare supplied source and target systems. A realization theorem for arbitrary admitted diagrams must construct an arithmetic system and show that its maps recover those particular transports.

Same-candidate factors. H5 remains about the actual candidate that realizes the packet. Conductor, torsion and self-pair identities are useful tests, but they do not supply the full characterizing family. A program seeking an independent factor comparison must construct that proof rather than invoke the reference correspondence through an implicit definition.

12.3 The route through the remaining constructions

The preceding sections develop parameter recursion, normalized corestriction, native traces, ordered full characters, and both low-rank enlarged carriers. They retain actual finite-index inducing data alongside compact quotients and central projectors. Section 13 states the principal classical inputs and their audit boundaries.

Sections 14–21 compare the earlier monomial, Clifford-descent, and binder constructions with the direct constructor. They retain both failed mechanisms and surviving positive results, distinguishing source-defined arithmetic induction from direct construction. Sections 22–30 examine the conductor and marking questions under their stated hypotheses.

The research atlas illustrates these constructions, obstructions, and evidence boundaries. The formal companion records the associated verification scope. Together they distinguish the available restricted results from the general realization and same-candidate comparison obligations.

13 Classical inputs and the proof boundary

13.1 What was read directly

The primary reference for the direct construction is Bushnell and Kutzko, The Admissible Dual of GL(N) via Compact Open Subgroups [25]. The retained book and its extracted text were available, and the cited passages were checked against page images. The PDF page number is twelve greater than the printed page number for the passages listed below. This locator offset is recorded rather than guessed from a search hit.

The audit establishes which published statement is used and how the current construction meets its stated interface. It does not turn a citation into a Lean proof or reprove the entire classical theory. Nor does it certify unrelated source-dependent conductor formulas simply because they occur in the same archive.

Input	Printed pages	Application and restriction
BK 1.4.10	38	Minimal commutator exactness used for the actual rank-four field approximation. It is not an integral bimodule splitting in wild ramification.
BK 2.2.6–7	55	Noncommuting refinement. A pure maximal derived field and the strict inequality $-2R > k_0(\gamma) + k_0(C)$ are supplied. The conclusion concerns the literal final sum.
BK 3.1.7–10	90–94	Recursive H and J groups, with distinct floor and ceiling thresholds. These identify the actual congruence subgroups and surviving high layer.
BK 3.2.1–5	98–100	Minimal and nonminimal character definitions, then extension from depth $\lfloor r/2 \rfloor + 1$. The determinant and normalization conditions are retained.
BK 3.3.2	105	Full-character intertwining. At the minimal rank-two full level it reduces to $K^{\times} J$, so the new coset has a genuine nontrivial character orbit.
BK 3.3.18	112–113	Correction at index $m = \lfloor r/2 \rfloor$ with $r < n$. The map is $\theta \mapsto \theta\psi_{\delta}^{-1}$, so the new character is $\Theta\psi_{\delta}$.
BK 3.4.1	114–116	Nondegenerate alternating form for the actual simple-character quotient. It does not assign a native quadratic refinement.
BK 3.6.13(ii), 3.6.14	136–137	Full-character transfer preserves the beta-determinant character. Multiplicity p gives $\chi(u^p)$. Both normalized full indices are zero.
BK 6.2.2–3	203–204	An actual extended maximal simple type induces to the supercuspidal candidate. The compact type alone fixes only an unramified-twist class.
BK 6.2.5	204–205	Torsion number and principal-order normalization. The period must be attached to the same actual type, not to an abstract lattice with the same index.

13.2 The exact refinement substitution

The refinement step is worth displaying as a substitution table. It is the arithmetic bridge between the explicit matrix recursion and a maximal field.

Published requirement	Value in the recursive construction
Initial simple stratum	$[\mathfrak{A}, n, R, \gamma]$
Perturbation	$b = \mathrm{Lift}_E(C) \in \mathfrak{P}^{-R}$
Derived parameter	$s(b) = C$
Pure maximal derived field	$E[C] \subseteq M_{p^{d-1}}(E)$ by induction
Outer critical exponent	$k_0(\gamma, \mathfrak{A}) = -n$
Inner critical exponent	$k_0(C, \mathfrak{B}) = -q_1$
Strict inequality	$-2R > -n - q_1$
Literal output field	$K = F[\gamma + b]$

For odd p, $n > pR > 2R$. For $p = 2$, $n > 2R$. Both imply the required strict inequality. Maximality of the derived field is a genuine induction hypothesis. It is not implied merely by counting its matrix entries.

13.3 Inputs that remain separately audited or deferred

The conductor formulas in Sections 6–8 retain their pinned arithmetic sources. Displayed numerical specializations are checked where indicated. This is not an end-to-end audit of every conductor theorem. The source-defined Bushnell–Henniart induction and descent branch remains separate from the direct matrix constructor and cannot serve as an unstated existence step in its proof.

The marked source attachment remains a scalar-pushout contract. Transporting the whole source marking does not identify it with an independently fixed host marking. The full finite-image center in low rank can exceed order two. Finally the native stabilizer obstruction and the same-candidate factor requirement are unchanged. These boundaries remain visible even though the parameter, character, and enlarged-induction arguments are now developed at greater length.

13.4 Distinguishing evidence from completion

Written proofs, finite tests and formal declarations have distinct scopes. None supplies a missing arithmetic input.

B Finite checks and their limits

The recorded replay covers four bounded gates. The initial evidence suite (Block 01) passed twelve test methods. The direct-construction suite passed eleven methods covering uniformizer identities, native and amplified traces, correction-depth endpoints, character extension, determinant transfer, low-rank commutators, filtration inequalities, and noncompact recovery. The exact rank-nine odd and rank-eight dyadic matrix scripts also passed unchanged in isolated working directories.

The direct-construction suite includes 256 binary leading-commutator cases, 153 low-rank normalization parameter pairs, 2,211 finite cyclic character-extension cases, and 972 finite Laurent-kernel cases. These are distinct finite model families, not a count of universal theorems. Other bounds and negative controls are listed separately in the JSON receipts. No aggregate assertion count is used as a measure of progress toward Conjecture 66.

The two matrix scripts use sparse Laurent arithmetic in positive characteristic. They check actual recursive matrix identities and grades, not merely floating-point approximations. They do not prove field maximality, simple-character existence, source attachment, the H5 factor comparison, or a universal realization statement. A proof reconstruction in prose is likewise not a Lean compilation.

The arithmetic proof route is complemented by the monomial, Clifford-descent, and binder analysis in Sections 14–21, the conductor and marking analysis in Sections 22–30, and the research atlas. These developments preserve the separate source and verification limits of each argument. They do not claim an exhaustive reconciliation of every archived construction.

Monomial and Clifford constructions

The first part of this research companion records the direct odd-prime and weighted dyadic constructions, including the low-rank carrier repairs. This continuation returns to the earlier monomial and Clifford branches. Their conclusions are not interchangeable. A genuine arithmetic candidate may have the right dimension and conductor while failing to contain a prescribed full simple character. A finite carrier may have enough dimension while failing the required action or marking. A compatible formal interface may still await its actual arithmetic input.

The purpose here is to make those distinctions mathematically usable. We extract the precise restricted implications, explain the negative results, and retain the surviving routes. The presentation includes elementary proofs where the argument is short enough to expose completely. Deeper arithmetic statements are identified as inherited ordinary arguments with named classical inputs. No theorem in this continuation is newly certified by Lean.

Source provenance. The first part of this companion is retained from a preserved reader. Its complete editable source archive was not recovered. The monomial and Clifford analysis uses the retained initial research archive. The source map records this boundary. This book does not claim to reconstruct unavailable source files.

Mathematical scope. Conjecture 66 remains the general arithmetic realization obligation, with the same-candidate H5 comparison kept separate. The positive constructions below are restricted statements. The negative examples refute specified shortcuts or prescribed candidates, not the entire conjecture.

14 The monomial branch and its actual scope

14.1 Three statements that must remain separate

The recovered monomial materials contain three different layers. The oldest manuscript develops a classical-input route from rank-one characters through automorphic induction. The finite formal core describes packet and group-theoretic interfaces. The ActualMonomialLocalGlobal module [M45] connects a degree-induced representation to actual residue and Frobenius data. None of these layers, merely by existing, constructs every arithmetic witness demanded by Conjecture 66.

A useful way to read the branch is to keep its input on the left:

rank-one character and admissible induction tower $\Longrightarrow$ the corresponding induced candidate.

This is not the implication from an arbitrary packet diagram to an admissible tower. The tower and its compatibility are substantial data. Nor does an equality between finite conductor profiles identify the full local factors of a separately specified candidate.

14.2 Actual Weil pullback and inertia invariants

Source [M45] uses an actual residue-action pullback and a degree homomorphism

$$\delta : W \longrightarrow \mathbf{Z}.$$

The subgroup for an induction of degree n is $\delta^{-1}(n\mathbf{Z})$. A finite cyclic inertia map is explicitly required to have image $\ker \delta$. This equality is a hypothesis to verify for the actual pullback, not an arbitrary identification of an abstract cyclic group with inertia.

Lemma 14.1 (Fixed vectors depend on the actual image)**.** *Let $\rho : G \to \mathrm{GL}(V)$ and let $\iota : H \to G$ be a homomorphism with image I. Then*

$$V^{\rho\circ\iota(H)} = V^{\rho(I)}.$$

Proof. A vector fixed by every $\rho(\iota(h))$ is fixed by every element of $\rho(I)$ because every element of I has a preimage. The reverse inclusion follows immediately from $\iota(H) \subseteq I$. □

The hypothesis that the first positive ramification group acts trivially places the representation in the tame sector. In the degree-induced examples, triviality of the inertia character gives an n-dimensional fixed space. A nontrivial inertia character, together with its Frobenius conjugates, gives no inertia-fixed coordinate. Thus the Artin conductor is respectively 0 or n, while the Swan conductor is zero. The local polynomial is formed on V^I, not automatically on the entire induced vector space.

This is meaningful arithmetic comparison at a finite interface. It is not a formal definition of an automorphic representation and does not import every analytic identity attached to one. The finite Gauss phase also does not become a fully normalized local epsilon factor without the relevant additive character and measure conventions.

Source and status. [M45] supplies the production module and binder conditions. The fixed-image lemma is proved here. The full module's terminal compilation receipt was not recovered. Earlier checked finite-tame comparison is not thereby invalidated.

14.3 Admissible towers rather than a blanket solvability claim

Let Ω be a finite group and $\Lambda \leq \Omega$. For the induction route in the older manuscript, the required condition is a chain

$$\Lambda = \Lambda_r \triangleleft \Lambda_{r-1} \triangleleft \cdots \triangleleft \Lambda_0 = \Omega, \qquad \Lambda_{i-1}/\Lambda_i \text{ cyclic of prime order.} \tag{14.1}$$

For a finite Galois extension with group Ω, the reversed fixed-field chain has cyclic prime-degree steps. The rank-one character can then be processed through the stated cyclic automorphic-induction inputs. Induction in stages identifies the resulting Weil parameter with the original induced character. Cuspidality requires the appropriate regularity and stabilizer conditions. Without them, an isobaric conclusion must not be relabeled as a cuspidal one.

Proposition 14.2 (Subnormality is the subgroup requirement)**.** *For a finite solvable group Ω, a subgroup Λ admits a chain of the form (14.1) if and only if it is subnormal in Ω.*

Proof. One direction is the definition of subnormality. Conversely, start with a subnormal chain. Each quotient of two successive terms is finite and solvable. A composition series of that quotient has cyclic prime-order factors. Pulling it back refines the original step into the required chain. Repeat for all steps. □

The statement does not say that every subgroup of a solvable group is subnormal. In S_3, a subgroup generated by a transposition has order two. There is no proper intermediate subgroup between it and S_3, and it is not normal in S_3. It cannot serve as the bottom of (14.1). Yet S_3 is solvable through its normal subgroup of order three. The exact finite suite includes this countercontrol.

The recovered manuscript has valid additional sectors, including nilpotent groups and suitable abelian-by-cyclic constructions. Their usefulness comes from producing the needed subgroup chain, not from deleting that requirement. Similarly, a virtual character identity with negative coefficients is not itself a construction of an actual automorphic representation. Dividing products of L-functions does not, by that operation alone, prove the required holomorphy.

14.4 What cyclic Clifford extension really supplies

Proposition 14.3 (Extension across a cyclic quotient)**.** *Let $H \triangleleft G$ be finite, with G/H cyclic of order d. Let τ be an irreducible complex representation of H whose isomorphism class is G-invariant. Then τ extends to G. Any two extensions differ by a character of G/H.*

Proof. Choose $t \in G$ lifting a generator. Invariance supplies an invertible operator A with

$$A\tau(h)A^{-1} = \tau(tht^{-1}).$$

The operator $A^d\tau(t^d)^{-1}$ commutes with $\tau(H)$ and is scalar by irreducibility. The same conjugation identity shows that A commutes with $\tau(t^d)$. Rescale A by a complex dth root so that $A^d = \tau(t^d)$. Sending t to this rescaled operator and retaining τ on H respects the defining conjugation and power relations, hence defines an extension.

After identifying the two restrictions with τ, the ratio between two possible operators at t commutes with $\tau(H)$ and is scalar. Its dth power is one. These scalars are precisely the characters of the cyclic quotient. □

This finite representation argument removes a cyclic projective extension obstruction. It does not prove automorphic descent for an arbitrary local-field construction. The latter needs an actual descent theorem and its hypotheses. This distinction explains why the monomial branch supplies a strong restricted route while leaving the general assembly problem intact.

Source and status. [M] contains the admissible tower and classical-input completion. [BH99, §2.3] supplies a characteristic-zero monomial route through cyclic prime-degree steps. The finite group proofs above are ordinary proofs, independent of any unverified compilation claim.

15 Genuine Clifford multiplicities and dimension

15.1 A projective multiplicity is not a decorative label

Clifford theory produces projective representations on multiplicity spaces. The carrier, cocycle, and actions must all come from the same actual restriction problem. Attaching several abstract Heisenberg packets to a diagram does not ensure that their multiplicities multiply inside a prescribed source representation.

Here is the dimension mechanism in a form that exposes its hypotheses. Let A be a finite abelian group and let $c : A \times A \to \mathbf{C}^\times$ be a unit-modulus multiplier. Write

$$T_a T_b = c(a,b) T_{a+b}, \qquad b_c(a,b) = \frac{c(a,b)}{c(b,a)}, \qquad R = \{a : b_c(a,b) = 1 \text{ for every } b \in A\}.$$

The commutator pairing b_c is alternating. The group R is its radical.

Proposition 15.1 (Degree of an irreducible projective multiplicity)**.** *For an irreducible projective representation with multiplier c on M,*

$$(\dim M)^2 = |A/R|. \tag{15.1}$$

Every finite-dimensional module with this same multiplier has dimension divisible by $\sqrt{|A/R|}$.

Proof. Average an inner product over the operators T_a. Unit modulus of the multiplier makes the averaged inner product invariant, so the operators may be taken unitary. If $r \in R$, then T_r commutes with all T_a and is scalar. Thus $|\operatorname{Tr} T_r| = \dim M$. If $a \notin R$, some T_b conjugates T_a to a nontrivial scalar multiple of itself, so $\operatorname{Tr} T_a = 0$.

The operators $\operatorname{Ad}(T_a)$ form an ordinary representation on $\operatorname{End}(M)$. Their average is the projection onto the commutant, which has dimension one by irreducibility. Its trace is

$$1 = \frac{1}{|A|} \sum_{a \in A} |\operatorname{Tr} T_a|^2 = \frac{|R|}{|A|} (\dim M)^2.$$

This proves (15.1). Finally, averaging a projection gives invariant complements, so modules with the fixed unitary multiplier are semisimple. Every irreducible summand has the degree already computed, proving divisibility. □

No assertion that the original cocycle literally descends to A/R is needed. Choosing a section can produce a quotient multiplier after incorporating the scalar radical action, but that is additional bookkeeping, not a reason to suppress the radical.

If A is elementary abelian of order a power of p and the nondegenerate quotient has dimension $2r$ over $\mathbf{F}_p$, the multiplicity degree is p^r. Independent commuting projective factors on the *same* carrier produce the tensor product degree $p^{r_1+\cdots+r_s}$. Both independence and commutation matter. A single Weyl plane represented twice on a p-dimensional space still has noncommuting cross-operators. It does not force divisibility by p^2.

15.2 The orbit factors in a normal chain

Proposition 15.2 (A compatible Clifford chain)**.** *Suppose*

$$G_0 \lhd G_1 \lhd \cdots \lhd G_s$$

is a chain of finite groups. Choose irreducible ρ_i of G_i such that ρ_{i-1} occurs in $\rho_i|_{G_{i-1}}$. Let I_i be the inertia group of ρ_{i-1} in G_i and $t_i = [G_i : I_i]$. For a fixed prime p, if G_i/G_{i-1} is elementary abelian of p-power order and the actual projective multiplicity pairing has rank $2r_i$, then

$$\dim \rho_s = \dim \rho_0 \prod_{i=1}^{s} t_i p^{r_i}. \tag{15.2}$$

Proof. The restriction at the ith step is a sum of t_i distinct conjugate irreducibles, each of dimension $\dim \rho_{i-1}$ and common multiplicity e_i. The corresponding isotypic component is irreducible as a module for I_i. Factoring out the G_{i-1} representation leaves the actual irreducible projective multiplicity representation of I_i/G_{i-1}. Its commutator rank is $2r_i$, so Proposition 15.1 gives $e_i = p^{r_i}$. Hence $\dim \rho_i = t_i p^{r_i} \dim \rho_{i-1}$. Multiplication over the chain proves the formula. □

For example, the two-dimensional irreducible of S_3 restricts to the two nontrivial characters of C_3. The multiplicity is one, and the orbit factor is two. Dropping the orbit factor would give the wrong dimension. A valid source bound therefore uses a genuine compatible chain, not merely a list of candidate projective factors.

A consequence is $p^{\sum r_i} \le \dim \rho_s$. This can make a proposed target dimensionally plausible. The fixed-rank constructor recorded in [C161] has, under its selected even-depth hypotheses, a host half-dimension $fn(n-1)/2$ over $\mathbf{F}_p$, where the residue field has order p^f. The source bound then provides enough room for the relevant abstract symplectic dimensions. That conclusion remains dimensional. It does not identify a native subgroup, prescribe its quadratic marking, make the action equivariant, or prove full-character occurrence.

Source and status. [C161] gives the genuine-chain constraint and the constructor comparison. Propositions 15.1 and 15.2 are expanded ordinary arguments. The executed finite models check small Weyl carriers, radicals, repeated-factor failures, and the S_3 orbit example, not arbitrary arithmetic host realization.

16 Genuine source fixtures and what they rule out

16.1 Two packets inside a single-slope source

The continuation112 fixtures were designed to avoid an artificial diagram whose purported packets did not come from one irreducible source. In the first construction, over $\mathbf{F}_5((t))$, an unramified degree-four extension supports two independent Heisenberg extensions. Their Schrödinger representations have dimensions five and five. The tensor product is irreducible of dimension 25.

For one factor the finite group law is

$$(u,v,w)(u',v',w') = (u+u', v+v', w+w'+uv'),$$

and its action on functions on $\mathbf{F}_p$ is

$$(T_{u,v,w}f)(s) = \zeta_p^{w+vs} f(s+u). \tag{16.1}$$

Direct composition verifies the group law. In the tensor product, the kernel on the product of the two centers is the anti-diagonal

$$\{(z(w), z(-w)) : w \in \mathbf{F}_5\}.$$

The quotient is the balanced central product, not the direct product with two unrelated central characters. The common central character remains the prescribed character.

The two arithmetic factors have ramification breaks $\{2,4\}$ and $\{3,6\}$. Their disjointness supplies the product filtration. After quotienting by the balanced central kernel, the ambient jumps are $2,3,6$. The ordinary representation has only slope six, while the actual chain still contains two multiplicity-five packets. Thus a sole ordinary slope does not force a single projective multiplicity packet.

The unramified Frobenius action has order four. It must not be relabeled as a nontrivial tame inertia group. The source fixture has trivial tame stabilizer in this sense, even though Frobenius acts nontrivially on the finite operators.

16.2 The symmetric characteristic-three fixture

The refined example works over $F = \mathbf{F}_3((t))$, with unramified degree-four field $K = \mathbf{F}_{81}((t))$. Choose a with $a^9 = -a \neq 0$ and put $b = a^3$. For $m = 1, 5$, write $f = at^{-m}$ and $g = bt^{-m}$. The torsor equations are

$$\wp x = f, \qquad \wp y = g, \qquad \wp z = \frac{fy - gx}{2}, \qquad \wp u = u^3 - u. \tag{16.2}$$

With $w = z + xy/2$, the final equation becomes

$$\wp w = fy + \frac{fg}{2}.$$

For the ramification formula in [Imai, Example 3.8(1)], the differential term is

$$d(fg/2) - f\,dg = \frac{g\,df - f\,dg}{2} = 0.$$

The pole orders m and $2m$ are prime to three. The leading coefficients a, b are linearly independent over $\mathbf{F}_3$: otherwise $a^2 = b/a$ would lie in $\mathbf{F}_3$, contradicting $a^8 = -1$. The total ramification condition is supplied by the torsor argument in [C112]. Under these hypotheses, the two remaining terms give

central break $4m/3$, not $2m$. The latter would correspond to the different unsymmetrized data. The factor break sets are therefore

$$\{1, 4/3\}, \qquad \{5, 20/3\}.$$

The balanced quotient has ambient jumps $1, 5, 20/3$. Its nine-dimensional irreducible source has a sole slope $20/3$, hence Swan conductor 60, and two genuine multiplicity-three packets. Native subgroup labels in a different upper-numbering convention cannot be substituted for these ambient labels.

The ordinary arithmetic analysis of [C112] then tests whether suitable per-break simple-character targets can all be replaced by one raw maximal-type quotient of the same rank. Its rank-nine spectrum excludes the exponent needed for a degree-nine Heisenberg representation in that specific quotient. The result is a failure of that proposed one-quotient shortcut. It does not show that the source satisfies every strengthened realization hypothesis and then violates Conjecture 66.

16.3 Why the fixtures and later enlargements coexist

The first fixture did not even supply all the per-break arithmetic targets required by the stronger test. The second supplies a sharper comparison but still does not provide the full native marking, Frobenius action, and same-candidate H5 package. These omissions are part of its status, not cosmetic caveats.

The later low-rank enlargements in Part I do not retroactively make a forbidden original quotient large enough. They change the assembly carrier while preserving a specified inducing representation. That is a different construction. The argument therefore separates: genuine source multiplicities, obstruction to a particular arithmetic quotient, and a search for a permitted larger carrier with explicit recovery. It is not a sequence of contradictory claims about one unchanged quotient.

Source and status. [C112] records the two arithmetic source fixtures and the maximal-type spectrum test. [Imai] supplies the selected ramification formula. The finite operator law and balanced-center kernel have been rerun here. The local-field torsor construction and full spectrum theorem remain inherited ordinary arguments, not newly formalized results.

17 An actual arithmetic candidate and a failed prescribed character

17.1 The field, the character, and the source

Continuation113 supplies an explicit characteristic-zero experiment in which the source representation and the arithmetic candidate exist independently of the proposed packet attachment. Fix compatible roots of unity and write

$$F = \mathbf{Q}_3(\zeta_3), \qquad L = \mathbf{Q}_3(\zeta_9), \qquad \varpi = \zeta_9 - 1, \qquad \varpi_F = \zeta_3 - 1, \qquad \beta = \varpi^{-10}. \tag{17.1}$$

The extension L/F is cyclic and totally ramified of degree three. The polynomial of ϖ over F is

$$X^3 + 3X^2 + 3X - \varpi_F.$$

Normalize $v_L(\varpi) = 1$. Then $v_L(3) = 6$ and the relative different has exponent six. Let $\psi_{\mathbf{Q}_3}$ have kernel $\mathbf{Z}_3$, and set

$$\psi_F(x) = \psi_{\mathbf{Q}_3}\left(\frac{\mathrm{Tr}_{F/\mathbf{Q}_3}(x)}{3}\right), \qquad \psi_L = \psi_F \circ \mathrm{Tr}_{L/F}.$$

The conductor ideal of ψ_L is $\mathfrak{p}_L^{-3}$. This negative exponent is essential. Replacing it by $\mathfrak{p}_L$ shifts the unit thresholds and changes the calculation.

Every element of $L^\times$ has a unique expression $\varpi^a \epsilon u$ with $a \in \mathbf{Z}$, $\epsilon \in \{1, -1\}$, and $u \in U_L^1$. Define the full multiplicative character by

$$\chi(\varpi^a \epsilon u) = \psi_L(\beta \log u). \tag{17.2}$$

The logarithm converges on U_L^1. At depths at least four, logarithm and exponential are inverse, so the conductor condition becomes $r - 10 \geq -3$. Consequently $a_L(\chi) = 7$. With $\sigma(\zeta_9) = \zeta_9^4$, one obtains

$$v_L(\sigma\beta - \beta) = -8.$$

The nontrivial conjugate quotient has conductor five. In particular, the three conjugate characters are distinct on the actual unit group, not merely assigned distinct labels.

The recorded exact program operates in the rational algebra

$$\mathbf{Q}[X]/(X^6 + 6X^5 + 15X^4 + 21X^3 + 18X^2 + 9X + 3).$$

It verifies field identities and rational trace witnesses such as

$$\chi(\exp(\varpi^6)) = \zeta_3, \qquad \psi_L((\sigma\beta - \beta)\varpi^4) = \zeta_3^2.$$

The program does not approximate a 3-adic exponential. The analytic reduction $\log(\exp x) = x$ is used only in its valid range, after which the calculation is exact rational arithmetic.

Regularity makes

$$\rho = \mathrm{Ind}_{W_L}^{W_F} \chi$$

irreducible of dimension three. The argument in [C113] excludes unramified self-twists. Under [BH99, Proposition 2.2], its wild restriction is irreducible as well. The conductor induction calculation gives

$$a_F(\rho) = 7 + 6 = 13, \qquad \mathrm{Sw}_F(\rho) = 10, \qquad \mathrm{slope}(\rho) = 10/3. \tag{17.3}$$

These are conductor statements for this source, not proofs of the general pair-factor contract.

17.2 The source-defined automorphic-induction candidate

The characteristic-zero cyclic monomial route in [BH99, §2.3] gives an actual supercuspidal candidate

$$\pi_F^0 = \mathrm{AI}_{L/F}(\chi). \tag{17.4}$$

The central character is $\omega = \chi|_{F^\times}$. This construction imports the established automorphic-induction input. It is not described as selecting a representation with convenient packet coordinates and then declaring it to be the realizer of ρ.

For this monomial subcase, the classical source has stronger comparison properties than conductor equality alone. Those properties belong to this actual candidate and its stated local correspondence. They do not prove that an independently specified simple character occurs in π_F^0, nor do they automatically identify a different constructed type with it.

17.3 The independent simple character

Let $\mathfrak{a}$ stabilize the $\mathcal{O}_L$ lattice chain on the three-dimensional F-space L. The element $\beta = \varpi^{-10}$ is minimal over F. The actual full-degree simple stratum gives

$$H^1 = U_L^1 U_{\mathfrak{a}}^6, \qquad J^1 = U_L^1 U_{\mathfrak{a}}^5.$$

The proposed simple character is

$$\theta_0(uy) = \chi(u)\,\psi_F\Big(\mathrm{tr}_{M_3(F)/F}(\beta(y-1))\Big). \tag{17.5}$$

The intersection condition is checked on U_L^6. The quotient J^1/H^1 has order nine, and the associated Heisenberg representation η_0 has dimension three. The type-side conductor agrees with 13.

At this point two real objects have been produced: the source-defined π_F^0 and the independently defined θ_0. The missing assertion is not their existence but

$$\mathrm{Hom}_{H^1}(\theta_0, \pi_F^0) \neq 0. \tag{17.6}$$

The computation below shows that this assertion is false. This is more informative than marking it as an unfinished verification.

17.4 A nontrivial tame descent that still leaves occurrence open

Set $K = F(i)$, the unramified quadratic extension, and $M = KL$. The character $\chi_M = \chi \circ N_{M/L}$ gives $\pi_K^0 = \mathrm{AI}_{M/K}(\chi_M)$. Its Galois invariance and norm-compatible central character meet the tame descent conditions in [BH99, Theorem 1.3]. In characteristic zero, Theorem 1.8 identifies the tame algebraic lift with cyclic base change here, since $[K : F] = 2$ is prime to three.

Lemma 17.1 (Central normalization of a descent fiber)**.** *Suppose a nonempty descent fiber is a torsor under a group X of characters of exponent dividing d. Suppose twisting a rank-n representation by $\alpha \in X$ multiplies its central character by α^n. If $\gcd(n, d) = 1$, every compatible specified central character selects a unique member of the fiber.*

Proof. Choose integers r, s with $rn + sd = 1$. The power map $\alpha \mapsto \alpha^n$ on X has inverse $\alpha \mapsto \alpha^r$, because $\alpha^d = 1$. Relative to one member of the nonempty fiber a compatible desired central-character ratio is an element of X. There is exactly one twisting character with that nth power. □

Here $n = 3$ and $d = 2$, so the central-normalized descent is unique. This is a useful actual descent conclusion. The applicable type transfer also provides an occurrence equivalence between F and K. It does not manufacture the initial occurrence. In this example $\dim \eta_K = 9$ while $\dim \eta_F = 3$, and the literal restriction of the transferred simple character has the power $\theta_K|_{H_F^1} = \theta_F^2$. Equating the two entire finite carriers would erase the actual transfer mechanism.

Source and status. [C113] contains the field, character, conductor, type and descent arguments. The cyclotomic identities and normalization checks were replayed in the recorded audit. [BH99, printed pp. 15, 18, 24 and 48] was read at the selected descent, monomial and central-type statements. A full new audit of every conductor formula and every transfer theorem is not claimed.

18 A full-extension scalar obstruction and its limited repair

18.1 Why testing only the compact part can mislead

The cubic norm-kernel character of $F^\times$ defines $\Omega = \omega_{\mathrm{cub}} \circ \det$ on $\mathrm{GL}_3(F)$. The source-defined automorphic induction satisfies

$$\pi_F^0 \otimes \Omega \simeq \pi_F^0.$$

If a proposed extended type is to induce to π_F^0, it must be compatible with this self-twist. Continuation113 finds an element g that makes the compact character appear compatible, but whose action on a noncompact generator leaves a nontrivial scalar.

In the basis $1, \varpi, \varpi^2$, multiplication by ϖ is

$$\Pi = \begin{pmatrix} 0 & 0 & \varpi_F \\ 1 & 0 & -3 \\ 0 & 1 & -3 \end{pmatrix}, \qquad g = I + \mathrm{diag}(0,1,2)\Pi^4. \tag{18.1}$$

The actual group calculations show that g normalizes the relevant compact groups and the extended inducing group $N = L^\times J^1$. With the convention $\tau^g(x) = \tau(g^{-1}xg)$, one has

$$\theta_0^g = \theta_0\Omega, \qquad \eta_0^g = \eta_0\,\Omega|_{J^1}$$

in the literal operator models used in the audit. The check includes H^1 and two quotient generators, not merely a comparison of characters on an abstract vector space.

The decisive element is

$$h = g^{-1}\Pi g \Pi^{-1} \in H^1, \qquad \theta_0(h) = \zeta_3. \tag{18.2}$$

In contrast, $\Omega(\Pi) = 1$. For every full central extension Λ of η_0, the compact equality remains true but

$$\Lambda^g(\Pi) = \zeta_3\Lambda(\Pi).$$

Lemma 18.1 (A generator scalar cannot be removed by an intertwiner rescaling)**.** *Let two representations of $N = \langle J, z\rangle$ have the same irreducible restriction to J. Suppose their operators at z differ by a scalar $\xi \neq 1$. Then they have no nonzero intertwiner.*

Proof. Any intertwiner on J is scalar by irreducibility. A nonzero scalar commutes with the invertible operator at z. The intertwining equation at z then forces $\xi = 1$, a contradiction. □

The inherited all-extension argument combines this lemma with the actual simple-character intertwining group and the maximal-type induction theorem. Those inputs rule out an alternative intertwining coset elsewhere in the ambient group. The conclusion is therefore not based on numerically searching a finite list of matrices. Every supercuspidal containing this prescribed θ_0 fails the required cubic self-twist, whereas π_F^0 has it. Thus

$$\boxed{\mathrm{Hom}_{H^1}(\theta_0, \pi_F^0) = 0.} \tag{18.3}$$

This is the exact failure of the original prescribed-character route. Neither rescaling an intertwiner nor assigning a different scalar to the same noncompact extension repairs it.

18.2 The independent check and its scope

The replay includes the original rational cyclotomic program, the central-type calculations for three corrections, and an independent scalar calculation. The independent program decomposes the actual matrix h into an L-unit and a deep congruence term. It computes the phase in (18.2) directly, without searching for a Weyl intertwiner or choosing a favored central-type matrix.

This is strong evidence for the specific scalar input. The universal phrase "every extension" still uses the ordinary group-generation and irreducibility argument. Finite arithmetic alone is not being credited with proving a quantified representation-theoretic statement.

18.3 A different full character passes the obstruction

Define a wild unit correction on U_L^1 by

$$\nu(u) = \psi_L(\varpi^{-8} \log u). \tag{18.4}$$

Its conductor is five. It leaves the deeper part used in (17.5) unchanged but changes the full unit character. The corrected simple character is

$$\theta'(uy) = \chi(u)\nu(u)\, \psi_F\Big(\mathrm{tr}_{M_3(F)/F}(\beta(y-1))\Big). \tag{18.5}$$

It is not merely a different choice of basis for θ_0.

The noncompact normalization matters here too. The correction is trivial on U_F^1, but that alone does not establish $\nu|_{F^\times} = 1$. The inherited calculation gives

$$\nu(\varpi_F/\varpi^3) = \zeta_3^2.$$

Assigning $\nu(\varpi) = 1$ would therefore change the central character. Instead set

$$\nu(\varpi) = \zeta_9, \qquad \nu(-1) = 1.$$

Then

$$\nu(\varpi_F) = \nu(\varpi)^3 \nu(\varpi_F/\varpi^3) = \zeta_3\zeta_3^2 = 1. \tag{18.6}$$

This is the required full central normalization.

For the correction powers ν^a, $a = 0, 1, 2$, the remaining generator scalars are respectively

$$\zeta_3, \qquad 1, \qquad \zeta_3^2. \tag{18.7}$$

The middle choice passes the cubic self-twist obstruction. The two other choices remain negative controls. The exact programs reproduce all three cases.

18.4 The remaining selection problem

Passing the self-twist test is necessary but not sufficient to establish

$$\mathrm{Hom}_{H^1}(\theta', \pi_F^0) \neq 0. \tag{18.8}$$

The fixed-center central-type family still has three members in this rank-three setting. [BH99, §5.4] describes such a family as a torsor under the corresponding unramified characters. The corrected scalar does not single out the source-defined automorphic-induction member of that family.

A successful next argument would have to establish occurrence in the actual π_F^0 and then identify the appropriate noncompact extension. Producing some representation containing θ' is a weaker statement. Replacing π_F^0 by a convenient member of the family would abandon the same-candidate obligation. Replacing the supplied canonical extension would be another change of input and would have to be tracked explicitly.

Source and status. [C113-S] gives the all-extension obstruction, central-type hypotheses and corrected character. The recorded exact checks establish the named cyclotomic identities and phases. Equations (18.3) and (18.7) retain that ordinary proof boundary. Equation (18.8) remains an unresolved occurrence assertion, not a failed theorem-prover build.

19 Compact binders and exact fixed-template obstructions

19.1 The compactness theorem with all hypotheses visible

A binder is intended to turn compatible finite constraints into one actual object. Compactness can perform that passage only after the admissible space and simultaneous finite solvability have been supplied. It does not supply those premises from unrelated finite successes.

Let $\mathcal{O}$ be the valuation ring of a nonarchimedean local field, with uniformizer π. Fix a closed subset $X \subseteq \mathcal{O}^m$ and continuous functions $f_j : X \to \mathcal{O}$, $j \geq 1$. Put

$$C_n = \{x \in X : f_j(x) \in \pi^n \mathcal{O} \text{ for } 1 \leq j \leq n\}. \tag{19.1}$$

Proposition 19.1 (A compact simultaneous binder)**.** *If $C_n \neq \varnothing$ for every n, there is $x \in X$ with $f_j(x) = 0$ for every j.*

Proof. The ring $\mathcal{O}$ is compact, so X is compact. Each C_n is closed by continuity and the closedness of $\pi^n\mathcal{O}$. Also $C_{n+1} \subseteq C_n$. The finite intersection property gives an element x in their intersection. For fixed j, the value $f_j(x)$ lies in every $\pi^n\mathcal{O}$ with $n \geq j$, so it is zero. □

The proof requires no surjectivity of the reduction maps between the sets of finite roots. For instance, $x^2 = 17$ has roots modulo every power of two, while the roots 3 and 5 modulo eight do not lift to roots modulo sixteen. An arbitrarily chosen partial root can fail even when the compactness conclusion applies to the full nested solution sets.

Separate solvability is also insufficient. The equations $x \equiv 0$ and $x \equiv 1 \pmod{3^n}$ each have solutions, but never have a common solution. Every finite test in the binder premise concerns one tuple satisfying all current constraints together.

19.2 What makes the result an arithmetic certificate

The variables must remain in one bounded, closed model with fixed rank, lattice data and normalizations. A nonzero leading coefficient should be encoded by a fixed nonzero residue class, a closed and open condition. Merely deleting the zero point from a compact model need not leave a compact space. In $\mathcal{O} \setminus \{0\}$, all congruences $x \equiv 0 \pmod{\pi^n}$ are solvable, but the only exact zero has been removed.

For polynomial constraints, or rational constraints with denominators uniformly units, congruence evaluation is compatible with a fixed finite quotient. An exhaustive empty solution set at some precision then certifies failure of that template. Conversely, if the exact common zero set in the compact template

is empty, Proposition 19.1 implies that some finite stage is empty. This is a finite obstruction certificate for the *specified model*, not automatically for every possible arithmetic host.

Full characters require particular care. The domain on which their finite quotients are modeled must be fixed, and the evaluation constraints must be jointly continuous or uniformly descend to the claimed finite quotient. Values on noncompact generators require their own normalization constraints. A binder that only remembers the deep commutator form does not recover a full inducing representation for free.

19.3 A corner with a complete leading-profile test

The earlier cubic calculation is a concrete example of a useful finite obstruction. Work over $\mathbf{F}_3((t))$. The four-coordinate square-zero corner has entries in positions $05, 16, 27, 38$. Adding a fifth coordinate gives

$$x = t(aE_{05} + bE_{16} + cE_{27} + dE_{38}) + \frac{t^2 h}{1+t} E_{08}. \tag{19.2}$$

The relevant leading target parameters are

$$u = cd, \qquad v = ab, \qquad w = bc, \qquad p = c(a-h), \qquad q = b(d-h). \tag{19.3}$$

Here u, v, w are required nonzero. The structural calculation for the larger sixteen-coordinate corner shows that its remaining entries and higher series terms do not change these decisive coefficients. That leading-coefficient fact is an inherited symbolic calculation, not an assumption that five coordinates exhaust all matrices.

Proposition 19.2 (The nonzero-leading corner spectrum)**.** *For targets in* $\mathbf{F}_3$ *with* $uvw \neq 0$*, equations* (19.3) *have a solution if and only if*

$$p + u = w(q + v). \tag{19.4}$$

Exactly 24 of the 72 possible targets satisfy this condition.

Proof. Write $b = s \neq 0$. The first three equations force

$$a = v/s, \qquad c = w/s, \qquad d = us/w.$$

The equation for q then forces $h = us/w - q/s$. Substitution into the equation for p gives

$$s^2(p + u) = w(q + v).$$

Over $\mathbf{F}_3$, every nonzero s has square one. This proves necessity and, by the displayed formulas, sufficiency. There are eight choices of the nonzero triple (u, v, w) and three choices of q, after which p is forced. Hence there are 24 admissible targets among $8 \cdot 3 \cdot 3 = 72$. □

The target $(u, v, w, p, q) = (1, 1, 1, 2, 2)$ cannot be obtained with $h = 0$ but is obtained by the fifth coordinate. The target $(1, 1, 1, 1, 2)$ violates (19.4), so the larger corner still cannot produce it. The first is an actual repair of an overly small ansatz. The second is an obstruction that survives that repair.

Neither conclusion proves that the target is impossible in every arithmetic matrix realization. It identifies precisely where this corner stops. That distinction is what makes the negative result reusable rather than misleading.

19.4 The arbitrary-exponent cubic family

The later general binder165 changes the construction rather than repeatedly enlarging the same leading-coefficient search. Let E/F be the cubic field with

$$e^3 + te + t = 0, \qquad \pi = -t = \frac{e^3}{1+e}.$$

On the period-nine lattice of E^3, let S denote the lattice shift. For $h > 0$ with $3 \nmid h$, set $a = 4h$ and take $x_h = S^a D$, where D is supported in residue positions

$$\{0, 2a, 4a, 6a\} \pmod 9.$$

Its image positions are $\{a, 3a, 5a, 7a\}$, disjoint from its support, so $x_h^2 = 0$. In the expression $x_h S^{-3a} x_h$, exactly the three starting positions $2a, 4a, 6a$ survive. Modulo three they meet the three E-lanes once each. This support statement holds for every allowed h because a is invertible modulo nine.

Under the retained normalized corestriction calculation, these paths give a primitive whole cycle. The full ordinary binder proposition then constructs the stated degree-nine parameter for allowed $h_1 < h_2$, with critical data $n = 12h_2$ and $k_0 = -4h_1$. The finite replay of support residues illustrates this mechanism. The universal construction rests on the symbolic proof and its refinement hypotheses, not on testing the first hundred exponents.

This family is genuine progress beyond one failed corner. It is still a parameter construction. It does not, without the additional full-character, stabilizer and transport arguments, provide the universal realization endpoint. The later direct odd-prime and dyadic constructions in Part I should be read as further developments of the constructor side, not as proofs that all the earlier occurrence obstructions disappeared.

Source and status. [B162] supplies the fixed compact model theorem. [Corner] supplies the whole-corner leading calculation. [B165] supplies the arbitrary-exponent construction. The compactness and finite profile implications are proved here. The underlying full arithmetic refinement is retained as an ordinary source argument.

20 What this synthesis closes and what it does not

20.1 A single dependency chain

The source history supports a coherent sequence. A monomial source with an admissible induction tower gives a restricted actual candidate through stated classical inputs. Genuine Clifford theory limits the multiplicities that can occur inside one source. Explicit fixtures show that ordinary slope data do not determine the packet chain. An independently constructed simple character then poses a genuine occurrence problem for that candidate.

Continuation113 resolves one such occurrence question negatively and repairs one necessary self-twist condition only by changing the full character. Compactness explains how a fixed admissible template can be assembled from simultaneous finite solutions, while explicit corners give finite obstruction certificates. The later constructor families enlarge what can be built but do not identify every constructed object with an independently fixed candidate.

Statement available	Obligation that is not supplied by it
Admissible monomial induction	An admissible tower for every allowed source.
Projective dimension bound	A native, marked and equivariant arithmetic embedding.
Conductor agreement	Occurrence of the prescribed full character.
Cubic self-twist compatibility	Selection of the source-defined central type.
Nonempty finite systems	A limit unless the model is fixed, compact and simultaneous.
A repaired matrix corner	Success in every target profile or arithmetic host.
A larger inducing carrier	Permission to change the original candidate or extension.

20.2 The most precise surviving occurrence task

For the characteristic-zero experiment, the next question is (18.8), followed by the identification of the full noncompact central-type extension. It is not sensible to retry the already excluded (17.6) by changing only an intertwiner scalar. Its negative proof addresses every such rescaling.

A future attempt at (18.8) should use an invariant or a theorem that actually distinguishes the three fixed-center possibilities. The cubic self-twist test does not do so. An explicit comparison of the full inducing character under the monomial construction, or a sufficiently discriminating normalized local-factor calculation for the same candidate, would address a stronger question than the conductor comparisons already performed. Neither is asserted as completed here.

20.3 Conductor and marking boundaries

The selected characteristic-zero monomial and tame-descent inputs do not by themselves audit the separate conductor arguments used by the direct positive-characteristic constructors. The hypotheses of [BH99, §2.3], where characteristic zero is explicit, cannot be imported into that route. The conductor analysis in Sections 22–25 keeps the source-defined and direct constructions separate.

A scalar pushout can carry a supplied subgroup and phase convention without matching a fixed native quadratic refinement. Sections 26–30 examine this distinction and the equal-capacity dyadic boundary.

21 Evidence and reproducibility

21.1 Evidence classes

Four positive evidence classes accompany the open obligations. An ordinary proof displays its hypotheses. An inherited arithmetic argument retains its classical dependencies. A bounded check records an executed program, input hash, and scope. A formal receipt records a compiler execution. None of these classes converts an open obligation into an established result or implies a new compiler run.

The selected [BH99] page images were inspected at printed pages 15, 18, 24 and 48. These passages establish the scope of the tame descent fiber, the characteristic-zero comparison with base change, the monomial route, and the residual fixed-center ambiguity. The Imai ramification formula is used only at the specialized Heisenberg example. Neither source audit is a claim to have checked the entirety of either work.

21.2 Executable checks

The tests are deliberately bounded. For example, the corner test checks all 72 leading target profiles, while the symbolic statement explaining why the other corner coordinates cannot change the decisive coefficients is a separate ordinary input. The Weyl tests verify finite operators, not local automorphic induction. The exact field calculation verifies rational identities, not a new proof of the classical type theory.

The corrected-character occurrence question remains

a separate mathematical obligation. It is not a premise silently supplied by the conductor or marking audits.

Conductors and native markings

A conductor is an arithmetic invariant, not a complete description of a type. A nondegenerate commutator is a finite invariant, not a complete description of a marked dyadic extension. These two distinctions meet at the smallest dyadic construction with exactly enough quotient capacity. There is no spare plane there to absorb an independently prescribed quadratic mismatch.

This continuation audits the conductor and marking branches at their actual hypotheses. It keeps three arithmetic objects separate: the original source representation, a candidate obtained through a classical induction and descent construction, and a candidate arising from a proposed explicit type. A comparison is useful only when its normalization and its subject are fixed.

The resulting finite theory is also constructive. A discrepancy between two quadratic refinements becomes one linear functional. When its Arf obstruction vanishes, a single transvection gives an explicit correction. For a supplied odd-order finite action, a further central discrepancy can be removed by a finite sum. Neither correction constructs the missing arithmetic action, chooses a canonical native marking, or settles the full phase equations.

Source provenance. The conductor and marking analysis retains the earlier parts' source and review boundaries. In particular, the first part is available as a preserved reader, while its complete editable archive remains unavailable. The evidence ledger distinguishes this documentary gap from the unresolved mathematical obligations.

Evidence status. Ordinary finite proofs are supplied below. The arithmetic construction records are inherited arguments audited against selected primary statements. Recorded exact tests check finite models and normalizations. No fresh Lean compilation or external peer review is claimed.

22 Conductor conventions and actual order periods

22.1 Four numbers, not one unnamed conductor

Let F be a nonarchimedean local field with residue cardinality q, and let V be a complex Weil representation with finite inertia image and no monodromy. Its ordinary Artin conductor is

$$a(V) = \dim V - \dim V^{I_F} + \mathrm{Sw}(V). \tag{22.1}$$

We use a for the ordinary conductor throughout this part. The Swan conductor, an epsilon exponent for a specified additive character, and the self-pair conductor of a representation of $\mathrm{GL}_n(F)$ are named separately.

Take ψ_0 trivial on $\mathcal{O}_F$ and nontrivial on $\mathfrak{p}_F^{-1}$. Set $\psi_1(x) = \psi_0(\varpi^{-1}x)$, so ψ_1 is trivial on $\mathfrak{p}_F$ and nontrivial on $\mathcal{O}_F$. Under the usual change-of-character convention, if the exponent is written as a power of $q^{1/2-s}$, then

$$f_{\psi_0}(V) = a(V), \qquad f_{\psi_1}(V) = a(V) - \dim V. \tag{22.2}$$

The determinant factor in the change of additive character is independent of s and does not alter this exponent shift. Equation (22.2) is a convention translation, not an assertion that every epsilon constant is determined by its exponent.

For a wild-irreducible source ρ of dimension nine with Swan conductor 24, the audited self-pair calculation below gives the following table.

Object	Dimension	I_F-fixed	Swan	Ordinary a	f_{ψ_1}
ρ	9	0	24	33	24
$\mathrm{End}\,\rho$	81	1	152	232	151
$\mathrm{Ad}\,\rho$	80	0	152	232	152

Here $\mathrm{Ad}\,\rho$ denotes the trace-zero summand. Over the complex coefficient field, $\mathrm{End}\,\rho = \mathbf{C} \oplus \mathrm{Ad}\,\rho$. The scalar summand is unramified, so it contributes no ordinary conductor. It does contribute one to the dimension shift in (22.2).

Thus the number 152 has two legitimate appearances, as the Swan conductor of $\mathrm{End}\,\rho$ and as the ψ_1 exponent of its trace-zero summand. It is *not* the ψ_1 exponent of all of $\mathrm{End}\,\rho$, which is 151. The formal-degree parameter δ appearing later also equals 152 in this particular torsion-one comparison. That numerical equality does not make the three definitions interchangeable.

Source and status. The ordinary conductor identity and additive-character normalization underlie [Q14]. [BH99, §6.1, Lemma 2] uses the character trivial on $\mathfrak{p}_F$. [AP, §4 and Theorem 6.9] uses the ordinary pair conductor. The table is an explicit reconciliation of these conventions using the source calculation in Section 23.

22.2 The principal-order grade calculation

Let $\mathfrak{A} \subset M_n(F)$ be a principal hereditary order of period e, with radical $\mathfrak{P}$. Then $e \mid n$. A principal lattice chain has e successive residue pieces, each of dimension $m = n/e$ over k_F. The homogeneous grade of an endomorphism is the direct sum of e matrix blocks of size m by m. Consequently

$$\dim_{k_F} \mathfrak{P}^j/\mathfrak{P}^{j+1} = em^2 = \frac{n^2}{e}, \qquad [\mathfrak{P}^{-r} : \mathfrak{A}] = q^{rn^2/e} \quad (r > 0). \tag{22.3}$$

The period here belongs to the actual principal order carrying the stratum. It cannot be borrowed from a more convenient unrelated lattice chain.

For an actual cuspidal representation containing a positive-level simple stratum $[\mathfrak{A}, r, 0, \beta]$ to which the hypotheses of [BH99, §6.1] apply, its Lemma 2 gives

$$f_{\psi_1}(\pi) = \frac{nr}{e}, \qquad a(\pi) = n + \frac{nr}{e}. \tag{22.4}$$

The first number is the native epsilon exponent in that source. In the present wild cuspidal comparison it equals the standard Swan conductor. A lower critical level in a defining sequence is not the leading level r in this formula.

Proposition 22.1 (Necessary period divisibility)**.** *Suppose an actual type satisfying* (22.4) *is to match a source of rank n and Swan conductor $w > 0$. Its principal period and leading level necessarily satisfy*

$$\frac{n}{\gcd(n, w)} \mid e \mid n, \qquad r = \frac{ew}{n}. \tag{22.5}$$

These are necessary numerical conditions, not sufficient existence conditions for a simple stratum or a prescribed source.

Proof. The principal condition gives $e \mid n$. Matching (22.4) gives $nr = ew$, so $n \mid ew$. Writing $n = gn'$ and $w = gw'$ with $\gcd(n', w') = 1$ yields $n' \mid e$. Conversely these divisibilities make ew/n an integer. They say nothing about purity, intertwining, or character occurrence. □

For $(n, w) = (9, 24)$, the possibilities are $(e, r) = (3, 8)$ and $(9, 24)$. A maximal-order construction of period one cannot have this conductor. The earlier unramified depth-two candidate has Swan conductor 18 and ordinary conductor 27, not 24 and 33. Replacing the leading level eight by a critical level four in the period-three formula would create a different error rather than repair the comparison.

22.3 A self-twist check that survives conductor matching

A second necessary invariant is the torsion number, the order of the group of unramified self-twists. For a maximal simple type, the exact formula in [BK, 6.2.5] identifies that number as $n/e(K/F)$ for the actual parameter field K.

Lemma 22.2(Wild irreducibility excludes nontrivial unramified self-twists) **.** *If $\rho|_{P_F}$ is irreducible and an unramified character χ satisfies $\rho \otimes \chi \simeq \rho$, then $\chi = 1$.*

Proof. An intertwiner restricts to an endomorphism of the irreducible P_F representation, because χ is trivial on P_F. It is therefore a nonzero scalar. Applying the intertwining identity to every Weil element forces χ to be one. □

A period-three candidate may pass the first conductor test and still fail this second test if its actual maximal parameter field has residue degree three. That candidate has torsion number three, while the prescribed source has torsion number one. This is why the conductor equation does not complete the arithmetic attachment.

23 The rank-nine self-pair filter

23.1 The source invariant is computed on the unchanged source

Retain the original source over $F = \mathbf{F}_3((t))$,

$$\rho = A_1 \otimes A_2,$$

where A_h is the rank-three Heisenberg representation attached to the projective equation $x_h^9 + x_h = t^{-h}$, for $h = 1, 2$. The independent quotient and wild-irreducibility hypotheses are those of the original source fixture, not newly imposed conditions on a replacement source.

After the recorded unramified splitting extension, take a nonzero constant v satisfying $v^9 = -v$. Then

$$y_v = v^3 x_h^3 + v x_h, \qquad y_v^3 - y_v = -v t^{-h}. \tag{23.1}$$

The cancellation follows by substituting $v^9 = -v$ and $x_h^9 + x_h = t^{-h}$. As v varies, these give the eight distinct nontrivial characters of the nine-element translation quotient. A nonzero polynomial of degree three cannot vanish on all nine translations, so the corresponding additive functional is nonzero. Distinct v give distinct functionals by the same argument. Since each pole order h is prime to three, the inherited Artin–Schreier ramification calculation gives break h.

Proposition 23.1 (Self-pair conductor of the retained source)**.** *Under the original independence and wild-irreducibility hypotheses,*

$$\mathrm{Sw}(\mathrm{End}\,\rho) = 152, \qquad a(\mathrm{End}\,\rho) = 232. \tag{23.2}$$

Proof. Conjugation on the nine Weyl operators for A_h gives each character of its projective quotient once. Hence $\mathrm{End}\,A_h$ is the sum of the trivial character and eight characters of break h after the unramified extension. In $\mathrm{End}\,A_1 \otimes \mathrm{End}\,A_2$, there is one trivial character, eight characters of break one, and $9 \cdot 8 = 72$ characters of break two. Independence retains the distinct quotient characters. Products of characters of different breaks have the larger break. The Swan conductor is therefore $8 + 2 \cdot 72 = 152$.

Unramified restriction preserves the Swan conductor. By wild irreducibility, the inertia-fixed endomorphisms are exactly the scalars. Thus $\dim(\mathrm{End}\,\rho)^{I_F} = 1$ over F itself. Equation (22.1) gives $81 - 1 + 152 = 232$. No assumption that Frobenius fixes each individual quotient character is needed. □

Source and status. [Q13] supplies the source and the ramification inputs. The displayed Artin–Schreier cancellation, character separation and conductor addition are expanded here. The recorded exact suite constructs the nine-element constant subspace inside $\mathbf{F}_{81}$ and checks all its additive character values. This finite check does not reprove local ramification theory.

23.2 The actual-order certificate cannot be omitted

The proposed rank-nine family has a complete principal order $\mathfrak{A}$ of period nine, radical $\mathfrak{P}$, and an actual final parameter field K/F that is totally ramified of degree nine. An intermediate field E has degree three. Write $\mathfrak{Q}$ for the radical of the induced order in the E-centralizer. The retained candidate certificate specifies leading level 24, lower even critical level $c = 2a$, and actual simple-character orders

$$\mathfrak{J} = \mathcal{O}_K + \mathfrak{Q}^a + \mathfrak{P}^{12}, \qquad \mathfrak{H} = \mathcal{O}_K + \mathfrak{Q}^{a+1} + \mathfrak{P}^{13}. \tag{23.3}$$

These equations are substantive construction inputs. The mere pair of numbers $(24, c)$ does not imply them.

The certificate also ensures that the K contribution adds no unexpected graded direction. In the notation of [Q13], minimality of the leading approximation γ and the correction $d \in \mathfrak{P}^{-c}$ give

$$[\gamma, \mathcal{O}_K] \subseteq \mathfrak{P}^{-c}, \qquad \mathcal{O}_K \subseteq \mathfrak{B} + \mathfrak{P}^{24-c}. \tag{23.4}$$

For $c = 4$ and $c = 10$, the last exponent exceeds thirteen. Through the grades used in (23.3), the K-grade therefore lies inside the three-dimensional centralizer grade. Its own dimension is one. This is an actual commutator and approximation assertion, not an integral splitting of a wildly ramified bimodule.

Let $I^+ = 1 + \mathfrak{P}$. The successive full grades have dimension nine, the intermediate grades dimension three, and the K-grades dimension one. It follows that

$$I = \log_q [I^+ : J^1] = 8(a-1) + 6(12-a) = 2a + 64, \tag{23.4a}$$

$$D = \log_q [J^1 : H^1] = 2 + 6 = 8, \qquad \dim \eta = q^4. \tag{23.4b}$$

Since K/F is totally ramified of full degree, the finite residue factor is a character and the torsion number is one.

23.3 A formal-degree calculation with its measure fixed

Normalize Haar measure by $\mathrm{vol}(\mathrm{GL}_9(\mathcal{O}_F)) = 1$ and central measure by $\mathrm{vol}(\mathcal{O}_F^\times) = 1$. Then

$$\mathrm{vol}(I^+) = \prod_{j=1}^{9} (q^j - 1)^{-1}, \qquad \mathrm{vol}(J) = (q-1) q^{-I} \mathrm{vol}(I^+).$$

The compact-induction degree formula and the Steinberg degree formula give

$$d(\pi) = \frac{q^4}{9 \,\mathrm{vol}(J)}, \qquad d(\mathrm{St}_9) = \frac{1}{9} \prod_{j=1}^{8} (q^j - 1),$$

so that

$$\frac{d(\pi)}{d(\mathrm{St}_9)} = \frac{q^9 - 1}{q - 1} \, q^{2a+68}. \tag{23.5}$$

The factor nine comes from the actual noncompact extension $[K^\times J : F^\times J]$. Omitting it before comparing the measures changes the calculation. An unramified twist may be used to unitarize solely for the formal-degree comparison. That operation does not replace the prescribed noncompact scalar in the construction, and it leaves the self-pair unchanged.

The primary all-characteristic formulas [AP, Theorems 6.5 and 6.9] use the torsion number r_t and an auxiliary parameter δ:

$$\frac{d(\pi)}{d(\mathrm{St}_n)} = r_t \frac{q^n - 1}{q^{r_t} - 1} q^{(r_t - n + \delta)/2}, \qquad a(\pi^\vee \times \pi) = \delta + n^2 - r_t. \tag{23.6}$$

These are the named classical inputs here, not a conjectural formal-degree identity. With $n = 9$, $r_t = 1$ and (23.5), they give

$$\delta = 4a + 144 = 2c + 144, \qquad a(\pi^\vee \times \pi) = 4a + 224 = 2c + 224. \tag{23.7}$$

Certified profile	c	I	D	δ	Self-pair a
First repair	10	74	8	164	244
Deeper repair	4	68	8	152	232
Retained source	—	—	—	152	232

Corollary 23.2 (A necessary selection inside this certified family)**.** *If a member of the actual-order family* (23.3) *is to match the retained source under a correspondence preserving the ordinary self-pair conductor, then* $c = 4$*. The critical-ten member is excluded. The critical-four member passes this invariant, but the comparison does not prove its source identification.*

Proof. Equate (23.2) and (23.7). The equation $2c + 224 = 232$ has the unique solution $c = 4$. Equality of this one invariant supplies no character-occurrence or full pair-factor identity. □

Source and status. [Q13] provides the conditional actual-order certificate and calculation. [AP, formulas (17), (29), Theorems 6.5, 6.9 and Remark 6.7] were checked at their stated measures and field scope. This block does not newly construct the proposed corrected stratum. It preserves the requirement to prove its actual order equations before applying the numerical filter.

24 Why pair conductors do not determine quotient capacity

24.1 The parity identity behind the graded calculation

For the totally ramified complete-order sector, write the successive graded centralizer dimensions as

$$n = b_0 > b_1 > \cdots > b_r = 1, \qquad \Delta_j = b_{j-1} - b_j.$$

Assume the actual defining sequence and its order compatibility give descending positive levels ν_j and the grade-count formulas

$$I = \sum_{j=1}^{r} \Delta_j \left\lceil \frac{\nu_j}{2} \right\rceil - (n-1), \qquad D = \sum_{j=1}^{r} \Delta_j \, \mathbf{1}_{2|\nu_j}. \tag{24.1}$$

Here $I = \log_q[I^+ : J^1]$, while $D = \dim_{k_F}(J^1/H^1)$. The different floor and ceiling thresholds are essential. In this torsion-one, full-degree setting, the same formal-degree calculation gives

$$a(\pi^\vee \times \pi) = n^2 - 1 + (n-1) + 2I + D. \tag{24.2}$$

As in the rank-nine calculation, the formula is conditional on actual orders. A list of integers is not a certificate of their arithmetic existence.

Proposition 24.1 (Parity cancellation)**.** *Under* (24.1),

$$(n-1) + 2I + D = \sum_{j=1}^{r} \Delta_j \nu_j.$$

Consequently

$$a(\pi^\vee \times \pi) = n^2 - 1 + \sum_{j=1}^{r} \Delta_j \nu_j. \tag{24.3}$$

The weighted conductor expression does not retain D as a separate invariant.

Proof. For each integer ν,

$$2\left\lceil \frac{\nu}{2} \right\rceil + \mathbf{1}_{2|\nu} = \nu + 1.$$

Insert this identity into $2I + D$. Since $\sum_j \Delta_j = n - 1$, the constant terms reduce to $-(n-1)$. Adding $n - 1$ proves the result. □

This cancellation explains a concrete limitation of the earlier numerical tests. Changing the parity distribution can change the Heisenberg quotient while preserving the weighted sum in (24.3). More conductor precision does not recover information that the formula has already summed away.

24.2 The full dyadic profile

In the inherited full dyadic construction, let $n = 2^d$ and let $h_1 < \cdots < h_d$ be positive odd integers satisfying its separation requirements. The consecutive profile has

$$b_j = 2^{d-j}, \qquad \nu_j = 2^{d-j}\,3h_{d-j+1} \quad (1 \le j \le d). \tag{24.4}$$

All levels except the final one are even. Therefore

$$D = 2^d - 2. \tag{24.5}$$

A source consisting of d nondegenerate binary symplectic planes has dimension $2d$. The original maximal-type quotient is too small for $d = 1, 2$, has exactly the needed dimension for $d = 3$, and has strict surplus for $d \ge 4$.

d	Arithmetic rank	Source dimension	Host D	Original quotient
1	2	2	0	Insufficient
2	4	4	2	Insufficient
3	8	6	6	Equal capacity
4	16	8	14	Strict surplus
5	32	10	30	Strict surplus

The rank-two and rank-four enlarged arithmetic carriers in Part I are not counterexamples to the first two rows. Those repairs change the assembly carrier while recovering the same inducing representation. The table concerns the original specified maximal-type quotient. At rank eight, dimension ceases to be the obstruction, but an independently fixed quadratic marking can still obstruct the attachment.

24.3 Two rank-eight profiles with the same conductor data

The retained dyadic capacity note contains a sharper example. In the full rank-eight profile, use

$$(b_0, b_1, b_2, b_3) = (8, 4, 2, 1), \qquad (\nu_1, \nu_2, \nu_3) = (12h_3, 6h_2, 3h_1).$$

A second constructed profile skips the intermediate quartic field and has

$$(b_0, b_1, b_2) = (8, 4, 1), \qquad (\nu_1, \nu_2) = (12h_3, c), \qquad c = h_1 + 4h_2. \tag{24.6}$$

The integer c is odd and $2c < 12h_3$. Its last jump therefore contributes nothing to D. The full profile has $D = 6$, while the skipped profile has $D = 4$.

Both weighted sums in (24.3) equal

$$48h_3 + 12h_2 + 3h_1. \tag{24.7}$$

Indeed, the full profile has jump sizes $4, 2, 1$, and the skipped profile has jump sizes $4, 3$. The identity $3(h_1 + 4h_2) = 3h_1 + 12h_2$ supplies the equality.

For $(h_1, h_2, h_3) = (1, 3, 5)$, the distinction becomes completely explicit.

Quantity	Full profile	Skipped profile
Levels	$(60, 18, 3)$	$(60, 13)$
Principal period	8	8
Standard Swan conductor	60	60
Standard ordinary conductor	68	68
Torsion number	1	1
I	133	134
D	6	4
Heisenberg dimension over $q = 2$	8	4
δ	279	279
Ordinary self-pair conductor	342	342

The compensating change is $2 \cdot 133 + 6 = 2 \cdot 134 + 4$. The three necessary invariants (standard conductor, torsion number, and self-pair conductor) cannot force the full six-dimensional quotient.

24.4 The skipped profile is an arithmetic claim, not an integer exercise

The inherited construction of (24.6) works over $\mathbf{F}_2((t))$. Put $q_0 = 3h_3$ and take $\alpha^2 + \alpha = t^{-q_0}$. A uniformizer z of the quadratic field satisfies

$$z = t^{(q_0+1)/2}\alpha, \qquad z^2 + t^{(q_0+1)/2}z + t = 0.$$

Over that field, the polynomial $X^4 + zX + z$ is separable and Eisenstein. If e is a root, let C be multiplication by e^{-c} in the quartic centralizer. The source note chooses a filtered corestriction lift using $s(P_0) = t/z^2$ and takes a correction proportional to $(z^2/t)CP_0$. The actual final parameter is the literal corrected matrix, not an assumed compositum of the approximation fields.

The conclusion that the correction supplies the claimed defining sequence uses the retained refinement argument and its strict inequalities. The conductor and capacity audit examines the consequences of that argument. It does not rerun a skipped-profile matrix constructor or recertify every step of the arithmetic field proof. Exact integer tests do not replace those inputs.

Nor is this example a counterexample to H5. Full local pair factors are substantially more information than the three numbers above. The example shows that those three numbers alone do not identify the needed native quotient, and that a source-defined candidate cannot be declared to contain a prescribed type merely because it passes them.

Source and status. [D167] supplies the actual profile formulas and the skipped-degree construction. Proposition 24.1 and the numerical comparison are fully derived here. The exact suite checks the example and 120 positive odd triples, as well as general parity identities. The underlying arithmetic construction retains its inherited ordinary-proof status.

25 The source-defined arithmetic candidate and its inputs

25.1 Do not identify two candidates by notation

The direct matrix recursion and the classical arithmetic-induction route start with different data. The first produces an actual type satisfying a restricted construction contract. The second starts from a complete source character and uses classical induction and descent to produce a candidate. We denote the latter

by $\pi_{\mathrm{BH}}(\rho)$ in this section. This notation does not identify it with any independently constructed compact type.

The audited source-defined branch is over $\mathbf{F}_3((t))$ and uses the original rank-nine source. It is distinct from the characteristic-zero continuation113 candidate discussed in Part II. Its existence through classical inputs does not prove the corrected-character occurrence question for that other candidate, nor does it place a prescribed native packet in the current one.

25.2 The degree-nine field does not initially have a cubic tower

Write $A = t^{-1}$, and retain the projective coordinates

$$x^9 + x = A, \qquad z^9 + z = A^2.$$

The source record takes $y = z - x - x^3$. In characteristic three,

$$y^9 + y = B, \qquad B = A^2 - A - A^3. \tag{25.1}$$

The inducing field is $M = F(y)$, of degree nine. Its retained Galois-closure analysis has translation subgroup $(C_3)^2$ with a C_4 action irreducible over $\mathbf{F}_3$. There is no cubic intermediate field over F. Therefore one cannot simply write two cubic automorphic-induction arrows over F without changing the base and proving the resulting descent.

Pass to the unramified extension $K = \mathbf{F}_{81}((t))$. The constants now split the translation action. Choose $a \neq 0$ with $a^9 = -a$ and i with $i^2 = -1$, and define

$$r = \frac{y^3 - a^2 y}{ia^3}, \qquad s = \frac{y}{a}.$$

Then

$$r^3 - r = \frac{B}{ia}, \qquad s^3 - s = ir. \tag{25.2}$$

To check the first equality, use $a^8 = -1$ to cancel the y^3 terms after cubing. The second follows immediately from the definition of r. These identities exhibit the cyclic cubic tower over K used by the classical route. The degree and regularity assertions remain part of the complete source fixture.

The inducing character is also complete data. The inherited record includes its ramified Artin–Schreier class, its unit values, and an actual unramified factor. Replacing it by the displayed pole order alone loses information needed for the resulting central character and noncompact extension. The noted different exponent 24 and character conductor 9 give the expected induced ordinary conductor 33, but do not determine that full character.

25.3 Induction, invariance, and descent are separate gates

The construction first applies cyclic automorphic induction at the two cubic stages over K. Cuspidality requires the recorded regularity at each relevant step. It then invokes the classical independence of the resulting monomial construction from an admissible cyclic tower. This independence is a substantial theorem. It is what allows a Galois conjugate of the chosen tower to be compared with the original construction. The fact that the source descends to F does not, by itself, make each arbitrarily chosen tower Frobenius invariant.

Only after this invariance has been established does the tame descent theorem apply. Its fiber is described by the unramified characters associated to K/F, here of order dividing four. The specified determinant of ρ selects the desired central character.

Lemma 25.1 (Unique fixed-center member in a coprime descent fiber)**.** *Let a descent fiber be a torsor for a cyclic character group X of order m. Suppose twisting a rank-n member by $\alpha \in X$ changes its central character by α^n. If $\gcd(n, m) = 1$, then any attainable target central character selects exactly one member of the fiber.*

Proof. The map $\alpha \mapsto \alpha^n$ is a bijection of X because multiplication by n is invertible modulo m. Given one member and an attainable ratio of central characters, there is a unique twist realizing that ratio. □

For $n = 9$ and $m = 4$, the required power map is invertible. This explains the central normalization rather than silently selecting a preferred descent. It differs from the fixed-center cubic ambiguity in continuation113, where the relevant power map is not coprime. The finite tests include both the unique and the nonunique cases.

25.4 What the primary-source audit does and does not establish

The selected audit uses three layers of classical material.

The 1999 monomial and tame-lifting statements. In [BH99], the definitions and properties of tame lifting in Section 1.3 identify the descent fiber twisting and central-character behavior. Section 2.3 gives the characteristic-zero monomial construction, including standard epsilon factors and pair L-functions and conductors. Its proof uses independence of the cyclic construction. Section 1.7 supplies the tame transfer rule for the relevant pair-conductor exponent. These statements were read at their exact pages.

The positive-characteristic extension. The original Section 2.3 is explicitly characteristic zero. The characteristic note on page eight of [BH13] states that the relevant earlier results extend to positive characteristic through the base-change and automorphic-induction work of [HL11]. That note was checked directly. The present audit therefore retains the positive-characteristic induction theorem as a named external input, rather than erasing the original hypothesis.

Source-access boundary. The full text of [HL11] was unavailable during the recorded audit. Its bibliographic record was checked, but the detailed statements III.2 and III.3, including the restricted pair statement used in [Q15], retain their inherited source-audit status. Other selected inputs to the arithmetic route were checked separately.

There are two particularly important exclusions. First, the effective construction in [BH13] treats the totally wildly ramified correspondence as given at its starting point. That paper's effective theorem is not used here as an independent solution of the same totally wild input. Its characteristic note is the relevant source interface. Second, the equality of pair conductors in [BH99, 2.3(vii)] is not equality of full pair epsilon factors. The introduction expressly distinguishes these strengths.

25.5 The resulting candidate still has a native attachment obligation

Under the recorded source and classical hypotheses, [Q15] obtains a cuspidal candidate with prescribed central character, torsion number one, standard Swan conductor 24, ordinary conductor 33, and ordinary self-pair conductor 232. The characterizing information required by the paper's H5 contract is not replaced by that list.

In particular, one cannot compare an essentially discrete source with a reducible principal series outside the scope of a pair theorem and then divide a pair conductor by nine to manufacture the standard conductor. Nor can a first-order calculation of a parameter on deep field units establish occurrence of a full simple character. The original unit domain and noncompact extension remain part of that question.

The next useful arithmetic step is therefore not another calculation of the same three integers. It is to construct or identify the actual native type and its complete character in this fixed candidate, and to compare its marked data with the supplied source. That is the boundary the finite results in the following sections are designed to expose.

Source and status. [Q15] records the source-defined constructor audit. The selected passages [BH99, printed pp. 15, 18, 23–25, 53–54] and [BH13, p. 8] were checked directly. [HL11] remains a named classical input whose detailed application has inherited audit status. A source-defined candidate cannot replace a separately fixed type candidate without proof of their identification.

26 A full dyadic extension remembers its squares

26.1 The extension criterion with a fixed center

Let V be a finite-dimensional vector space over $\mathbf{F}_2$, and consider central extensions

$$1 \longrightarrow Z \longrightarrow E_s \longrightarrow V \longrightarrow 1, \qquad 1 \longrightarrow Z \longrightarrow E_t \longrightarrow W \longrightarrow 1,$$

where Z is the same abelian group in both extensions. In applying this to a represented scalar pushout, the represented center and any already factored character kernel must be recorded. A pushout cannot recover invisible elements that have been discarded.

Fix a linear isomorphism $f : V \to W$. Choose an ordered basis (e_i) of V, lifts a_i in E_s, and lifts b_i of $f(e_i)$ in E_t. Put $s_i = a_i^2$ and $t_i = b_i^2$ in Z. Write $Z^2 = \{z^2 : z \in Z\}$.

Proposition 26.1 (Center-fixing extension criterion)**.** *There exists an isomorphism $F : E_s \to E_t$ fixing Z pointwise and lifting f if and only if*

$$[a_i, a_j] = [b_i, b_j] \quad \text{for every } i, j, \qquad s_i t_i^{-1} \in Z^2 \quad \text{for every } i. \tag{26.1}$$

If the generating lifts themselves must satisfy $F(a_i) = b_i$, then their squares must agree exactly, not merely modulo Z^2.

Proof. Any such isomorphism has $F(a_i) = \lambda_i b_i$ for some $\lambda_i \in Z$. Preservation of squares gives $s_i = \lambda_i^2 t_i$, while preservation of commutators gives the first condition. Conversely choose λ_i with these squares. Every group element has a unique normal form

$$z a_1^{v_1} \cdots a_r^{v_r}, \qquad z \in Z, \quad v_i \in \{0, 1\}.$$

Define its image by replacing a_i with $\lambda_i b_i$. Normal-form multiplication uses only central elements, the displayed squares, and the pairwise commutators. The conditions ensure that each multiplication relation is preserved. The inverse construction proves bijectivity. Taking every $\lambda_i = 1$ gives the final assertion. □

For $Z = \mu_2 = \{1, -1\}$, each square is independent of the chosen lift and defines a quadratic refinement

$$a_v^2 = (-1)^{q(v)}, \qquad q(v + w) = q(v) + q(w) + B(v, w), \tag{26.2}$$

where $(-1)^{B(v,w)}$ is the commutator. A center-fixing extension isomorphism over a specified symplectic map f therefore requires $q_t \circ f = q_s$.

For $Z = \mu_4$, multiplying a lift by i changes its square by -1. The unmarked square classes are consequently weaker. For $Z = \mathbf{C}^\times$, every square ratio has a square root and the unmarked criterion reduces to matching commutators. Neither statement deletes a separately marked finite subgroup or a prescribed family of lifts.

26.2 Dihedral and quaternion data inside the same scalar pushout

Consider the matrices

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad Z_0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

They satisfy $X^2 = Z_0^2 = 1$ and $XZ_0 = -Z_0X$. The group $H_D = \langle X, Z_0 \rangle$ is a dihedral group of order eight. The group $H_Q = \langle iX, iZ_0 \rangle$ is a quaternion group of order eight. On their common two-dimensional quotient, their refinements are

$$q_D(x,y) = xy, \qquad q_Q(x,y) = xy + x + y. \tag{26.3}$$

Marked extension	$q(e)$	$q(f)$	$q(e+f)$	$\sum_v (-1)^{q(v)}$
H_D	0	0	1	$+2$
H_Q	1	1	1	-2

Both scalar pushouts identify with

$$P = \{zX^aZ_0^b : z \in \mathbf{C}^\times,\ a,b \in \{0,1\}\}.$$

The marked subgroups remain different. In H_D, five nonidentity elements have order two and two have order four. In H_Q, only the central nonidentity element has order two and six have order four. In particular, no center-fixing automorphism of P carries one marked subgroup onto the other.

On the other hand, a quaternion source does embed into P through iX, iZ_0. Its squares and negative Gauss sign are retained. What fails is identifying it with the *independently chosen* dihedral subgroup H_D. This example separates a successful transported marking from a false assertion about a fixed native marking.

26.3 A full marked section contains more than a square table

Suppose a normalized section $\sigma : V \to E$ has product cocycle

$$\sigma(v)\sigma(w) = c(v,w)\sigma(v+w).$$

If an isomorphism must send each specified section element to a specified target section element, the two cocycles must agree after transport on *every* pair. Equality of polar forms and square tables only identifies their extension class, not all those pointwise choices.

For example, start with the ordered section $\sigma(x,y) = X^xZ_0^y$ of H_D. Change only the value at $e+f$ by a central sign. Every square remains unchanged because $(-1)^2 = 1$, but the product of the specified lifts at e and f now differs by a sign from the specified lift at $e+f$. An isomorphism fixing the two generating lifts cannot also implement this changed third assignment. The recorded tests retain this counterexample rather than treating it as a harmless convention change.

26.4 The valid scalar-pushout attachment contract

There is nevertheless a positive attachment statement in the restricted sector used in Chapter XI. Suppose an actual type, its full character and its Heisenberg representation η_W are supplied. Suppose the graph has one vertex, the prescribed stabilizer is trivial, and the source scalar pushout has the same

faithfully represented center and a nondegenerate quotient V with $\dim V \le \dim W$. No conflicting host-native finite marking is independently fixed.

Choose a symplectic embedding $f : V \to W$. Proposition 26.1 gives a scalar-center-fixing isomorphism of the source pushout with the restriction over $f(V)$. Carry every supplied finite subgroup, every lift, and every section value through this *same* isomorphism. Since it is a homomorphism fixing scalars, it preserves all squares, commutators and section products, not just their classes.

Writing $W = f(V) \perp U$, the finite Heisenberg representation factors as $\eta_V \otimes \eta_U$. A projector onto a line in the second factor gives the source Heisenberg sector inside the actual image algebra. The inherited recovery theorem then returns the unchanged full inducing representation and candidate, under its stated recovery hypotheses. There is no stabilizer equation because the stipulated stabilizer is trivial.

This is an attachment into the scalar extension of the actual type. It is not a claim that every source lift is an unscaled arithmetic matrix, nor that the transported subgroup equals an independently specified canonical host subgroup. A package that records only the unmarked ambient scalar extension loses precisely the information displayed by (26.3).

Source and status. [Q16] contains the complete marked scalar-pushout contract. The normal-form proof, the dihedral/quaternion calculations and the section counterexample are explicit finite arguments. Their application uses the already supplied actual type and inherited recovery theorem. This section does not construct those arithmetic inputs.

27 The sharp boundary for a fixed native refinement

27.1 Quadratic type and its Gauss sign

Let (V, B) be a nondegenerate alternating space over $\mathbf{F}_2$ of dimension $2s$, and let q be a quadratic refinement. In a symplectic basis (e_j, f_j),

$$q(x_1, y_1, \dots, x_s, y_s) = \sum_{j=1}^{s} \big(x_j y_j + q(e_j)x_j + q(f_j)y_j\big).$$

Its Gauss sum factors into plane sums:

$$G(q) = \sum_{v \in V} (-1)^{q(v)} = 2^s (-1)^{\sum_j q(e_j)q(f_j)}. \tag{27.1}$$

Define $\mathrm{Arf}(q) \in \mathbf{F}_2$ by the sign in (27.1). The sum is intrinsic, so this definition is independent of the symplectic basis.

Lemma 27.1 (Classification in the required finite setting)**.** *Two nondegenerate quadratic spaces over $\mathbf{F}_2$ are isometric if and only if they have the same dimension and Arf invariant. Both Arf types occur in every positive even dimension.*

Proof. The coordinate expression decomposes a space into nondegenerate planes. On a plane, the three refinements with Arf invariant zero are isometric to $H(x, y) = xy$, while the unique remaining type is $A(x, y) = xy + x + y$. This can be checked on its three nonzero vectors.

Two anisotropic planes can be replaced by two hyperbolic planes. In $A \perp A$, the vector $u = e_1 + e_2$ is nonzero and isotropic. Choose v with $B(u, v) = 1$. Replacing v by $v + q(v)u$ makes it isotropic too, so u, v span a hyperbolic plane. Its nondegenerate orthogonal complement is a plane whose Gauss sign is

positive by multiplicativity of (27.1). It too is hyperbolic. Pairing all anisotropic planes leaves either only hyperbolic planes or one anisotropic plane. The parity of the remaining anisotropic planes is exactly the Arf invariant. These normal forms prove classification and existence. □

In dimension six, (27.1) gives $G(q) = +8$ or -8. The numbers of zero values are respectively

$$\#q^{-1}(0) = \frac{64+8}{2} = 36, \qquad \#q^{-1}(0) = \frac{64-8}{2} = 28. \tag{27.2}$$

These counts include the zero vector. The suite verifies both refinements on all 64 vectors. They supply a concrete signature of the distinction that dimension alone misses.

27.2 One spare plane is enough only when the embedding is free

Proposition 27.2 (Fixed-refinement capacity criterion)**.** *Let (V, q_V) and (W, q_W) be nondegenerate quadratic spaces of dimensions $2s$ and $2R$. When the embedding may be freely chosen, a quadratic isometric embedding $V \to W$ exists exactly when*

$$R \geq s, \qquad R = s \implies \operatorname{Arf}(q_V) = \operatorname{Arf}(q_W). \tag{27.3}$$

If $R > s$, either source Arf type embeds.

Proof. An embedding requires the dimension inequality. At equal dimension it is an isometry, so the Arf invariants must agree. If $R > s$, choose a nondegenerate space U of dimension $2(R-s)$ with

$$\operatorname{Arf}(q_U) = \operatorname{Arf}(q_W) + \operatorname{Arf}(q_V).$$

Both choices are available by Lemma 27.1. The space $V \perp U$ has the same dimension and Arf invariant as W, hence is isometric to W. Restrict that isometry to V. The equal-dimension sufficiency follows from the same classification. □

After the quadratic embedding is chosen, the preimage of its image in an actual μ_2-central extension of W has the source refinement. Proposition 26.1 supplies the extension isomorphism. Exact generating lifts can be matched when their squares and commutators match. Additional prescribed section values retain the stronger product condition from Section 26.

The spare-plane argument does not permit arbitrary changes to fixed depth placements, transport maps, or stabilizer actions. It proves existence of an otherwise free quadratic embedding. These qualifications are important even when the host has a large dimensional surplus.

27.3 The exact rank-eight consequence

At $d = 3$ in (24.5), the full dyadic quotient and the three-plane source both have dimension six. Suppose the source planes have Arf invariants $\epsilon_1, \epsilon_2, \epsilon_3$, and a particular actual host refinement has Arf invariant ϵ_W. Then the necessary and sufficient test for a *free* quadratic embedding is

$$\epsilon_W = \epsilon_1 + \epsilon_2 + \epsilon_3 \quad \text{in } \mathbf{F}_2. \tag{27.4}$$

There is no orthogonal complement in which to absorb a mismatch. For $d \geq 4$, the full profile has a positive-dimensional complement, so the finite Arf obstruction disappears when the embedding is free and the actual host refinement is supplied.

This does not compute ϵ_W for a particular arithmetic type. A Heisenberg commutator quotient alone supplies an alternating form. It does not canonically select a finite two-element-center extension or its square refinement. Determining an independently required native refinement and its lift phases for the chosen candidate remains an arithmetic obligation.

Conversely, under the transported scalar-pushout contract of Section 26, the host refinement is part of the transported output rather than independently prescribed. Every source marking can then be retained in the same scalar extension once the symplectic capacity and recovery hypotheses hold. There is no contradiction between this positive statement and (27.4). They quantify over different data.

Source and status. The capacity criterion was recorded in [Q16]. Its finite classification input and proof are made explicit here. The rank-eight deduction combines that criterion with [D167]. The block does not assign a canonical native Arf invariant to an actual arithmetic candidate that has not supplied one.

28 An explicit correction for a quadratic marking defect

28.1 The discrepancy is a vector, not an unspecified search

Suppose a symplectic embedding $f : (V, B_V) \to (W, B_W)$ has already been supplied. Put

$$q'(v) = q_W(f(v)), \qquad \ell(v) = q'(v) + q_V(v).$$

The two quadratic refinements have the same polar form, so ℓ is linear. Nondegeneracy gives a unique vector $a \in V$ such that

$$\ell(v) = B_V(a, v) \quad \text{for every } v. \tag{28.1}$$

Finding a is therefore one linear solve over $\mathbf{F}_2$. It is not a search over all symplectic automorphisms.

Lemma 28.1 (Arf change under a linear defect)**.** *With the above notation,*

$$\mathrm{Arf}(q') + \mathrm{Arf}(q_V) = q_V(a). \tag{28.2}$$

Proof. The refinement identity gives

$$q_V(v) + B_V(a, v) = q_V(v + a) + q_V(a).$$

Translation by a permutes V. Summing the signs yields $G(q') = (-1)^{q_V(a)} G(q_V)$. Equation (27.1) identifies the two signs. □

Define the transvection

$$T_a(v) = v + B_V(a, v)a. \tag{28.3}$$

It is symplectic and satisfies $T_a^2 = 1$. For $a = 0$ it is the identity.

Proposition 28.2 (One-transvection quadratic correction)**.** *If $q_V(a) = 0$, then*

$$q'\big(T_a(v)\big) = q_V(v) \quad \textit{for every } v. \tag{28.4}$$

Thus $f \circ T_a$ is a quadratic isometric embedding. The condition is equivalent to equality of the Arf invariants of q' and q_V.

Proof. Write $b = B_V(a, v)$. Since $B_V(a, a) = 0$, one has $B_V(a, T_a v) = b$. Also

$$q_V(T_a v) = q_V(v) + b q_V(a) + b.$$

Adding the defect term $B_V(a, T_a v) = b$ gives

$$q'(T_a v) = q_V(v) + b q_V(a).$$

This equals $q_V(v)$ when $q_V(a) = 0$. For completeness, expanding the two cross terms in $B_V(T_a v, T_a w)$ makes them cancel in characteristic two, so T_a is symplectic. Its square is the identity because the same value b is added twice. Lemma 28.1 proves the equivalence of the condition. □

This yields a direct finite correction procedure: compute the defect on a basis, solve for a, test $q_V(a)$, and, when it vanishes, compose with T_a. The test suite verifies the formula for all linear defects in dimensions two, four and six, against every vector. It also checks the symplectic identities independently.

28.2 Equal Arf does not validate an unchanged map

Take $V = \mathbf{F}_2^2$ with $q_V(x, y) = xy$ and $q'(x, y) = xy + y$. Both refinements have Arf invariant zero. The identity map does not preserve the refinement: their values differ at $(0, 1)$. The defect vector is $a = (1, 0)$, which is isotropic. The transvection $(x, y) \mapsto (x + y, y)$ repairs the map.

The existence of that repair is not a proof that the original identity map worked. When the original embedding is prescribed by an arithmetic placement or a transport diagram, replacing it must itself be permitted and checked. A corrected finite embedding must never be silently substituted into a diagram that required the old map.

28.3 Preserving a previously correct subspace

There is a useful relative form. Let $U \subseteq V$ be a subspace on which the defect vanishes. Then $a \in U^{\perp}$, so $T_a(u) = u$ for every $u \in U$. Under the isotropy condition $q_V(a) = 0$, the correction therefore fixes all previously correct vectors in U pointwise.

This statement does not automatically preserve selected lifts above those vectors. It fixes the quotient embedding there. The extension criterion and section products still determine whether the chosen lifted correction respects all prescribed elements. The distinction is small in notation but essential in a full marked packet.

28.4 A conditional equivariant form

Suppose a finite group C acts symplectically on V and W, preserves q_V and q_W, and the supplied f is C-equivariant. Then

$$\ell(gv) = q_W(f(gv)) + q_V(gv) = \ell(v).$$

Nondegeneracy in (28.1) implies $ga = a$ for every $g \in C$. Consequently T_a commutes with the action. When $q_V(a) = 0$, the correction $f \circ T_a$ remains equivariant.

Corollary 28.3 (Equivariant finite correction under supplied actions)**.** *A supplied equivariant symplectic embedding with matching pullback Arf invariant admits the explicit equivariant quadratic correction of Proposition 28.2. If its defect already vanishes on a prescribed subspace, the correction fixes that subspace pointwise.*

Proof. The invariance computation makes a fixed by C. Inserting $ga = a$ into (28.3) gives $gT_a = T_a g$. The subspace assertion follows from $a \in U^{\perp}$. □

These are finite statements conditional on actual actions and an initial equivariant embedding. They do not construct such actions inside an arithmetic normalizer. Nor do they show that an arbitrary quadratic embedding provided by a dimension argument can be chosen equivariantly. The relative correction is a way to finish a specified finite step, not a replacement for its input.

Source and status. This section develops an explicit elementary repair from the linear-defect observation in [Q16]. The Gauss-sum proof and transvection computation are given in full. They are ordinary finite deductions, not a new Lean result or a claim of a new general arithmetic existence theorem.

29 Full extension actions and the remaining phase boundary

29.1 The discrepancy after a quadratic embedding has been chosen

Even an equivariant quadratic embedding need not give the required equivariant isomorphism of the full finite extensions with every prescribed marking. This section isolates a conditional repair of the group-action part.

For clarity, take nondegenerate μ_2-central extensions of the same quotient dimension, or restrict a larger target extension to a supplied invariant quadratic subspace. Suppose C acts genuinely on the source and target extensions, fixes the center, and induces the same quotient action after identification. Let $F : E_s \to E_t$ be a center-fixing extension isomorphism inducing that quotient identification. Such an F is supplied by the quadratic extension criterion, but is not initially assumed equivariant.

An automorphism of E_t that fixes its center and quotient is uniquely of the form

$$u_\chi(x) = (-1)^{\chi(\bar{x})} x, \qquad \chi \in \mathrm{Hom}_{\mathbf{F}_2}(W, \mathbf{F}_2). \tag{29.1}$$

Indeed, the ratio between the image of x and x is a central sign depending only on $\bar{x}$, and preservation of multiplication makes it additive. Conversely every such character gives an automorphism. These vertical automorphisms form the additive $\mathbf{F}_2$-space $A = \mathrm{Hom}(W, \mathbf{F}_2)$.

Write α_g for the target action and $\beta_g = F\alpha_g^s F^{-1}$ for the transported source action. Their discrepancy is

$$\delta_g = \beta_g \alpha_g^{-1} \in A.$$

The action of C on A is conjugation by α_g. Using additive notation in A, the genuine group-action equations give

$$\delta_{gh} = \delta_g + g\delta_h. \tag{29.2}$$

Thus the discrepancy is an actual 1-cocycle, rather than an arbitrary list of mismatched operators.

29.2 An explicit odd-order averaging repair

Proposition 29.1 (Conditional odd-action correction)**.** *Under the preceding hypotheses, suppose $|C|$ is odd. Put*

$$u = \sum_{h \in C} \delta_h \in A. \tag{29.3}$$

Replacing F by $u \circ F$, with u interpreted through (29.1), makes the extension isomorphism C-equivariant.

Proof. Sum (29.2) over h. Left multiplication permutes C, so

$$u = |C|\delta_g + gu = \delta_g + gu$$

in the characteristic-two space A. Thus $\delta_g = u + gu$. Replacing F by uF changes its discrepancy to $u + \delta_g + gu$, which is zero for every g. □

The correction fixes the scalar center and the quotient. It may change a chosen lift by a central sign. If all generating lifts or an entire section are independently fixed, that modification may be forbidden. The valid conclusion is existence of an equivariant center-fixing extension isomorphism when these vertical corrections are allowed. It is not an equivariant pointwise identification of every independently prescribed lift.

The exact suite enumerates all cocycles for a C_3 action on a two-dimensional $\mathbf{F}_2$ module and checks the averaging formula. It also retains the opposite boundary. For C_2 acting trivially on a nonzero $\mathbf{F}_2$ module, a nonzero value of δ at its generator is a 1-cocycle. Every coboundary $u + gu$ is zero. No correction of this form can remove it. Odd order is therefore a substantive hypothesis, not a cosmetic simplification.

29.3 What has not been repaired by this finite sum

The result starts after the arithmetic host, actual finite actions, invariant quotient subspace and an extension isomorphism have been supplied. It does not construct them from the original source diagram. A native-normalizer obstruction can prevent the initial action from existing even when the later finite cocycle would be removable.

There is a further representation-level boundary. An action by automorphisms of a Heisenberg group preserves the isomorphism class of its representation with fixed nontrivial central character. Intertwining operators can therefore be chosen, but their products can carry scalar discrepancies. Passing from those projective operators to the specified honest phase operators is a separate problem. Proposition 29.1 removes a discrepancy in the action on the *finite extension group*. It does not prove vanishing of every scalar projective obstruction in a representation, nor does it choose the prescribed Gauss or transport phases.

The original full character domain, its central quasicharacter, the noncompact root, and all specified section products remain part of the arithmetic contract. A finite central sign correction is acceptable only when its interaction with that contract is explicitly checked.

29.4 A useful order of operations

The two finite corrections should be used in the following order. First supply an actual invariant host and a quotient-equivariant symplectic embedding. Compare its pulled-back quadratic refinement with the source. When the defect vector is isotropic, use the equivariant transvection to correct the quadratic embedding. Next lift to the finite extensions and compute the resulting action cocycle. When the stipulated hypotheses permit it, use the odd-order sum to correct that action. Finally check every prescribed lift, section, and honest representation phase that these corrections were not authorized to change.

Each stage has a certificate and a failure mode. Combining them into one phrase such as “equivariant attachment” would hide which input is missing. In the equal-capacity case, even the first quadratic stage needs the native Arf match. In a source problem with a fixed embedding, the transvection may be disallowed. In even-order action problems, the 1-cocycle may survive. In all cases, the same arithmetic candidate must remain the subject of the construction.

Source and status. The source marking note leaves nontrivial stabilizer actions outside its established attachment theorem. This section adds a conditional finite group-action correction with a complete averaging proof and explicit even-order control. It is not a claim to have constructed general arithmetic stabilizers or solved the honest phase equations.

30 Audited claim map and the next arithmetic obligations

30.1 What this continuation adds to the progress paper

The conductor branch has a single normalization map, a proof of the necessary period divisibility, an expanded source self-pair calculation, and a precise conditional rank-nine filter. The actual-order certificate remains visible. The full and skipped rank-eight profiles show why even several correct conductor invariants cannot establish the needed native quotient.

The classical induction branch identifies its field tower, tower-independence input, tame descent, and central normalization separately. It names the characteristic extension and the source-access limitation affecting its positive-characteristic input. This supports a selected input audit, not a new proof of all local correspondence results.

The marking branch contains the full center-fixing extension criterion, the dihedral/quaternion distinction, the sharp free-embedding capacity test, and the exact rank-eight Arf condition. The explicit transvection and odd-order action corrections then explain how two later finite discrepancies can be repaired when their actual inputs and allowed changes are supplied.

Statement	Status here	Boundary retained
Principal period and conductor	Ordinary derivation with [BH99] input	Does not construct a stratum
Source self-pair 232	Expanded inherited ramification argument	Original source independence is retained
Critical-four filter	Conditional actual-order consequence	Passing is not type occurrence or H5
Rank-eight profile separation	Audited inherited construction and exact grade calculations	Three invariants do not force the native profile
Classical source candidate	Selected primary-interface audit	Detailed [HL11] reread unavailable in this block
Fixed-center extension criterion	Complete finite proof	Full sections can impose additional pointwise relations
Free quadratic embedding	Complete finite proof	Requires the actual host refinement as input
Transvection correction	Complete finite proof and exact tests	May change a preassigned embedding
Odd-action correction	Complete conditional finite proof	Does not construct arithmetic actions or honest phases
Native rank-eight refinement	Explicit remaining arithmetic obligation	Its value is not inferred from capacity
General realization and H5	Open in this project	No replacement by profile matching

30.2 A certificate for the next native-marking step

For a fixed arithmetic candidate at rank eight, a useful next certificate must identify the actual finite central extension or specified finite subgroup in its scalar pushout. It must give the chosen lift of each of the six symplectic basis vectors and compute its square under the full central character. These six bits determine the refinement once the commutator basis is fixed. Their three pairwise products determine the Arf sign through (27.1).

The certificate must also say whether the target marking is independently fixed or is allowed to be transported from the source. If it is fixed, compute the defect of the required quotient map. A vanishing defect directly certifies that map. An isotropic nonzero defect supplies the transvection only when changing the map is allowed. Every additional section element and transport lift then needs its actual multiplication check.

This task cannot be replaced by evaluating a canonical-looking quadratic form on an abstract six-dimensional space. That would choose new data rather than calculate the data of the specified arithmetic object. It also cannot be replaced by choosing another candidate with the same conductors. The candidate and full inducing character must remain fixed throughout.

30.3 Verification and reproducibility boundaries

The conductor and marking exact suite contains 23 test methods. Its conductor tests cover the normalization table, grade dimensions, period divisibility, the rank-nine formal-degree identities, the rank-eight profiles and the finite field used for the projective source characters. Its marking tests cover extension group laws, square and section controls, Gauss signs, all labeled symplectic bases in dimension four, all linear-defect corrections through dimension six, relative and equivariant corrections, and odd versus even action cocycles.

The research atlas follows these distinctions through normalized conductors, rejected and surviving rank-nine candidates, equal invariants with unequal capacity, transported and native markings, the equal-capacity Arf obstruction, and the two conditional finite corrections. These illustrations retain the general conjecture as an open realization problem.

FURTHER STUDY

Visual studies of arithmetic realization

The plates give worked constructions and counterexamples, with explicit links to the corresponding arguments and their hypotheses.

READING ROUTES

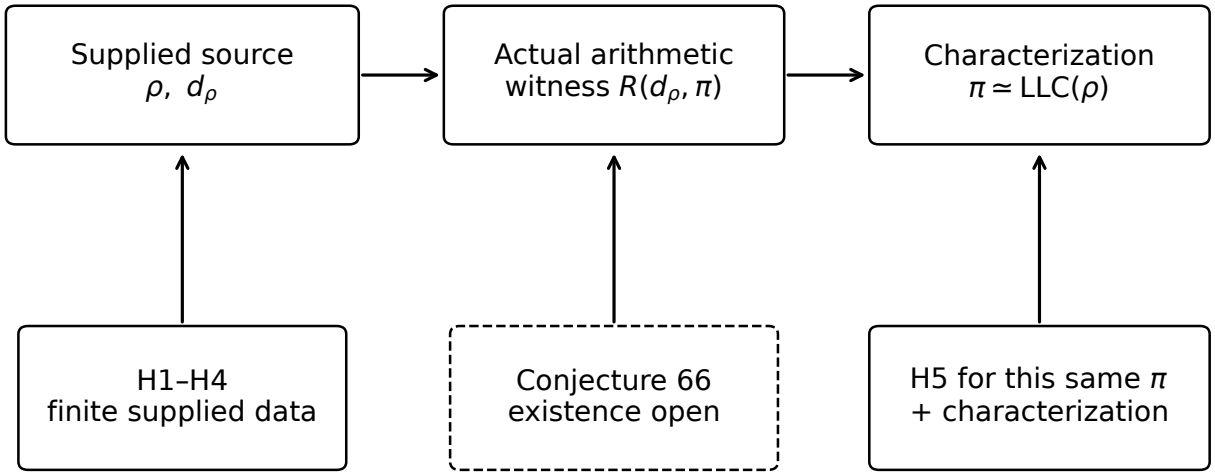
Research atlas 1552

A reading route through the argument

This atlas accompanies the arithmetic realization studies following Chapter XI. Each plate combines a mathematical graphic with an explicit claim boundary and a route back to those studies. The figure data are exact finite calculations or labeled dependency diagrams, not invented measurements.

The central distinction. A finite packet, an actual arithmetic host, and the same candidate's full local factors are different objects. The first two plates fix the quantifiers. The rest explain what can be constructed, what a particular obstruction rules out, and which stronger inputs are still required.

Route	Mathematical purpose
XI.1–XI.5	The witness contract, balanced products, compact binders, and a complete finite corner obstruction.
XI.6–XI.10	Whole characters, trace depth, defining sequences, native quotient capacity, and enlarged-carrier recovery.
XI.11–XI.19	Conductor conventions, candidate filters, information loss, descent, Clifford dimensions, and occurrence/action obstructions.
XI.20–XI.26	Full finite extensions, section products, quadratic markings, the equal-capacity boundary, and transvection repair.
XI.27–XI.32	Genuine action correction, its even-order limit, honest phases, the missing native certificate, and the remaining endpoints.



Evidence labels. An exact finite model verifies the displayed example. A conditional profile comparison retains the actual arithmetic construction hypotheses. A contract diagram records dependencies but does not supply their inputs. Ordinary general proofs remain in the companion study. None of these labels denotes a new Lean run or external peer review.

The source line on each plate links to its argument in this book. The final concordance lists the corresponding book pages.

PLATE XI.1

The three obligations

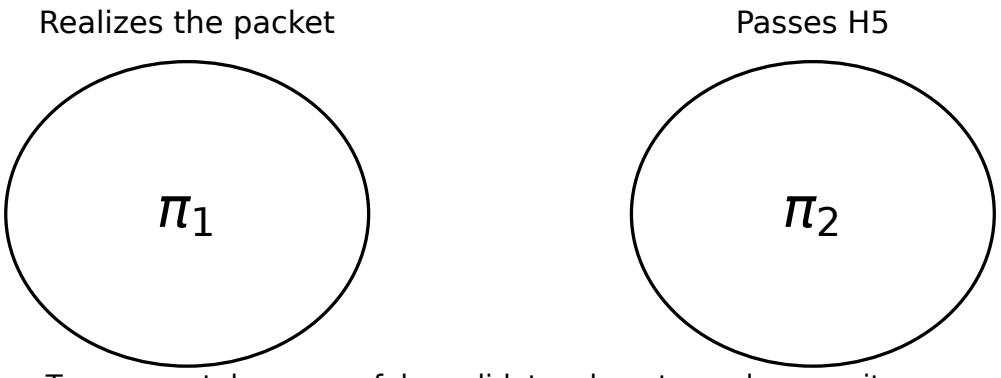
Finite comparison, arithmetic existence, and characterization have different inputs.

The source is a wild Weil atom ρ with the supplied datum d_ρ. H1–H4 include the declared finite break decomposition, symplectic bridges, central extensions and phases, and coherent transports. They describe an admitted input. They do not assert that every possible source arrives with canonical data.

The middle box is an actual arithmetic witness $R(d_\rho, \pi)$. It carries the prescribed packet and recovers the same supercuspidal representation, including the central character and noncompact completion. The final arrow additionally needs H5 for that particular π and the applicable characterization theorem.

$$\forall \rho \in \mathcal{A} \quad \exists \pi\ R(d_\rho, \pi) \qquad \text{is the general realization endpoint.}$$

An arrow is a dependency, not a declaration that its input has been constructed. Restricted witnesses and finite comparison theorems remain useful even while this quantified endpoint is open. Historical obligation 66 is not a measure of the amount of mathematics still required.



Evidence: Contract diagram.

Companion source: Part I, Section 1. Book page 1486.

PLATE XI.2

One candidate must satisfy both conditions

Separate existential statements cannot be joined by changing the witness.

Two separately successful candidates do not supply one witness.

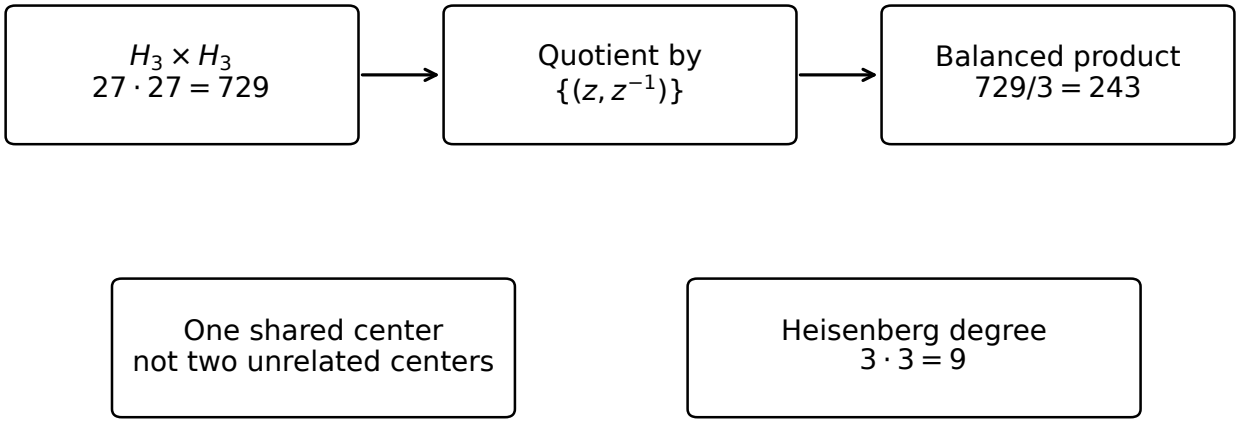
$$\{\pi_1\} \cap \{\pi_2\} = \varnothing$$

Let $A = \{\pi : R(d, \pi)\}$ and $B = \{\pi : H5(\pi)\}$. The desired comparison uses a member of $A \cap B$. The diagram is an exact two-element countermodel: $A = \{\pi_1\}$ and $B = \{\pi_2\}$, with $\pi_1 \neq \pi_2$. Each condition has a witness. Their conjunction has none.

$$(\exists \pi\, R(d, \pi)) \wedge (\exists \pi\, H5(\pi)) \quad \not\Rightarrow \quad \exists \pi\, (R(d, \pi) \wedge H5(\pi)).$$

There is a second pitfall. An implication about every realizer can be true when there are no realizers. A comparison interface whose structure already contains an existence field does not construct that field merely by using it.

These finite sets are logical illustrations, not a claim that the arithmetic realization and H5 classes are actually disjoint. Their purpose is to make a change of candidate visible before it enters a proof.



Evidence: Exact logical countermodel.

Companion source: Part I, Section 1.2. Book page 1486.

PLATE XI.3

A balanced central product

The shared center is identified once, while the orthogonal packet factors remain.

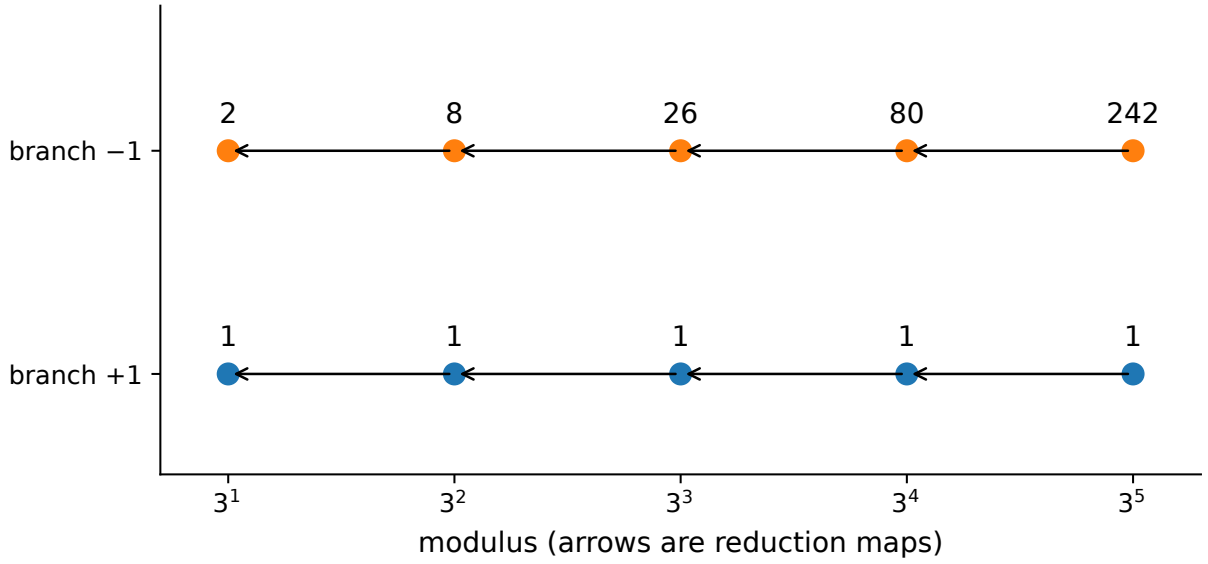
Orthogonal factors commute. The actual extensions are inputs.

Take two Heisenberg groups of order $3^3 = 27$. Their direct product has order 729. Quotient by the central subgroup $\{(z, z^{-1})\}$ of order three. The balanced central product has order $3^5 = 243$, with a four-dimensional quotient over $\mathbf{F}_3$ and one common center.

$$(H_3 \times H_3)/\{(z, z^{-1})\} \quad \text{has Heisenberg degree} \quad 3^2 = 9.$$

The figure's order calculation is checked by enumerating every fiber of the multiplication model. Each fiber has exactly three elements. The representation degree agrees with the tensor product of two degree-three Heisenberg representations whose central characters match.

The general argument requires the actual factor extensions and commutation between distinct factors. A list of break labels does not supply either condition. Once those conditions hold, the balanced product removes the proposed extra mixed extension ambiguity. It does not construct an arithmetic host or identify independently fixed lifts.



Evidence: Exact finite model.

Companion source: Part I, Section 3. Book page 1488.

PLATE XI.4

What a compact binder can do

Compatible solutions in one fixed compact space can survive every precision.

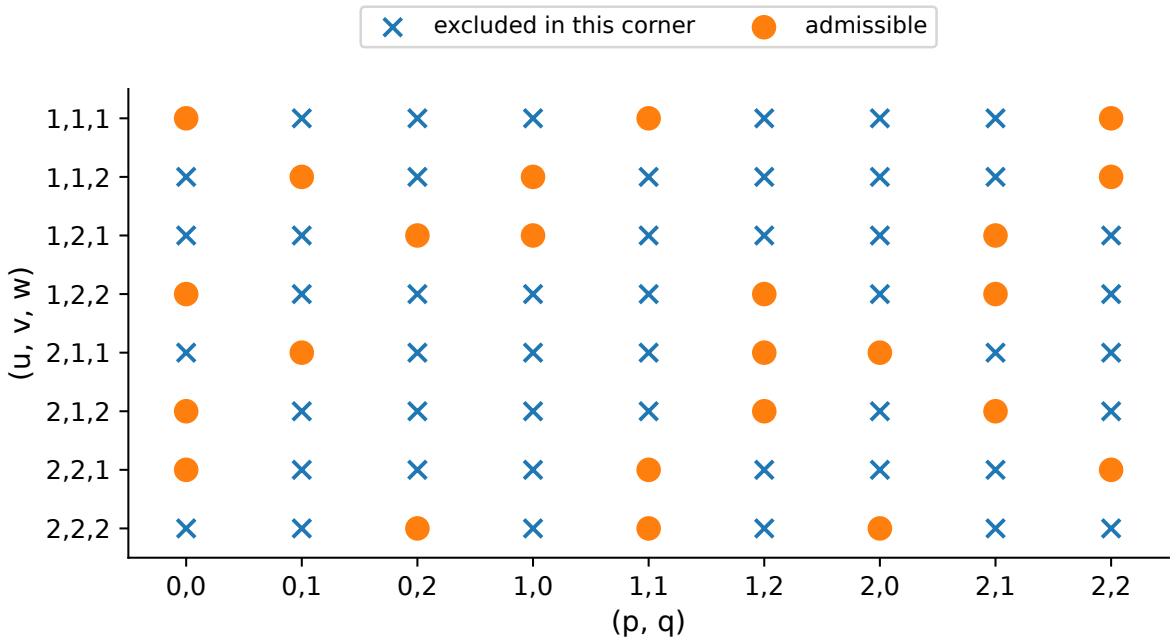
The points are all roots of $x^2 - 1$ modulo 3^n, for $1 \le n \le 5$. The labels are canonical residue representatives. The arrows reduce a root modulo 3^n to a root modulo 3^{n-1}. Both branches persist, corresponding to 1 and -1 in $\mathbf{Z}_3$.

For the general binder, fix a closed $X \subseteq \mathcal{O}^m$ and continuous constraints f_j. The sets

$$C_n = \{x \in X : f_j(x) \in \varpi^n \mathcal{O} \text{ for every } j \le n\}$$

are closed and nested. If every C_n is nonempty, compactness supplies a point satisfying every exact equation.

The example does not prove simultaneous finite solvability for the arithmetic problem. Even $x = 0$ and $x = 1$ have separately solvable congruences but no joint solution modulo three. Allowing the number of coefficients or pole bounds to grow also changes the compact model. Those missing hypotheses cannot be replaced by more isolated successful tests.



Evidence: Exact finite illustration.

Companion source: Part I, Section 5; Part II, Section 19.1. Book page 1490.

PLATE XI.5

The complete cubic corner spectrum

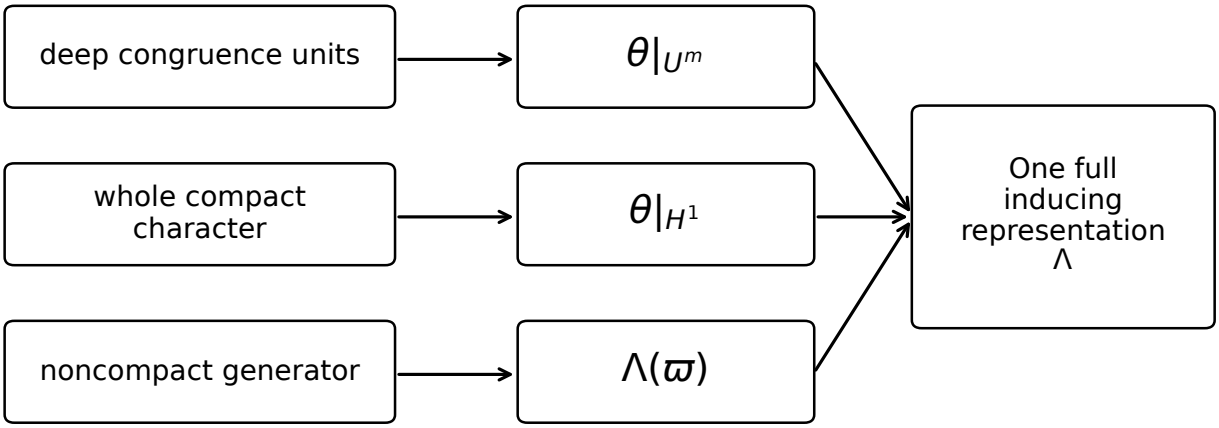
A finite obstruction can exclude a template without excluding every host.

Rows run through the eight nonzero triples $(u, v, w) \in \mathbf{F}_3^3$. Columns run through all nine pairs (p, q). A circle marks a solvable target in the specified corner. A cross marks an excluded target.

$$u = cd, \quad v = ab, \quad w = bc, \quad p = c(a - h), \quad q = b(d - h).$$

Elimination gives the exact criterion $p + u = w(q + v)$. Thus precisely 24 of the 72 targets are admissible. The data enumerate all five coefficients over $\mathbf{F}_3$ and independently compare their image with this criterion.

The target $(1, 1, 1, 2, 2)$ becomes possible when the fifth coefficient h is allowed. The target $(1, 1, 1, 1, 2)$ remains impossible. The inherited structural calculation explains why the larger corner has the same decisive leading condition. Its scope is that corner. The later arbitrary-exponent binder changes the construction rather than claiming that this negative result vanished.



Evidence: Exhaustive finite spectrum.

Companion source: Part II, Section 19.2. Book page 1527.

PLATE XI.6

Do not truncate the full character

Deep values, the full compact domain, and a noncompact generator are distinct certificates.

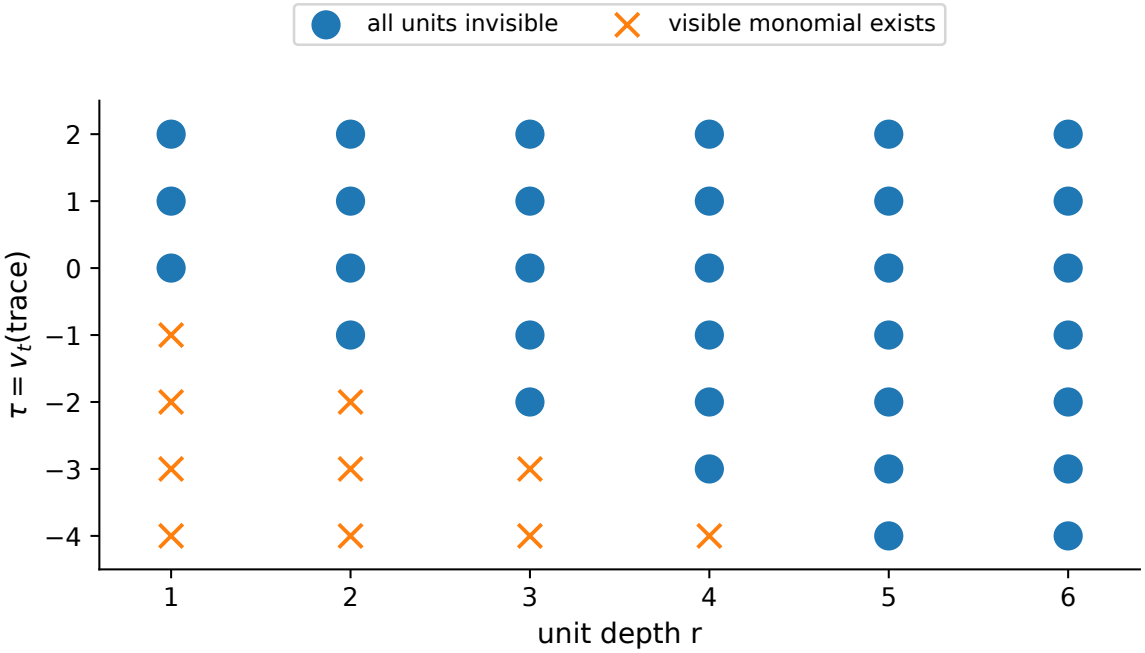
A deep equality cannot fill in the two larger-domain certificates.

A trace expression first describes a character on sufficiently deep congruence units. The full simple character also has values on the larger native unit domain. A full inducing representation retains further central and noncompact data. These are successive obligations, not three interchangeable notations for the same calculation.

The direct character construction transfers the whole preceding character, applies the actual permitted correction, and then checks the intersection needed for shallow extension. The correction exhibits why noncompact normalization matters. In exponents of ninth roots of unity,

$$\nu(\varpi) = \zeta_9, \qquad \nu(\varpi_F/\varpi^3) = \zeta_3^2 \quad \Longrightarrow \quad \nu(\varpi_F) = 1.$$

Setting $\nu(\varpi) = 1$ instead gives ζ_3^2, changing the central character. The accompanying finite check verifies this root-of-unity identity only. The full unit character, intertwining, and type-extension statements retain the arithmetic hypotheses developed in the progress paper.



Evidence: Domain diagram.

Companion source: Part I, Sections 7.5–8.5; Part II, Section 18. Book page 1495.

PLATE XI.7

Depth can make native trace one invisible

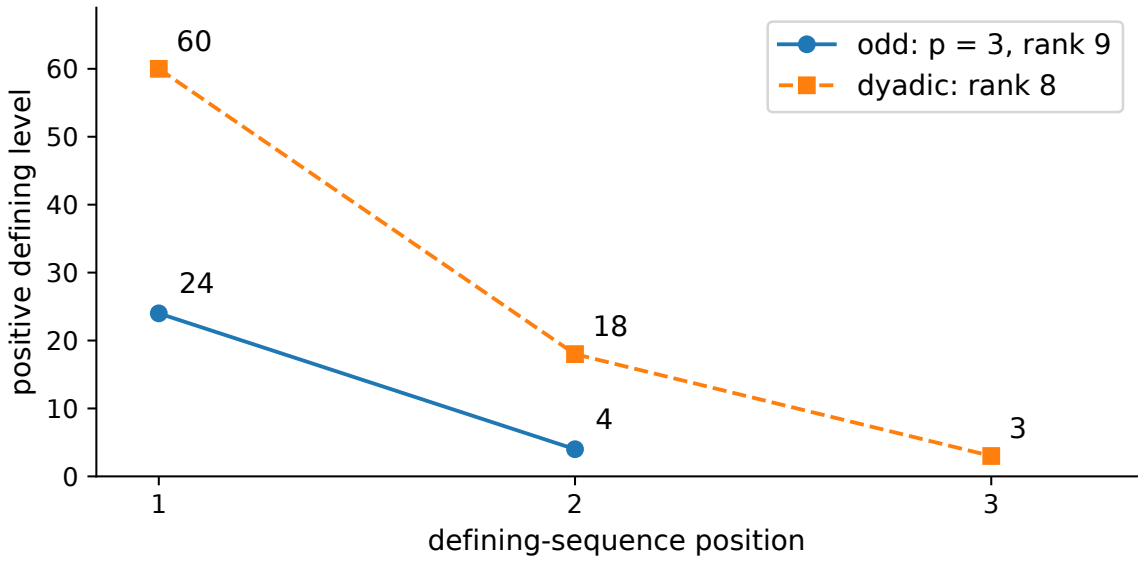
The valuation inequality is the mechanism, not an assertion that the trace is zero.

In $\mathbf{F}_2((t))$, let the additive character read the coefficient of t^0. Model the trace coefficient by t^τ, and let the variable range over $t^r\mathcal{O}$. A circle means every such product has positive valuation and is invisible to the character:

$$\tau + r \geq 1.$$

At a cross, $t^{-\tau}$ belongs to the allowed domain and produces the visible product 1. This gives an explicit negative control, rather than treating failure of a sufficient bound as proof of visibility without a witness.

The native trace-one row is $\tau = 0$. It is invisible at every positive unit depth in the displayed range. Native trace one, zero trace after amplification, and the trace of the correction remain different quantities in the arithmetic recursion. The exact floor in the correction depth is retained in the written proof. This monomial picture explains the inequality but does not replace the full shallow-character extension argument.



Evidence: Exact Laurent-monomial model.

Companion source: Part I, Section 8. Book page 1498.

PLATE XI.8

Two defining-sequence examples

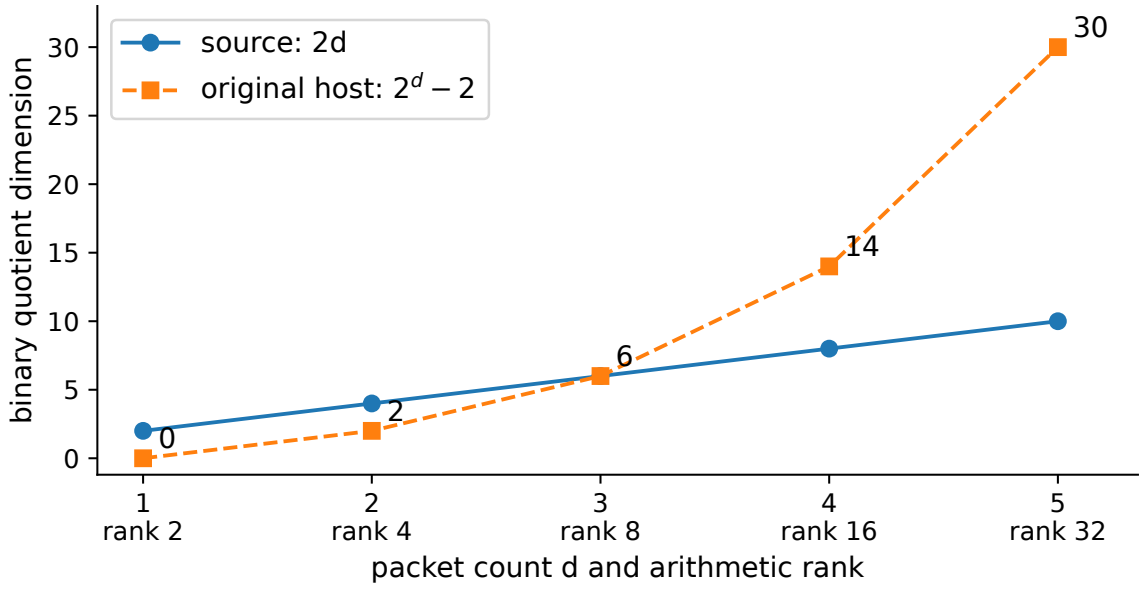
The recursion records levels and field refinements, not just its final matrix size.

The odd example uses $p = 3$, $d = 2$, and $(h_1, h_2) = (1, 2)$. Its displayed levels are $(24, 4)$. The dyadic example uses $d = 3$ and $(h_1, h_2, h_3) = (1, 3, 5)$, giving $(60, 18, 3)$. Each position refers to that example's own defining sequence.

$$\nu_j = p^{d-j}(p+1)h_{d-j+1} \quad \text{or} \quad \nu_j = 2^{d-j}3h_{d-j+1}.$$

The two plotted lines are not empirical fits or samples of one common arithmetic family. They make the inherited level formulas legible. In the odd example, $24 > 3 \cdot 4 > 2 \cdot 4$ illustrates the separated scales used in refinement.

Supplying the levels does not prove that the literal corrected matrix generates the asserted maximal field. That conclusion uses the filtered corestriction lift and the precise refinement theorem. In the dyadic argument, separability from native trace one is established only after the full field degree has been obtained.



Evidence: Inherited formulas, exact evaluation.

Companion source: Part I, Sections 7.1–7.4 and 8.1–8.3. Book page 1492.

PLATE XI.9

Where the original dyadic quotient runs out of room

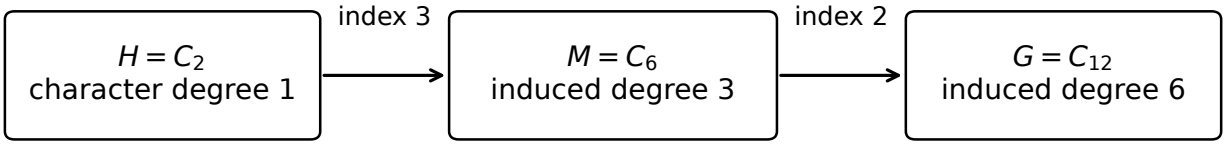
The rank-eight case is the first equality, not a low-rank surplus.

For d source planes, the binary source quotient has dimension $2d$. In the full dyadic profile the specified original maximal-type quotient has dimension $D = 2^d - 2$. The first five values are shown without normalizing away their difference.

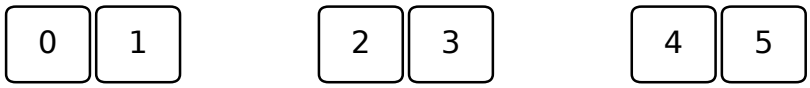
d	1	2	3	4	5
$2d$	2	4	6	8	10
$2^d - 2$	0	2	6	14	30

Ranks two and four are too small in that original quotient. Rank eight has exactly six dimensions for six required dimensions. Only from rank sixteen is there a strict surplus in this family.

The later low-rank repair uses a larger actual assembly carrier and recovers the same representation. It does not change the first two numbers in this table. At equality, a fixed native quadratic refinement can still obstruct attachment. With spare dimension, the free quadratic embedding problem is easier, but prescribed actions, lifts, and transports remain separate constraints.



Evidence: Exact capacity formula.



Companion source: Part I, Section 9; Part III, Section 24.2. Book page 1501.

PLATE XI.10

A larger inducing carrier can return the same object

Induction in stages changes the intermediate group without changing the result.

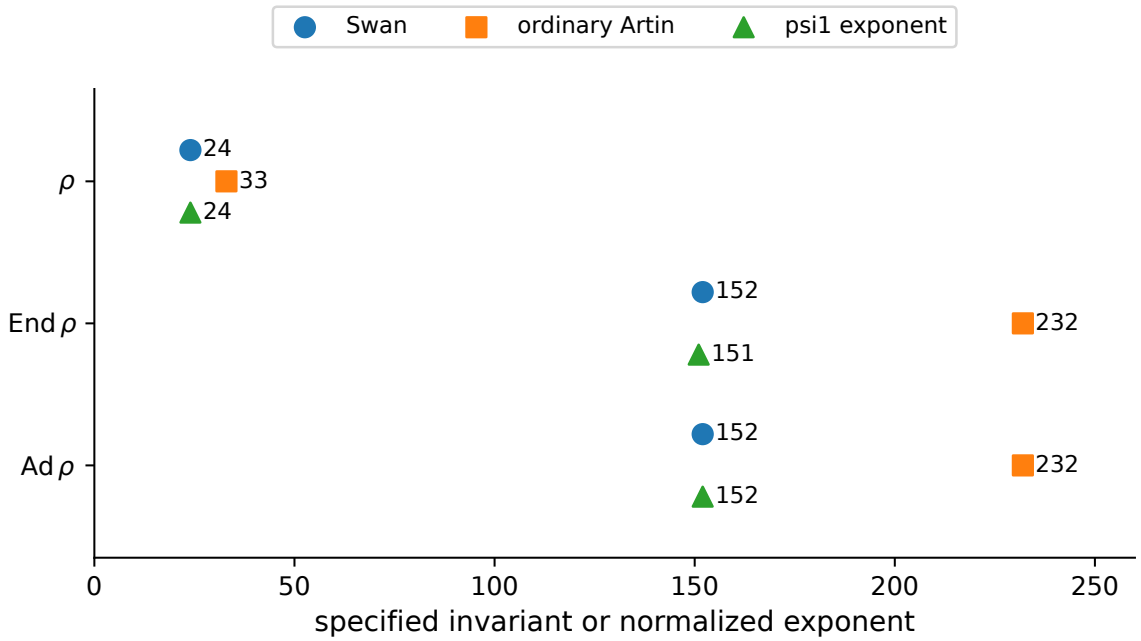
Six cosets, whether induced directly or in two stages.

The diagram is a finite analogue, not the actual local-field construction. Use $H = C_2 \subset M = C_6 \subset G = C_{12}$ and a character of H. Induction to M has dimension three, and induction onward to G has dimension six. Direct induction has the same six cosets, represented by $i + 2j$ with $i \in \{0, 1\}$ and $j \in \{0, 1, 2\}$.

$$\operatorname{Ind}_M^G \operatorname{Ind}_H^M \lambda \simeq \operatorname{Ind}_H^G \lambda.$$

The arithmetic recovery uses the corresponding compact-induction transitivity with the original full inducing representation Λ. Its larger intermediate carrier must be an actual permitted subgroup, and the original central character and noncompact extension must be retained.

The rank-two and rank-four proofs supply additional group, normalization, and character-orbit arguments before transitivity applies. The finite coset calculation isolates the recovery mechanism. It neither constructs those arithmetic groups nor proves irreducibility of a new local-field representation.



Evidence: Exact finite analogue of recovery.

Companion source: Part I, Section 10. Book page 1502.

PLATE XI.11

Three conductor columns are not interchangeable

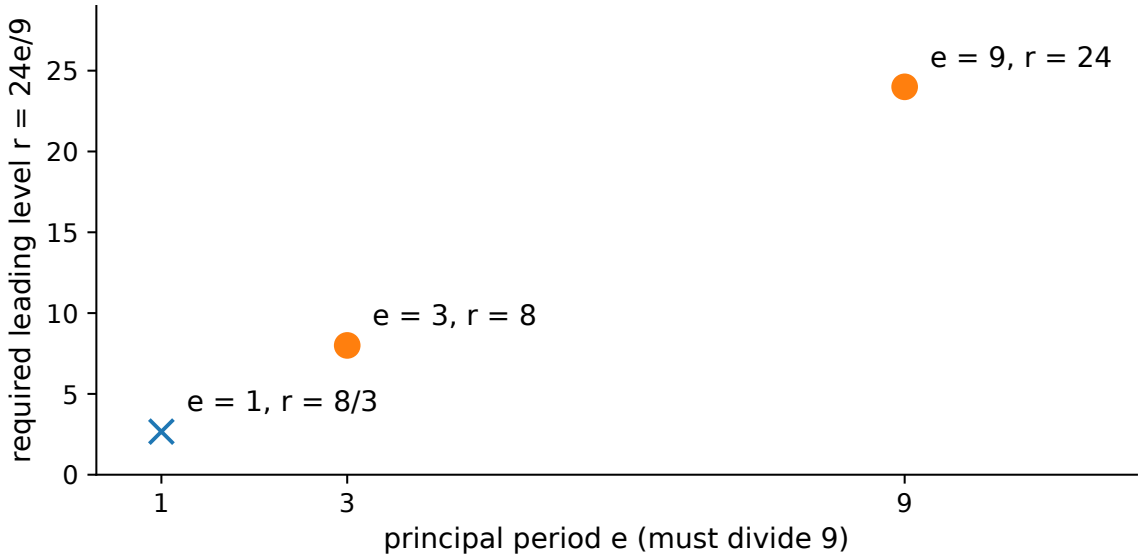
The scalar summand changes an epsilon exponent even when the ordinary conductor is unchanged.

The ordinary conductor is $a(V) = \dim V - \dim V^{I_F} + \mathrm{Sw}(V)$. For the additive character ψ_1 trivial on $\mathfrak{p}_F$ but not on $\mathcal{O}_F$, the stated normalization gives $f_{\psi_1}(V) = a(V) - \dim V$.

V	$\mathrm{Sw}(V)$	$a(V)$	$f_{\psi_1}(V)$
ρ	24	33	24
$\mathrm{End}\,\rho$	152	232	151
$\mathrm{Ad}\,\rho$	152	232	152

Here $\mathrm{Ad}\,\rho$ means the trace-zero summand. The scalar summand in $\mathrm{End}\,\rho = \mathbf{C} \oplus \mathrm{Ad}\,\rho$ has zero ordinary conductor, but it contributes one to the dimension subtracted in the epsilon normalization.

The plot keeps the three definitions separate even when values happen to coincide. An exponent is still not the full epsilon factor. The arithmetic conductor inputs and additive-character convention are inherited from the audited progress paper, not freshly established by drawing these numbers.



Evidence: Exact normalization worksheet.

Companion source: Part III, Section 22.1. Book page 1532.

PLATE XI.12

The principal-period filter

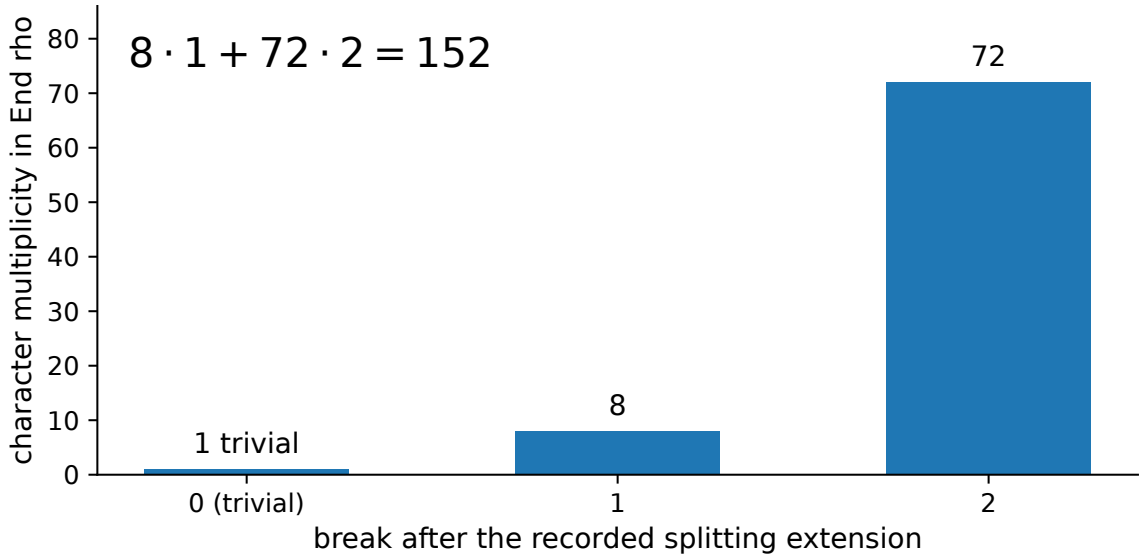
The period belongs to the actual order, and the level must be integral.

Under the stated actual-type conductor formula, a rank-n source with Swan conductor w requires $nr = ew$, where the principal period satisfies $e \mid n$. Therefore

$$\frac{n}{\gcd(n,w)} \mid e \mid n, \qquad r = \frac{ew}{n}.$$

For $(n,w) = (9,24)$, period one would demand the nonintegral level $8/3$. Periods three and nine leave $(e,r) = (3,8)$ and $(9,24)$. The cross is excluded numerically. The circles pass only this integrality condition.

A period-three candidate can still fail the independent torsion-number test when its actual maximal parameter field has residue degree three. The prescribed wild-irreducible source has no nontrivial unramified self-twist. Neither a convenient lattice period nor a lower critical level can be substituted for the actual period and leading level in the formula. A necessary numerical pass supplies no simple stratum or character occurrence by itself.



Evidence: Exact necessary filter.

Companion source: Part III, Section 22.2–22.3. Book page 1532.

PLATE XI.13

The rank-nine source has a visible break count

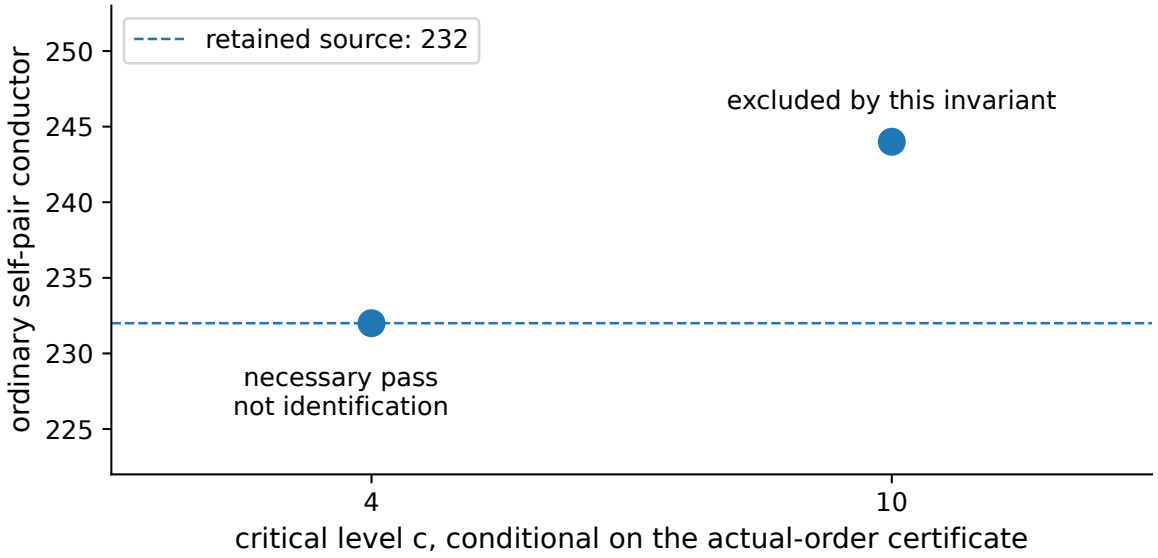
The self-pair conductor comes from the unchanged source and its actual independence assumptions.

For the recorded source $\rho = A_1 \otimes A_2$, each degree-three Heisenberg factor contributes one trivial conjugation character and eight nontrivial characters, at break one or two respectively. Under the original independence hypotheses, the tensor product contributes one trivial character, eight at break one, and seventy-two at break two.

$$\mathrm{Sw}(\mathrm{End}\,\rho) = 8 + 2 \cdot 72 = 152, \qquad a(\mathrm{End}\,\rho) = 81 - 1 + 152 = 232.$$

The last subtraction uses wild irreducibility: the invariant endomorphisms are exactly the scalars. It does not require Frobenius to fix every individual character after the splitting extension.

The histogram is computed by enumerating the 9×9 pairs and taking the larger of the two unequal breaks. The arithmetic assertions that these are the source's genuine characters, that their breaks are as stated, and that the quotient factors are independent remain the inherited source hypotheses. Their role is exposed rather than replaced with a finite counting experiment.



Evidence: Exact character-count model.

Companion source: Part III, Section 23.1. Book page 1533.

PLATE XI.14

A conductor filter is not an identification

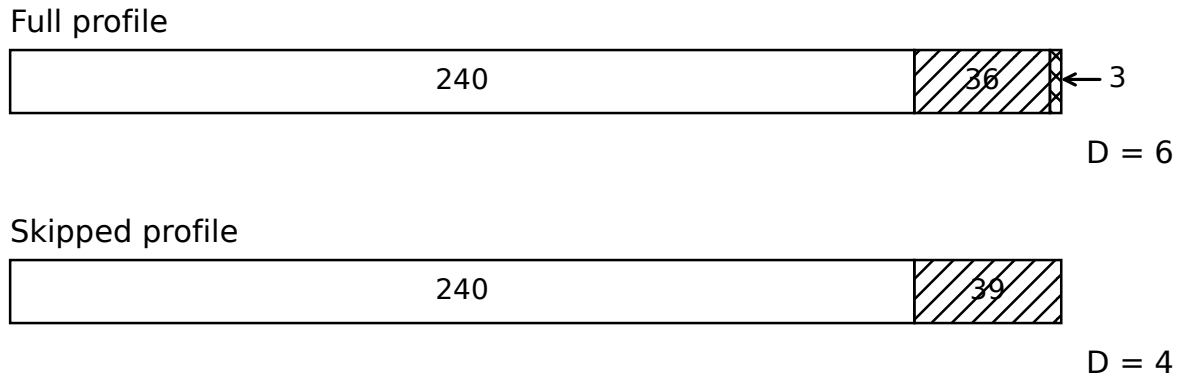
The critical-four candidate passes one invariant. It is not thereby identified with the source.

The two points use the recorded period-nine actual-order certificate. It gives leading level 24, an even critical level c, index exponent $I = c + 64$, and quotient dimension $D = 8$. With the stipulated measures and torsion number one, the self-pair conductor is

$$a(\pi^{\vee} \times \pi) = 2c + 224.$$

At $c = 10$ this is 244, contradicting the unchanged source value 232. At $c = 4$ it is 232, so this necessary comparison no longer excludes the candidate. The figure shows only these two conditional evaluations, not an asserted family of actual constructions for all intermediate values of c.

The order equations are substantive inputs. The pair $(24, c)$ does not imply them. Passing the horizontal line neither constructs the corrected stratum nor establishes occurrence of the complete prescribed character. Full pair-factor equality for the same candidate remains a stronger obligation than this conductor comparison.



Evidence: Conditional profile comparison.

Companion source: Part III, Section 23.2–23.3. Book page 1534.

PLATE XI.15

Equal weighted sums can conceal different capacity

The conductor formula has already discarded the parity information needed for the quotient.

$$240 + 36 + 3 = 240 + 39 = 279$$

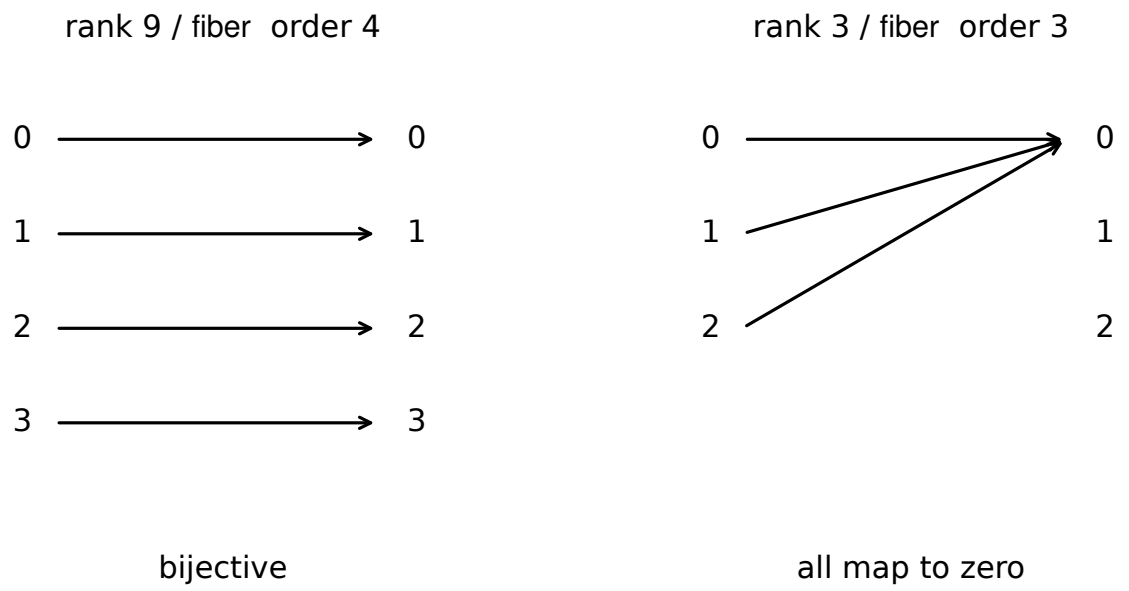
$$2 \cdot 133 + 6 = 2 \cdot 134 + 4 = 272$$

The full rank-eight profile has centralizer dimensions $(8, 4, 2, 1)$ and levels $(60, 18, 3)$. The skipped profile has dimensions $(8, 4, 1)$ and levels $(60, 13)$. The bar segments are the products $\Delta_j \nu_j$. Both sum to 279, giving ordinary self-pair conductor $63 + 279 = 342$.

$$(I, D)_{\text{full}} = (133, 6), \qquad (I, D)_{\text{skipped}} = (134, 4).$$

The compensation $2 \cdot 133 + 6 = 2 \cdot 134 + 4$ explains the equality. The identity $2\lceil \nu/2 \rceil + \mathbf{1}_{2 \mid \nu} = \nu + 1$ removes the parity distribution from the weighted conductor sum, while D retains it.

Under their inherited arithmetic construction hypotheses, both profiles also have standard conductor 68 and torsion number one. Yet only the full profile has room for the six-dimensional source quotient in this specified host. The recorded tests verify the grade consequences. They do not construct the skipped-profile parameter or turn three agreeing integers into H5.



Evidence: Exact information-loss example.

Companion source: Part III, Section 24. Book page 1536.

PLATE XI.16

Central normalization of a descent fiber

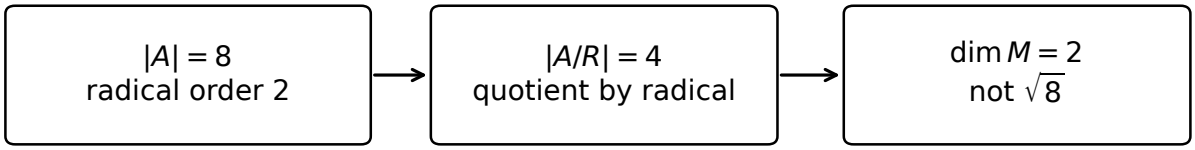
A power map can be bijective in one fiber and collapse an entire family in another.

A descent fiber that is a torsor for a cyclic character group X of order m is normalized by the central-character power map $\alpha \mapsto \alpha^n$. Additive exponents identify it with $x \mapsto nx \pmod{m}$.

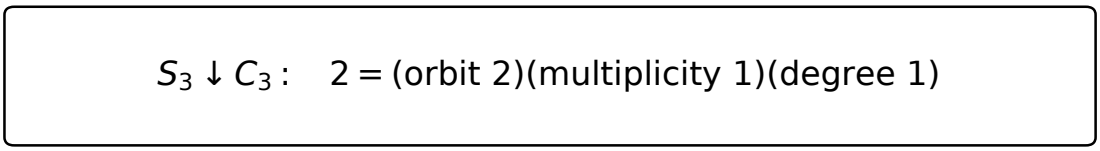
On the left, $n = 9$ and $m = 4$. The map is the identity modulo four, so every attainable central-character ratio selects one twist. On the right, $n = 3$ and $m = 3$. Every exponent maps to zero, so the fixed-center condition leaves all three twists available.

$$\gcd(n, m) = 1 \quad \Longrightarrow \quad \text{unique member for each attainable central ratio.}$$

The two examples correspond to different source branches. The rank-nine positive-characteristic descent and the rank-three fixed-center ambiguity are not one candidate under two names. Uniqueness in the coprime fiber does not prove a native character occurs in that candidate. Ambiguity in the cubic fiber does not disappear because a scalar obstruction has been removed.



Evidence: Exact finite character-group model.



Companion source: Part II, Sections 17.3 and 18.4; Part III, Section 25.3. Book page 1523.

PLATE XI.17

Clifford dimensions keep the radical and orbit factors

An abstract packet count must match an actual restriction problem.

A second copy of one noncommuting Weyl plane is not an independent factor.

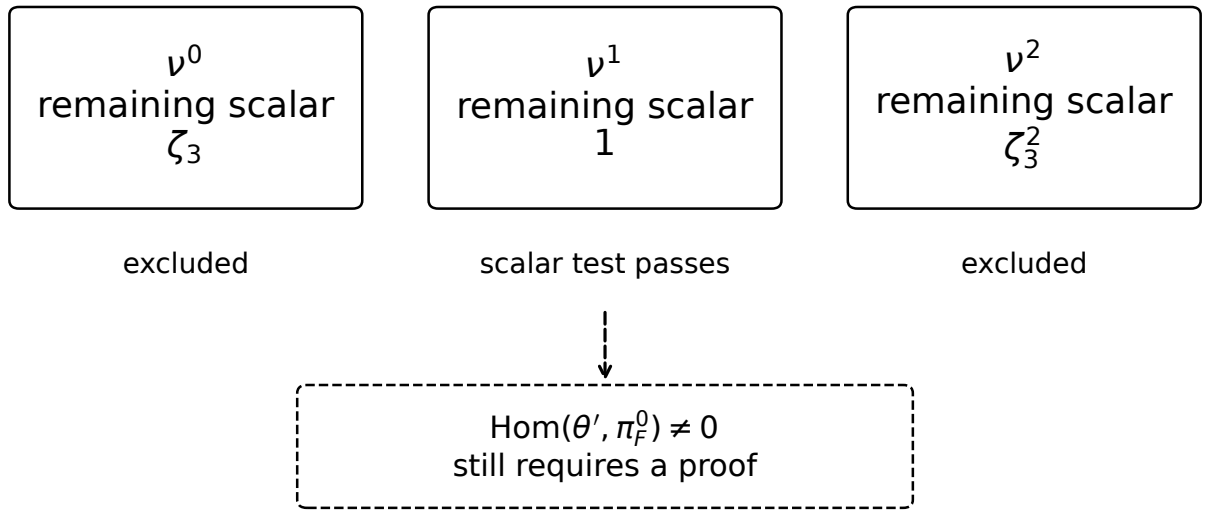
For a finite abelian projective quotient A, let R be the radical of its commutator pairing. An irreducible projective multiplicity has degree

$$(\dim M)^2 = |A/R|.$$

The first example uses $A = \mathbf{F}_2^3$, with the standard symplectic pairing on the first two coordinates and the third coordinate radical. Thus $|A| = 8$, $|R| = 2$, and $\dim M = 2$. Suppressing the radical would incorrectly produce $\sqrt{8}$.

The second example retains the inertia orbit. The two-dimensional irreducible of S_3 restricts to two distinct nontrivial characters of C_3. Each multiplicity is one, but the orbit has size two. Along a genuine compatible chain, every orbit factor and every projective multiplicity must be retained.

Independent commuting projective factors on the same carrier multiply their degrees. Representing one Weyl plane twice on the same space does not create independent commuting factors. The finite matrix checks include the S_3 relations, while the general restriction argument remains in the paper.



Evidence: Exact projective and orbit models.

Companion source: Part II, Section 15. Book page 1518.

PLATE XI.18

The noncompact scalar obstruction survives compact agreement

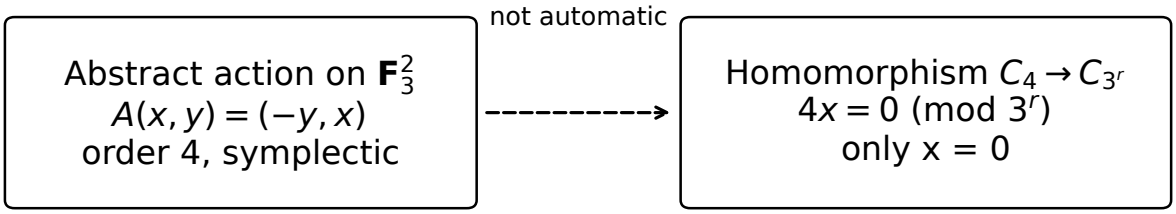
Changing the full character removes one obstruction, not the occurrence problem.

In the descent study, the original θ_0 is compatible with the tested compact action but produces the wrong scalar at a noncompact generator. The retained intertwining and maximal-type arguments yield $\mathrm{Hom}_{H^1}(\theta_0, \pi_F^0) = 0$ for the prescribed source-defined candidate.

The correction powers ν^a, for $a = 0, 1, 2$, leave generator scalars $\zeta_3, 1, \zeta_3^2$. Only the middle correction passes this test. It changes the full character, rather than merely changing a basis. Its uniformizer value must also preserve the central normalization shown on Plate XI.6.

$$\mathrm{Hom}_{H^1}(\theta', \pi_F^0) \neq 0 \quad \text{is still not established.}$$

The atlas records the exact scalar exponents. It does not rerun the earlier local-field matrix programs or supply a new occurrence proof. Choosing some other representation that contains θ' would abandon the fixed-candidate question. Rescaling an intertwiner cannot remove a nontrivial scalar between two representations whose common compact restriction is irreducible.



Evidence: Inherited arithmetic obstruction with exact scalar model.

Companion source: Part II, Section 18. Book page 1524.

PLATE XI.19

Abstract actions and native normalizers

Abstract lifting and arithmetic realization are different existence statements.

A nontrivial finite action may fail in a specified native normalizer.

This excludes that action mechanism, not every allowed arithmetic host.

The linear map $A(x,y) = (-y,x)$ on $\mathbf{F}_3^2$ is symplectic and has order four. Thus there is a genuine nontrivial abstract C_4 action. In contrast, every homomorphism $C_4 \to C_{3^r}$ is trivial: an image x satisfies $4x = 0$, and multiplication by four is invertible modulo 3^r.

The arithmetic obstruction uses its stated native-normalizer quotient and inner-action requirements. When that permitted quotient is a p-group, a prime-to-p subgroup cannot implement the desired nontrivial action through it. The cyclic groups in the drawing isolate the elementary coprimality mechanism. They are not asserted to be the entire normalizer of every type.

Finite central-extension actions can still lift under their own coprimality hypotheses, and projective intertwiners can sometimes be linearized. Neither result supplies the missing arithmetic conjugating matrices. An obstruction to this normalizer mechanism therefore remains compatible with success through a different allowed host or a different stated attachment contract.

Evidence: Exact coprimality analogue.

Companion source: Part I, Sections 4 and 11. Book page 1489.

PLATE XI.20

The finite subgroup remembers its squares

Dihedral and quaternion markings survive inside the same complex scalar extension.

$$[X, Z] = [iX, iZ] = -I$$

finite subgroup	q(e)	q(f)	q(e+f)	order 2	order 4
D8	0	0	1	5	2
Q8	1	1	1	1	6

Same scalar pushout, different marked finite subgroups.

Let $X^2 = Z^2 = I$ and $XZ = -ZX$. The subgroup generated by X, Z is dihedral of order eight. The subgroup generated by iX, iZ is quaternion of order eight. Both have the same quotient polarization and commutator $-I$.

$$q_D(x, y) = xy, \qquad q_Q(x, y) = xy + x + y.$$

Their lift squares differ. The order columns count elements of exact order two and four, excluding the identity. They distinguish the finite groups even though adjoining all complex scalars gives the same ambient scalar extension.

For a fixed two-element center, a center-fixing extension map over a prescribed symplectic map must preserve the quadratic refinement. With complex scalar center, square ratios have square roots, but this freedom does not erase a separately prescribed finite subgroup. Transporting a quaternion marking into the common scalar extension is valid. Identifying it with the independently fixed dihedral marking is not.

Evidence: Exact finite-group enumeration.

Companion source: Part III, Section 26.1–26.2. Book page 1541.

PLATE XI.21

A square table does not specify an entire section

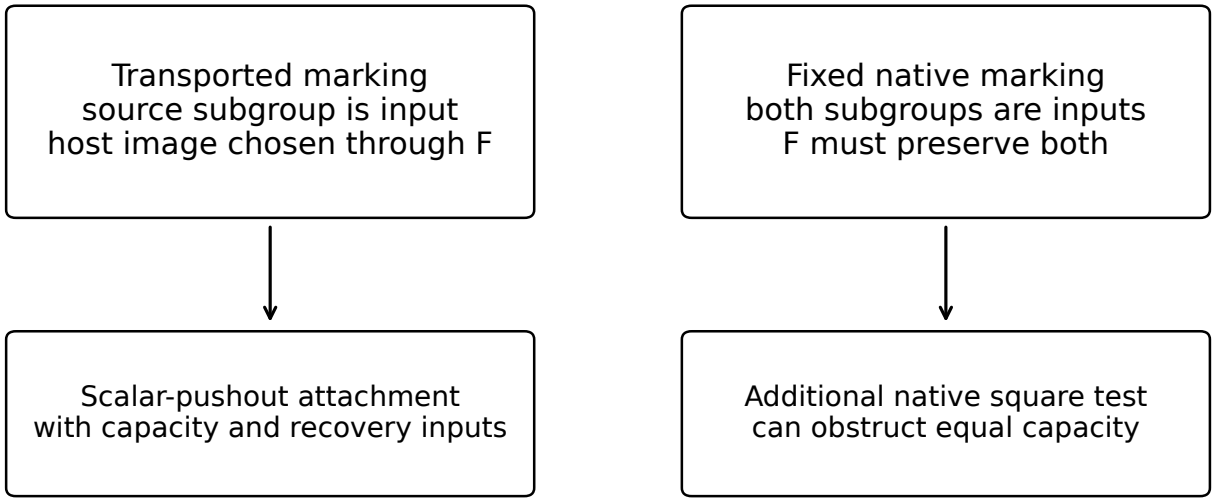
Changing one section value can preserve every square and still change products.

Start from the ordered section $\sigma(x,y) = X^x Z^y$ in the dihedral example. Change only $\sigma(e+f)$ by a central sign. Write the sign function as $a(v) = \mathbf{1}_{v=e+f}$. The displayed entries are the resulting cocycle differences

$$\Delta c(v,w) = a(v) + a(w) + a(v+w) \in \mathbf{F}_2.$$

Every diagonal entry is zero, so every square is unchanged. But $\Delta c(e,f) = 1$. A map fixing the specified generating lifts cannot also implement the changed assignment at $e+f$. The cross marks a nonzero product discrepancy, not failure of the two extensions to be isomorphic in some other way.

This is why the native certificate needs all specified section products, not only a quadratic table. When the entire section is transported through one homomorphism, those products are retained automatically. When the target section is independently prescribed, its pointwise assignments must be checked. The distinction concerns what is fixed, not a contradiction in extension theory.



Evidence: Exact cocycle counterexample.

Companion source: Part III, Section 26.3. Book page 1542.

PLATE XI.22

Two different marking contracts

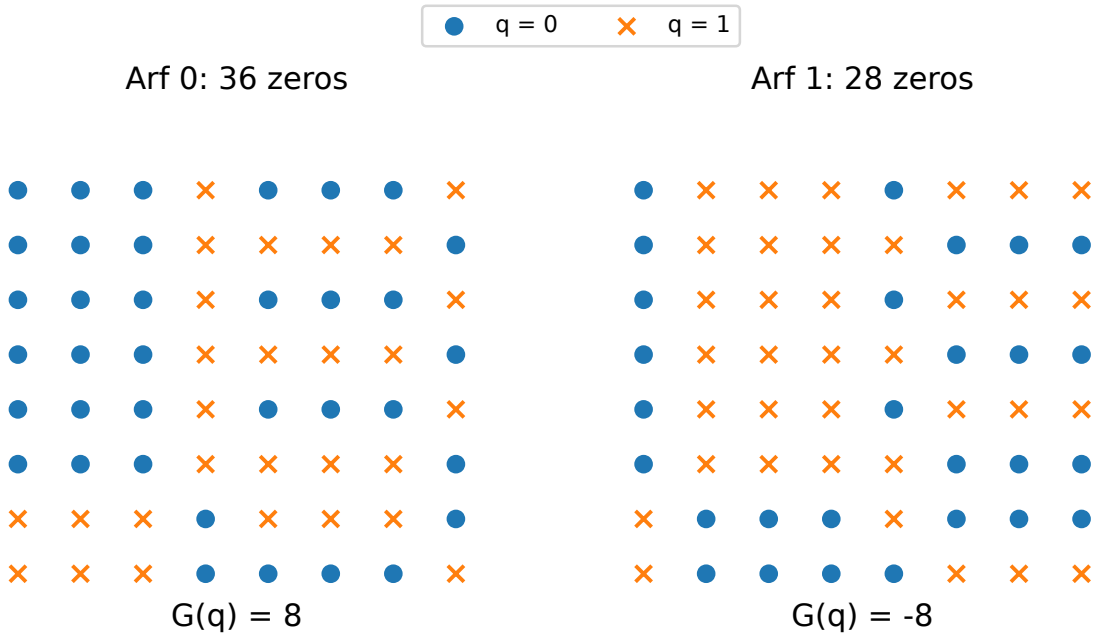
A positive attachment and a native obstruction can both be correct.

In the transported-marking contract, the source marking is supplied. After a permitted symplectic embedding and scalar-extension isomorphism have been chosen, the host marking is their image. A homomorphism fixes the represented center and carries squares, products, and specified lifts together.

In the independently fixed native contract, the target finite subgroup and its refinement are already given. The comparison must hit that subgroup with its existing marking. A scalar rescaling that changes it may be disallowed.

$$\text{choose a compatible target marking} \quad \neq \quad \text{match this prescribed target marking.}$$

The restricted one-vertex, trivial-stabilizer attachment retains its actual-type, capacity, full-character, and recovery hypotheses. It should not acquire an extra native-marking premise merely because a stronger problem is also studied. Conversely, that positive theorem cannot certify the stronger problem without computing the additional datum. The two branches in the figure remain separate throughout the atlas.



Evidence: Contract comparison.

Companion source: Part III, Sections 26.4 and 27.3. Book page 1542.

PLATE XI.23

Two six-dimensional refinements with different signs

The alternating form and dimension do not determine the Arf invariant.

Each grid contains all 64 binary vectors in dimension six. Columns encode the lower three bits and rows the upper three bits, with row zero at the top. Circles have quadratic value zero. Crosses have value one. The two forms share the standard polarization:

$$q_+ = x_1y_1 + x_2y_2 + x_3y_3, \qquad q_- = q_+ + x_1 + y_1.$$

Their Gauss sums are $+8$ and -8. Consequently the zero counts, including the zero vector, are $(64 + 8)/2 = 36$ and $(64 - 8)/2 = 28$. The diagrams use exact binary evaluation at every vector.

These are explicit abstract refinements, not a claim that either has been computed on the actual rank-eight arithmetic candidate. The example shows the datum still required when the host marking is independently fixed. At equal capacity, an Arf mismatch has no orthogonal complement in which to be absorbed.

Evidence: Exhaustive 64-vector displays.

Companion source: Part III, Section 27.1. Book page 1543.

PLATE XI.24

The equal-capacity test is sharp

One spare quadratic plane removes the free Arf obstruction, not every attachment constraint.

Source dimension is 6. The embedding may be freely chosen.

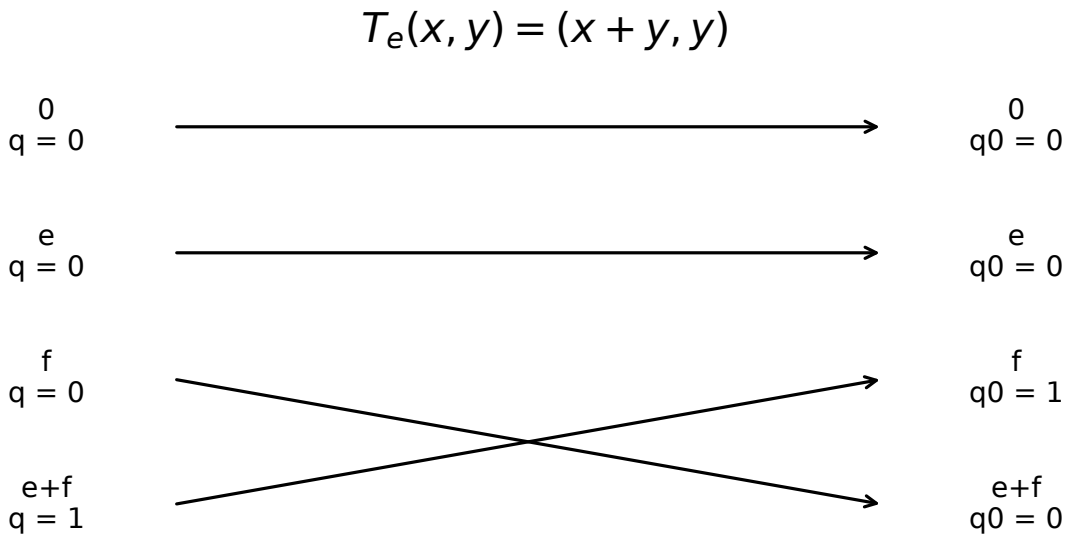
host dim	host Arf	source Arf 0	source Arf 1
4	0	no	no
4	1	no	no
6	0	yes	no
6	1	no	yes
8	0	yes	yes
8	1	yes	yes

Fix a nondegenerate source of dimension six. The table varies the host dimension and its supplied Arf invariant. The embedding may be freely chosen. A four-dimensional host cannot contain the source. At dimension six, the map is an isometry and the Arf signs must agree. At dimension eight, the complementary plane can have either sign.

$$\mathrm{Arf}(U) = \mathrm{Arf}(W) + \mathrm{Arf}(V) \quad \text{for } W \simeq V \perp U.$$

This is the finite classification argument, not a numerical search over arithmetic matrices. It combines with the original full dyadic capacity formula to isolate the rank-eight equality case.

The word “free” matters. A prescribed depth placement, an already fixed quotient embedding, or a stabilizer-equivariance condition may forbid the required change of subspace. The table assumes the actual quadratic host has been supplied. It does not compute that host’s native marking, choose its lifts, or authorize modifications to the transport diagram.



Evidence: Finite classification criterion.

Companion source: Part III, Section 27.2–27.3. Book page 1543.

PLATE XI.25

A single transvection repairs an isotropic defect

The repair is explicit, and the previously correct line stays fixed.

0 and e stay fixed. f and e+f are exchanged.

Take $q(x,y) = xy$ and $q_0(x,y) = xy + y$. Their discrepancy is $B(e,-)$, with $e = (1,0)$ and $q(e) = 0$. The transvection is

$$T_e(x,y) = (x+y,y), \qquad q_0(T_e v) = q(v).$$

The arrows show its action on every vector. Zero and e remain fixed. The vectors f and $e+f$ exchange places. Each arrow therefore lands on the same quadratic value shown at its source.

The original identity map did not work: $q(f) = 0$ while $q_0(f) = 1$. Matching Arf invariants guarantees a correction here, not the validity of an unchanged map. More generally, a defect vanishing on a subspace U gives a defect vector in $U^{\perp}$, so the transvection fixes U pointwise.

The correction fixes quotient vectors, not automatically independently fixed lifts above them. Its use in an arithmetic diagram requires permission to change the embedding and a separate check of the relevant section and phase data.

Evidence: Exact four-vector correction.

Companion source: Part III, Section 28.1–28.3. Book page 1545.

PLATE XI.26

The defect vector supplies a decision procedure

The same formula displays both the successful correction and its genuine obstruction.

$$q_0 = q + B(a, -)$$

defect a	q(a)	mismatched vectors	T_a correction
0	0	0	works
e	0	0	works
f	0	0	works
e+f	1	2	fails

When q(a) = 1, Arf changes and the obstruction is genuine.

For the fixed hyperbolic plane $q = xy$, every refinement with the same polar form is $q_0 = q + B(a, -)$ for one vector a. The table lists all four defect vectors. Its mismatch column counts the vectors at which $q_0(T_a v) \neq q(v)$.

$$q_0(T_a v) = q(v) + B(a, v)q(a), \qquad \mathrm{Arf}(q_0) + \mathrm{Arf}(q) = q(a).$$

When $q(a) = 0$, the correction works everywhere. For $a = e + f$, the Arf sign changes and two vectors still fail. This is not an unlucky choice of basis. In equal dimension, the two forms are not isometric.

In a larger host this test applies to the pullback along the supplied embedding. A different permitted subspace may behave differently. Under genuine supplied actions preserving both refinements and an initially equivariant embedding, the defect vector is fixed by the group. The same transvection is then equivariant. Those initial actions are hypotheses, not outputs of this linear solve.

Evidence: Exact defect enumeration.

Companion source: Part III, Section 28. Book page 1545.

PLATE XI.27

An odd-order action discrepancy can be summed away

The correction acts on a supplied finite extension, not on an unconstructed arithmetic host.

$$u = \sum_{h} \delta_h = e$$

group element	delta_g	g u	u + delta_g + g u
1	0	e	0
g	e+f	f	0
g²	f	e+f	0

$$g(x, y) = (y, x + y) \quad \text{on } \mathbf{F}_2^2$$

Let C_3 act on $A = \mathbf{F}_2^2$ by $g(x, y) = (y, x + y)$. Use the cocycle values $\delta_1 = 0$, $\delta_g = e + f$, and $\delta_{g^2} = f$. Their sum is $u = e$. The final column displays the corrected discrepancy, which is zero at every group element.

$$\delta_{gh} = \delta_g + g\delta_h, \qquad u = \sum_h \delta_h, \qquad \delta_g = u + gu.$$

The last identity follows by summing the cocycle equation and using that the group order is odd in characteristic two. Replacing the comparison by the vertical sign correction u makes it equivariant.

In the extension theorem, the source and target already have genuine actions and an initial center-fixing extension isomorphism. The cocycle lives in the character space $\mathrm{Hom}(W, \mathbf{F}_2)$. The diagram is an exact module example of that calculation, not a new construction of those actions. A vertical correction may also be forbidden when particular lifts must remain unchanged.

Evidence: Exact C3-module model.

Companion source: Part III, Section 29.1–29.2. Book page 1547.

PLATE XI.28

The even-order negative control

A nonzero cocycle survives when every permitted coboundary vanishes.

C2 acts trivially. The cocycle has delta_s = e.

candidate u	u + s u	remaining delta_s
0	0	e
e	0	e
f	0	e
e+f	0	e

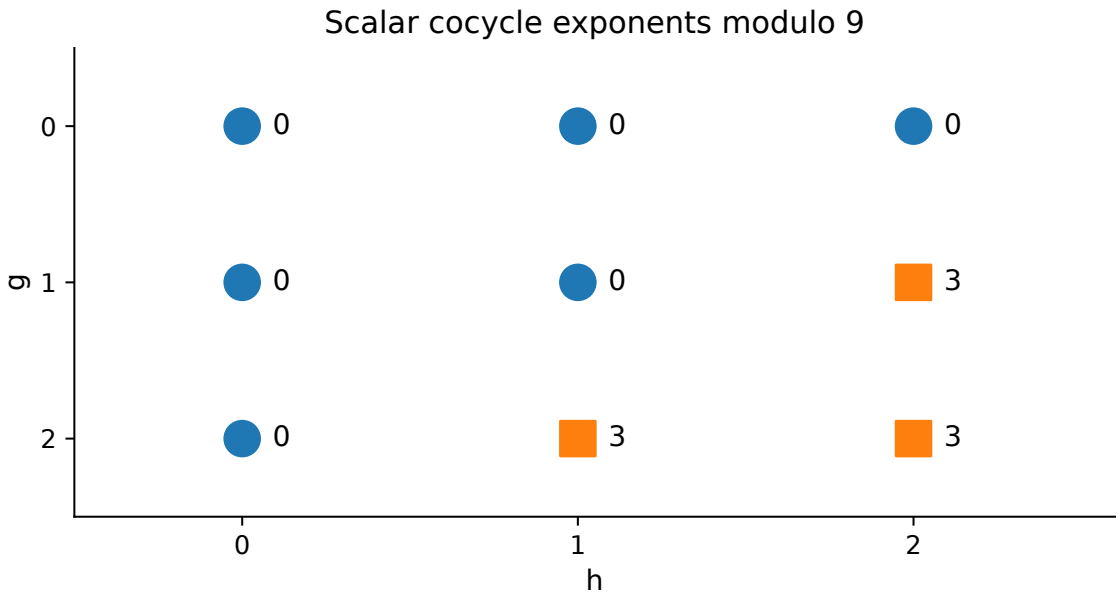
Every permitted coboundary is zero. None removes this cocycle.

Let $C_2 = \{1, s\}$ act trivially on the nonzero module $A = \mathbf{F}_2^2$. The assignment $\delta_1 = 0$, $\delta_s = e$ satisfies the cocycle equation, since $e + e = 0$. For every proposed correction u,

$$u + su = u + u = 0, \qquad u + \delta_s + su = e.$$

The four rows exhaust the module. None removes the discrepancy. Thus the odd-order hypothesis of the preceding plate is mathematically active.

This does not say that every even-order action problem is obstructed. It supplies one exact counterexample to an unrestricted averaging claim. Other actions and cocycles may admit corrections. In the arithmetic problem, it remains necessary to compute the actual discrepancy and respect the permitted transformations. Declaring every projective or equivariance mismatch removable would erase precisely the information this example retains.



Evidence: Exact obstruction model.

Companion source: Part III, Section 29.2. Book page 1548.

PLATE XI.29

Honest phases remain a separate layer

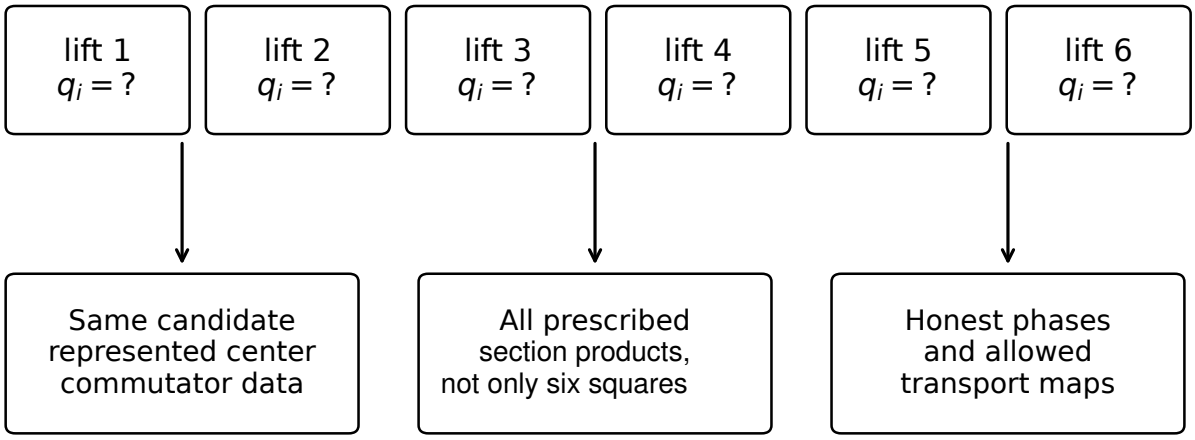
An action on the extension group is not yet the specified action on its representation.

Let $g, h \in \{0, 1, 2\}$ represent C_3, and take the one-dimensional operators $U_g = \zeta_9^g$. Their multiplication has scalar discrepancy

$$U_g U_h = \zeta_9^{c(g,h)} U_{g+h \bmod 3}, \qquad c(g,h) = 3 \left\lfloor \frac{g+h}{3} \right\rfloor .$$

The figure records its exponents modulo nine. Replacing U_g by $\zeta_9^{-g} U_g$ gives an honest action. Yet the three honest characters $g \mapsto \zeta_3^{kg}$ are still distinct choices.

This scalar toy model isolates two separate questions: whether a projective multiplier can be removed, and which honest linearization the contract prescribes. It is not the phase system of the actual arithmetic candidate. The finite extension-action correction on Plate XI.27 addresses a different discrepancy, in the group automorphisms. Canonical extension phases, Gauss conventions, and coherent transports must still be checked on the same full representation.



Evidence: Exact scalar projective toy model.

Companion source: Part I, Section 4.2; Part III, Section 29.3. Book page 1489.

PLATE XI.30

The missing native certificate has explicit fields

Question marks are not zeros and must not be filled with a convenient abstract form.

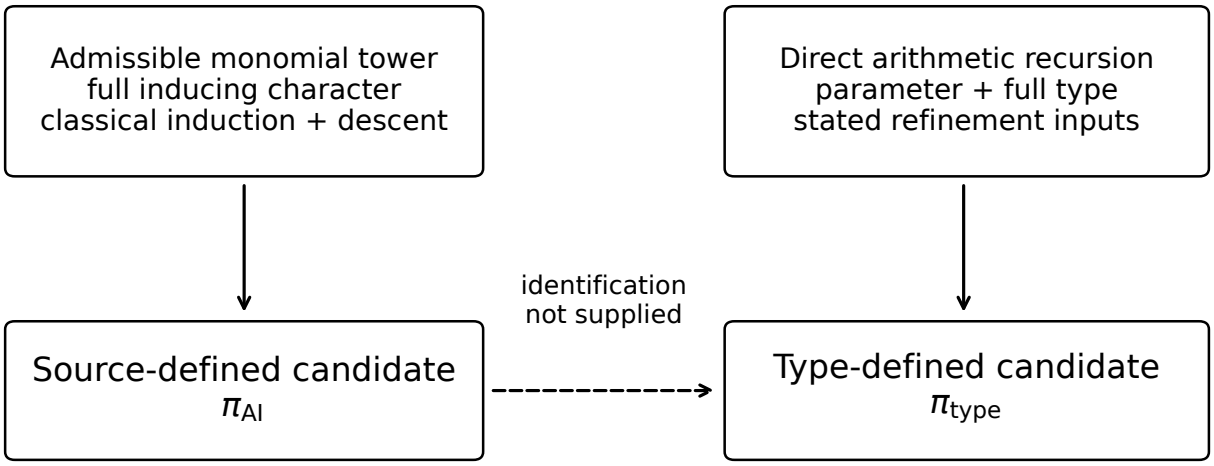
The six question marks are deliberate: no native bit is fabricated.

When the stronger contract independently fixes a native rank-eight marking, the certificate must name the actual candidate, the relevant finite subgroup and represented center, and the six genuine lifts of a symplectic basis. Their squares determine six bits only after those lifts and the two-element central representation have been established.

$$q_W(v_i) \in \mathbf{F}_2 \quad \text{must come from the actual lift square.}$$

All prescribed section products must also be verified. Genuine extension actions do not by themselves choose the required honest representation phases. The certificate must state which maps or lifts may change and verify the resulting transport conditions.

No native square bit is supplied by this atlas. The data file records these fields as null, and the tests ensure they remain uncomputed rather than silently assigning zero. This is a conditional stronger obligation. It is not an extra premise inserted into the already valid transported-marking contract, where the finite marking is carried through the chosen comparison map.



Evidence: Unresolved arithmetic certificate.

Companion source: Part III, Section 30.2. Book page 1549.

PLATE XI.31

Keep the two construction routes distinct

A source-defined candidate and a type-defined candidate require an identification theorem.

The monomial route begins with a full inducing character and an admissible tower. Under the stated classical induction and descent inputs it produces a source-defined candidate. Solvability of an ambient finite group does not make every proposed subgroup admissible for a prime-cyclic tower.

The direct route begins with an explicit parameter and type construction. Its refinement and full-character arguments produce an actual candidate under a restricted contract. Even when both routes match rank, standard conductor, torsion number, and self-pair conductor, those invariants do not identify their outputs.

$$\pi_{\mathrm{AI}} \simeq \pi_{\mathrm{type}} \quad \text{needs its own argument on the same source and field.}$$

The positive-characteristic rank-nine source-defined route and the characteristic-zero example in the descent study remain separate. The complete Henniart–Lemaire text was unavailable during the recorded conductor audit, so its detailed applications retain inherited audit status. The visual argument supplies no new classical-source certification.

Evidence: Source-lineage diagram.

Companion source: Part II, Sections 14 and 17; Part III, Section 25. Book page 1516.

PLATE XI.32

The current frontier

Completed finite and restricted work remains reusable without relabeling the open endpoints.

One proof ledger, not a percentage of a conjecture.

reusable result or endpoint	current boundary
restricted constructions	written arguments retained
finite corrections	conditional proofs, exact models
general realization	OPEN
same-candidate H5	OPEN
corrected-character occurrence	OPEN
fixed native marking	OPEN when independently required

The progress record has a distinct visual reading route through the restricted constructors, finite comparison mechanisms, exact obstructions, and conditional corrections. These are substantive results and reusable arguments. Their existence does not make the remaining arithmetic statements interchangeable.

General realization requires an actual common host with the admitted actions and transports. Same-candidate H5 requires the characterizing factors for that very realizer. The corrected-character problem requires occurrence in the original specified induction candidate. An independently fixed native marking, when required, needs the actual certificate on Plate XI.30.

The atlas accompanies the arithmetic research companion and its evidence record. Finite illustrations, ordinary proofs, classical inputs, and historical formal receipts retain their separate scopes. Neither the atlas nor its assembly into this book supplies a fresh Lean compilation or external peer review, and the recorded checks do not measure a percentage of conjecture completion.

Evidence: Claim and source map.

Companion source: Part I, Section 12; Part II, Section 20; Part III, Section 30. Book page 1509.

Plate concordance

Executable checks and scope

The atlas suite contains 28 test methods. It checks the displayed finite data and deliberate false controls, including the 72-target corner, conductor translations, cocycle products, all 64 vectors in each display of dimension six, and explicit correction formulas. These finite tests do not measure theorem completion. The native certificate remains uncomputed.

Formal companions

The formal companions connect the mathematical chapters to their Lean declarations, hypotheses, source correspondences and verification evidence. Read each statement with the coverage described by its companion.

Return to Chapter I

Computational records and interfaces

This computational companion represents Chapter I as a collection of mathematical records that can be inspected and queried, with a finite subset supported by executable interfaces. The statement inventory is formal/coverage/COVERAGE_108.json. The executable runtime has a separate source entry in the source register. The catalogue and runtime have the distinct scopes explained below.

The catalogue contains 108 mathematical records, including 69 theorem, proposition, corollary, and lemma records with source proofs. The formal correspondence is reported alongside each record. The preserved runtime interface has twenty typed signatures, and its separate Lean runtime map has eight mappings. Those inherited interfaces and receipts retain their original scope.

The mathematical source supplies the statements and proofs, including the split-semisimple hypotheses and explicit map qualifications. The supplementary worked models remain in the mathematical text. Stable identifiers connect the mathematical, formal, and computational material. Statement hashes and source locators distinguish the catalogue from the archived runtime payloads.

The verification record distinguishes evidence for the mathematical correspondence from the runtime receipts. Its source inventory and formal correspondence map are available under `formal/coverage/`, and compiler and replay receipts are under `formal/evidence/`. The Lean guide explains the formal sources, their hypotheses, and how to interpret those checks.

How to use this volume. Read Sections 1–3 for mathematical and evidence semantics. Sections 4–6 give the executable contracts and an exact worked example. Section 7 describes reproduction. Appendix A reproduces every canonical source statement and every attached proof body, with source locators and machine metadata. Later appendices give signatures, action coverage, operation vocabulary, and the runtime Lean map.

1 The mathematical object behind the interface

1.1 Operator systems, generated hulls, and seed rank

A seed problem consists of an acting algebra, a module, and a family of seed vectors. The algebra must be fixed before the generation question is asked. For a unital algebra A acting on a module M and a finite seed family $S = \{s_1, \dots, s_r\}$, the algebraic generated hull is

$$\mathrm{Hull}_A(S) = \sum_{j=1}^{r} As_j.$$

A one-seed system is cyclic. Seed rank measures the minimum cardinality of a generating family, under the regime declared in the source. Enlarging the acting algebra changes the question. Replacing algebraic span by a closure changes it again. The machine record therefore keeps the acting regime and hypotheses beside the statement.

Chapter I begins with typed operator grammars and their realizations, then passes through free presentations, generator number, packet coordinates, block algebras, transfer graphs, and realization. The resulting record graph covers the whole expanded foundation. It is not limited to the finite matrix examples that the runtime executes.

For finite families of nonnegative integers, the ambient convention is $\max \varnothing = 0$. The height of an empty finite poset is zero. A nonempty poset with no strict comparable pair also has height zero, so height counts strict steps. These conventions clarify the empty cases without adding stable records.

The source separates algebraic, linear, and topological claims. A finite-dimensional matrix computation can exercise a linear identity. It cannot establish the Banach space result in the countable setting or a generator formula over every division ring. Those claims retain their own source proofs and dependencies.

1.2 Exact packet coordinates

For a finite index set I, a packet system on X consists of linear maps P_α satisfying

$$P_\alpha^2 = P_\alpha, \qquad P_\beta P_\alpha = 0 \quad (\beta \neq \alpha), \qquad \sum_{\alpha \in I} P_\alpha = I_X.$$

The packet spaces are the ranges $X_\alpha = P_\alpha X$. Analysis and synthesis are

$$\mathcal{A}_P x = (P_\alpha x)_{\alpha \in I}, \qquad \mathcal{S}_P((x_\alpha)_\alpha) = \sum_\alpha x_\alpha.$$

Their inverse laws are exact. No assumption of inner product orthogonality is needed. This distinction is visible in the oblique two-dimensional example later in this companion.

Machine execution represents each packet as an ambient vector. It does not construct a basis of every range or replace the ambient representation by smaller coordinate arrays. This choice makes exact identities easy to compare with the source formulas while retaining the packet index structure.

1.3 Transfer blocks and composition

For an endomorphism T, the transfer block from packet α to packet β is

$$T_{\beta\alpha} = P_\beta T P_\alpha.$$

Its source is X_α and its target is X_β. In the finite runtime it is stored as a full ambient matrix. Completeness gives

$$T = \sum_{\alpha,\beta} T_{\beta\alpha}, \qquad (ST)_{\gamma\alpha} = \sum_{\beta} S_{\gamma\beta} T_{\beta\alpha}.$$

The order matters: the rightmost factor acts first. The runtime uses the same convention. Its nested block array is indexed first by target and then by source.

The graph records source dependencies for these identities. It does not infer every implicit mathematical dependency. The packet-system hypotheses remain required even when a compact source statement inherits them from the surrounding section.

1.4 Intertwining and reconstruction

For packet systems P on X and Q on Y, an intertwiner $U : X \to Y$ satisfies $UT = SU$. Resolving both sides yields

$$\sum_{\beta} U_{\gamma\beta} T_{\beta\alpha} = \sum_{\delta} S_{\gamma\delta} U_{\delta\alpha}, \qquad U_{\gamma\alpha} = Q_\gamma U P_\alpha.$$

All local equations together are equivalent to the global equation under the packet hypotheses. The runtime returns the global Boolean, every local residual, and the conjunction of the local Booleans. It provides the data needed to inspect agreement or failure in a concrete exact case.

1.5 The boundary of finite execution

Countable packet sums require a topology and a convergence condition. Quotient descent requires invariance. Coordinate transport requires a suitable invertible map. Packet-pure seed counts differ from unrestricted seed counts because one mixed-support seed can contribute to several source components. These are mathematical hypotheses, not formatting conventions.

The source records seven explicit boundaries. Their presence is part of the interface. Runtime action names do not imply that every associated theorem has an implementation, and metadata listing a boundary does not itself execute that boundary check.

2 Canonical machine representation

2.1 Entrypoint and package identity

The mathematical records are located at `formal/coverage/COVERAGE_108.json`. Appendix A is generated directly from those records. Each includes the statement, source proof where present, source location, hashes, formal status, and declaration correspondence. The archived mathematical source identified by those hashes is the statement authority.

The source register identifies the executable runtime. Runtime commands assume its working directory. Its entrypoint, PSC_I.machine.json, points to the preserved record collection, statement AST, dependency graph, action registry, and evidence index. A

runtime result therefore retains the exact interface scope explained below. It is not a certificate for every current manuscript statement.

The preserved runtime source digest is:

```
37bf8f03dbbf66ce41f8b07a8e7be8fa5fca44176bdd56dd25b483f72736ff77
```

That digest identifies the archived runtime source, including explicit nonzero-packet assumptions for two corollaries and the empty-family and poset-height conventions. The mathematical inventory has its own statement and proof hashes, printed in Appendix A. Runtime receipts remain attached to their original bytes. They do not transfer automatically to the mathematical inventory.

2.2 Record identity and source provenance

Each current record has a stable ID, kind, title, statement text, optional proof text, source locator, hashes, formal status, declaration targets, and a scope note. These fields identify the actual current statement and the proof text that accompanies it. The preserved executable payload additionally supplies its own dependency annotations, semantic profiles, evidence coordinates, and fingerprints for its source.

There are 28 definitions, 28 theorems, 22 corollaries, 16 propositions, three lemmas, three classical inputs, seven boundaries, and one remark. The 69 theorem/proposition/corollary/lemma records have attached proof bodies. Definitions and boundary statements are not counted as proved theorems merely because they occupy records.

> A fingerprint in the preserved runtime provides a content identity under that payload's generating convention. It is not a proof certificate. The runtime verifier checks the source digest, ID count, graph, AST coverage, selected API behavior, and exact fixtures. It does not establish all mathematical content through independent formal reconstruction.

2.3 Statement AST and typed signatures

The runtime statement AST has one entry per stable ID in its source. The statuses are 20 TYPED_CORE, 81 STRUCTURED_SYMBOLIC, and seven TEXTUAL_SEMANTIC. A typed-core record points to a signature declaring parameters, requirements where supplied, and a return description.

The AST segments statements into prose and mathematical surfaces. Some expressions are recognized as relations or direct-sum expressions. Others retain `latex_expr` leaves. Even a typed-core record can contain these leaves. Consequently, "typed core" refers to the attached interface signature, not to a complete formal elaboration or a proof term.

The signature for block intertwining describes a logical equivalence between the global and local equations. Its source proof remains attached separately. The runtime can evaluate a finite instance. These are three different representations with three different evidentiary roles.

2.4 Dependencies and closure

The preserved runtime dependency graph contains 108 nodes and 97 internal edges. The runtime verifier confirms that the recorded internal dependencies resolve and that the graph is acyclic. Direct dependencies are stored on each record. The API can also return a transitive closure.

Closure queries return sorted identifiers. They do not produce a proof order, carry out the proof, or resolve external classical inputs. A consumer can use the graph to inspect a prerequisite set and then obtain source statements and evidence for each record.

2.5 Operation profiles and actions

Each preserved runtime record carries source-derived operation metadata, with a transitive profile alongside the direct profile. The ontology distinguishes structural operations from hypothesis classes. These annotations support planning and inspection. They should not be interpreted as a verified extraction of every semantic operation used by an arbitrary proof.

The action registry contains 37 action names associated with 75 records. Eight names are implemented in the runtime. Other entries are marked planner-only or fixture-only. The source has broader mathematical scope than the executable subset.

3 Evidence semantics and certification scope

3.1 Independent evidence coordinates

The preserved runtime evidence object separates source, KIR, Python, and Lean. Its source coordinate identifies that payload's source, and its KIR coordinate records validation of that source. Python evidence reports exact finite fixtures for 26 records. Its Lean coordinate points to eight runtime source mappings.

The catalogue uses the formal correspondence map instead. Each of the 108 records carries a status and scope note, and each proof-level statement has its own correspondence assessment. The verification index distinguishes the execution evidence attached to each component.

No coordinate upgrades another automatically. Exact arithmetic removes floating-point ambiguity from a finite computation. It does not quantify over arbitrary fields, modules, dimensions, or topological spaces. A mapped Lean declaration proves its own formal statement under its dependencies. Its relation to the source statement must still be read from the mapping.

3.2 Formal correspondence and checks

The correspondence map classifies the 69 proof-level records as 69 covered, 0 partial, and 0 not mapped. The classifications describe the complete statements at their recorded scopes. They do not count independent theorems or executable actions. Every statement, source proof, and correspondence scope is reproduced in Appendix A. The exact declaration lists are in `formal/coverage/COVERAGE_108.json`.

The recorded audit checks 116 formal source modules plus the retained boundary suite. Including that suite, it inventories 3513 source-owned entries and checks 3500 logical declarations. Of these, 3499 are checked by logical replay and one declaration sharing an upstream name receives a fresh-name kernel body check after exact type/value comparison. It inventories 13 runtime helpers separately and records 12 rejected negative controls. The allowed transitive axiom set is `Classical.choice`, `Quot.sound`, `propext`. The receipt is `formal/evidence/RELEASE_VERIFICATION.json`. Its detailed compiler and logical-replay evidence is under `formal/evidence/whole_closure/`.

The recorded computational checks pass for 96 exact finite or symbolic visual assertions, 33 companion tests, and 10 regenerated PDF/PNG figure pairs. These bounded computations have their own scope and do not replace the formal declarations.

The pinned upstream dependency cache is reused. Logical replay uses Lean's official kernel. It is not an independently implemented checker. The source-to-manuscript correspondence is a separate reviewed mathematical artifact.

3.3 Runtime Lean linkage

The attached seven-module formalization uses the environment specified in the accompanying source records. Its eight mappings include definitions, generalized theorems, one-directional correspondence, and a related sufficient direction. The support-pattern algebra mapping is explicitly partial. It must not be counted as a full formal certificate for every direction of the source criterion.

A separate predecessor report records 35 of 35 obligations for its identified source. That lineage is not the canonical correspondence for the expanded mathematical inventory. The predecessor count, the eight attached runtime mappings, and the expanded correspondence map describe different scopes.

3.4 Recorded runtime checks

The documented verifier and exact fixture suite were run from the archived runtime payload. Both passed. The verification log is attached in the companion's `build/` directory. All 65 files extracted from the original machine archive retain their original bytes.

An initial invocation used an interpreter without SymPy and failed when the blockification action imported that dependency. The successful replay used an existing environment containing SymPy. No runtime action implementation was changed to resolve that environment failure. The two audited statement corrections were applied separately and have their own provenance record.

> Typesetting this companion does not execute Lean. Lean checks are reported in the verification index and explained in the formal companion. The runtime status file is retained with its original source identity.

3.5 What PASS means

A runtime-verifier pass means the named package checks succeeded. A fixture pass means a concrete exact computation satisfied its assertion. A transport-gate pass means all operation flags that this runtime checked were accepted. None of these strings, taken alone, means that the entire 108-record foundation has been formally proved by the runtime.

The full source proof catalog is included so that a reader can inspect mathematical arguments beyond the runtime. Editorial reproduction of those arguments is not an adversarial proof audit or a new formal verification claim.

4 Executable action contracts

4.1 Input and output conventions

The API is a Python command that emits JSON on successful calls. Exact arithmetic actions use SymPy matrices. Integers and rational strings such as `"3/7"` preserve rational values. JSON floating-point numbers should be avoided when the intended claim is an exact rational identity. Returned scalar entries are strings.

Payload shapes are conventional rather than comprehensively validated at the API boundary. Supply nonempty compatible square projector matrices and compatible operators or vectors. Malformed inputs can raise Python exceptions. The command parser does not present a universal contract for structured errors.

Most computational actions do not call packet validation automatically. Validate the packet family before interpreting block or analysis output through the theorems. With invalid projectors, a matrix expression may still be computable while its theorem interpretation fails.

4.2 The six exact finite actions

Action	Payload	Returned information
`VALIDATE_PACKET_SYSTEM`	`projectors`	Idempotence, annihilation, completeness, and their conjunction.
`ANALYZE_PACKETS`	`projectors`, `vector`	Ambient packet vectors and a reconstruction Boolean.
`BLOCKIFY_OPERATOR`	`projectors`, `operator`	Target/source array of ambient transfer matrices.
`RECONSTRUCT_OPERATOR`	`blocks`	Sum of every supplied block. Compatibility with a packet family is not independently checked.
`COMPOSE_TRANSFER_BLOCKS`	`projectors`, `S`, `T`	Array of block products and equality with directly resolved ST.
`LOWER_INTERTWINER`	`P`, `Q`, `T`, `S`, `U`	Global equation, local equations, residuals, and local conjunction.

4.3 The two semantic gate actions

`CHECK_REALIZATION_PROFILE` and `TRANSPORT_THEOREM` share the same runtime gate. Their payload contains a record ID and a profile. The gate reads that record's direct `action_required_operations` and checks the corresponding profile flags.

The accepted flags are true, `VERIFIED`, or `PRESERVED`. False and `NOT_PRESERVED` produce a negative list. Other or missing values are unknown. Any negative or unknown required operation blocks the gate.

This archived implementation does not evaluate the profile's `verified_hypotheses`, does not use the transitive operation closure as its required set, and does not execute the returned boundary guards. It also does not construct a target theorem, a proof object, or an independently verified realization functor. The preservation flags are declarations supplied by the caller.

Thus the action named `TRANSPORT_THEOREM` is an operation-profile gate. A consumer must separately justify target hypotheses, source-to-target interpretation, and any constructions used by the proof. Unknown flags fail closed only within the operation list actually inspected by the function.

4.4 Planner-only and fixture-only actions

The full registry in Appendix C makes execution status explicit. A planner-only action can identify a mathematically meaningful next step without implementing it. A fixture-only association records that a finite check exercises related mathematics. Calling an unimplemented action through `execute` exits with an unsupported-action error.

5 An exact worked execution

5.1 Oblique packets and reconstruction

Use

$$P_0 = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}, \qquad P_1 = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}, \qquad x = \begin{pmatrix} 3 \\ 5 \end{pmatrix}.$$

These are complementary idempotents but are not self-adjoint under the usual Euclidean inner product. The example therefore exercises the algebraic packet hypotheses without adding orthogonality.

```
python runtime/machine_api.py execute VALIDATE_PACKET_SYSTEM tests/packet_input.json
python runtime/machine_api.py execute ANALYZE_PACKETS tests/analyze_input.json
```

```
{
  "complete": true,
  "idempotent": true,
  "pairwise_annihilating": true,
  "valid": true
}
```

The analysis output is exact:

```
{
  "packets": [
    [
      [
        "-2"
      ],
      [
        "0"
      ]
    ],
    [
      [
        "5"
      ],
      [
        "5"
      ]
    ]
  ],
  "reconstructs": true
}
```

The two vectors $(-2, 0)^t$ and $(5, 5)^t$ sum to x. Each belongs to its own projector range. The runtime's zero-based packet indexing corresponds to the displayed P_0, P_1.

5.2 Resolving and rebuilding an operator

Take

$$T = \begin{pmatrix} 2 & 3 \\ 5 & 7 \end{pmatrix}.$$

The command `BLOCKIFY_OPERATOR` returns four ambient 2×2 matrices. In target/source order, they are

$$T_{00} = \begin{pmatrix} -3 & 3 \\ 0 & 0 \end{pmatrix}, \quad T_{01} = \begin{pmatrix} 0 & -7 \\ 0 & 0 \end{pmatrix}, \quad T_{10} = \begin{pmatrix} 5 & -5 \\ 5 & -5 \end{pmatrix}, \quad T_{11} = \begin{pmatrix} 0 & 12 \\ 0 & 12 \end{pmatrix}.$$

Their sum is T. The exact reconstruction API returns:

```
{
  "operator": [
    [
      "2",
      "3"
    ],
    [
      "5",
      "7"
    ]
  ]
}
```

The input and output JSON files for this reconstruction are supplied in `examples/`. The reconstruction action performs the block sum. Its interpretation as recovery of the original operator uses the validated packet system and the way those blocks were formed.

5.3 Composing resolved operators

Now set

$$S = \begin{pmatrix} 11 & 13 \\ 17 & 19 \end{pmatrix}, \qquad ST = \begin{pmatrix} 87 & 124 \\ 129 & 184 \end{pmatrix}.$$

The runtime forms the blocks of S and T, then sums over the middle packet index. It compares the resulting array with the directly resolved product. The supplied worked output has `equals_direct: true`. The full block arrays are retained in `examples/composition.json`.

The comparison checks a concrete instance of the multiplication identity. The general identity follows from inserting the complete family between the factors, as in the source proof reproduced in Appendix A.

5.4 An intertwining computation

Let

$$U = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad Q_i = UP_iU^{-1}, \qquad S' = UTU^{-1} = \begin{pmatrix} 7 & 3 \\ 5 & 2 \end{pmatrix}.$$

The target packets are $Q_0 = \left(\begin{smallmatrix} 1 & -2 \\ 0 & 0 \end{smallmatrix}\right)$ and $Q_1 = \left(\begin{smallmatrix} 0 & 2 \\ 0 & 1 \end{smallmatrix}\right)$. The global identity is $UT = S'U$.

The recorded execution of `LOWER_INTERTWINER` returns true for both the global identity and the conjunction of the four local equations. Each local residual is the zero matrix. One complete local result is:

```
{
  "holds": true,
  "lhs": [
    [
      "-3",
      "3"
    ],
    [
      "0",
      "0"
    ]
  ],
  "residual": [
    [
```

```
      "0",
      "0"
    ],
    [
      "0",
      "0"
    ]
  ],
  "rhs": [
    [
      "-3",
      "3"
    ],
    [
      "0",
      "0"
    ]
  ],
  "source": 0,
  "target": 0
}
```

This example deliberately changes packet coordinates as well as the operator. The complete input and four outputs are retained in `examples/intertwining_input.json` and `examples/intertwining.json`.

5.5 Inspecting the dependency set

The API exposes the dependencies used by the intertwining record linked to the source:

```
python runtime/machine_api.py deps PSC-I-T-BLOCK-INTERTWINING --transitive
```

```
{
  "dependencies": [
    "PSC-I-D-ANALYSIS-SYNTHESIS",
    "PSC-I-D-PACKET-SYSTEM",
    "PSC-I-D-TRANSFER-BLOCK",
    "PSC-I-T-BLOCK-MULTIPLICATION",
    "PSC-I-T-EXACT-PACKET-COORDINATES",
    "PSC-I-T-OPERATOR-RECONSTRUCTION"
  ],
  "record": "PSC-I-T-BLOCK-INTERTWINING"
}
```

This is a dependency closure, not a newly generated proof. Reading each named record supplies its exact source statement, proof, and evidence coordinates.

6 Transport profiles in use

6.1 Finite packet multiplication

The packet-linear profile declares preservation of the direct operations required by packet multiplication. The command

```
python runtime/machine_api.py transport PSC-I-T-BLOCK-MULTIPLICATION profiles/packet_linear.json
```

returns:

```
{
```

```
  "boundary_guards": [],
  "not_preserved": [],
  "record": "PSC-I-T-BLOCK-MULTIPLICATION",
  "required_operations": [
    "composition",
    "finite_sum",
    "packet_idempotents",
    "transfer_blocks"
  ],
  "status": "PASS",
  "unknown": []
}
```

The pass applies to the listed operation flags. It does not construct the target packet system or independently check a concrete functor's preservation laws.

6.2 A countable result is blocked

Using the same profile for the countable unconditional packet theorem returns:

```
{
  "boundary_guards": [],
  "not_preserved": [
    "completion",
    "topology"
  ],
  "record": "PSC-I-T-COUNTABLE-UNCONDITIONAL-PACKETS",
  "required_operations": [
    "completion",
    "packet_idempotents",
    "topology"
  ],
  "status": "BLOCKED",
  "unknown": []
}
```

The profile does not preserve the topological and completion operations required by this gate. A finite linear profile therefore cannot be used to pass this countable request.

The source theorem additionally requires a real or complex Banach space, unconditional reconstruction, and a uniform multiplier bound. These hypotheses remain visible in its statement. Supplying permissive operation flags would not prove those hypotheses. The richer source contract and the narrower executable gate must be kept distinct.

6.3 Changing a profile without changing evidence

A profile file is a declaration supplied to the runtime. Editing its flags changes the gate's output. It does not create mathematical preservation evidence. A downstream system that wants a transport certificate must retain the arguments or formal certificates justifying those flags and the target hypotheses.

To use the gate, identify the exact record, inspect its source and dependency context, establish a target realization, justify the relevant preservation properties and hypotheses, then use the gate as an explicit consistency check. Its output can be attached to the resulting evidence record as one component.

7 Reproducing the computational material

7.1 Documented payload checks

From the runtime directory identified in the source register, use an interpreter containing SymPy:

```
python runtime/verify_release.py
python runtime/exact_fixture_suite.py
python runtime/nonzero_packet_regression.py
```

The first script checks entrypoint identity, record IDs, graph acyclicity and resolution, AST coverage, consistency of the action registry, source hash, selected API queries and actions, structured transport response, and fixture replay. The second emits the detailed fixture results. The latter does not replace a theorem prover.

7.3 A source change is a new evidence task

If a source statement changes, its source and statement identity change. The KIR, AST, dependency annotations, operation profile, formal map, and tests must be reviewed for impact. A recorded pass cannot be assigned to a new statement solely because the stable ID stayed the same.

The catalogue is generated from the archived mathematical source and records each statement and proof hash. The archived runtime payloads retain their own evidence. The additional traditional models and visual appendix are outside the 108-record inventory. They are not silently counted as extra machine records.

7.4 Runtime interfaces and mathematical statements

The source archive retains the computational source records. This companion supplies the statement catalogue and the runtime's exact transport-gate specification. Planner metadata remains distinct from executed proof machinery.

A Mathematical record catalogue

This catalogue is generated from the archived mathematical inventory's 108 stable records. Every statement and attached proof comes from that inventory. The source locator and statement hash identify the exact archived wording. Cross-references are linked to stable records in this catalog.

The formal-status line reports the reviewed correspondence map, not the older machine payload's eight-entry Lean map. Scope notes are part of each correspondence: "partial" is not a formal certificate for the complete source statement. The full declaration lists and source hashes are preserved in `formal/coverage/COVERAGE_108.json`.

The executable runtime contracts and runtime maps remain separate evidence for their stated scopes. Reproducing a source proof in this catalog does not give that proof a Lean certificate.

A.1 Foundations of seed generation

1. Coefficient and module regimes

Stable ID. `PSC-I-D-COEFFICIENT-REGIME`

Kind. definition

Statement.

All modules are left modules unless stated otherwise. The algebraic regime consists of a unital ring A and a unital left module M over A. When linear dimensions, tensor products, quivers, or operator blocks are used, A is a unital algebra over $\mathbb{k}$, where $\mathbb{k}$ is a field, and M is a vector space over $\mathbb{k}$. The topological regime consists of a Hausdorff topological vector space over a complete valued field, together with a unital algebra of continuous linear operators. Every infinite sum, completion, quotient topology, and closure below is interpreted only in the regime explicitly declared in its statement.

Formal correspondence. documentary. Regime declarations are distributed through Lean typeclass hypotheses, not one encoded regime object.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 7–10.

Statement SHA-256. `3350ba8d143f60c74ec0f3c1ea24b7208cc0346c6f292b8590f68a9520efd7cb`

2. Canonical theorem record

Stable ID. `PSC-I-D-THEOREM-RECORD`

Kind. definition

Statement.

A canonical theorem record is the tuple

$$(\mathrm{ID}, \mathrm{status}, \mathrm{hypotheses}, \mathrm{statement}, \mathrm{dependencies}, \mathrm{proof}, \mathrm{exports}, \mathrm{boundary}).$$

A downstream paper cites the stable record ID. A domain specialization may add domain hypotheses, but it does not repeat a generic proof from this paper.

Formal correspondence. documentary. Publication metadata. JSON records are not Lean proof declarations.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 14–22.

Statement SHA-256. `cd1763a1091beb27f77276664bfaa37d65f73f2b14b41b36f4b9692284853761`

3. Symbolic scope

Stable ID. `PSC-I-B-SYMBOLIC-SCOPE`

Kind. boundary

Statement.

This edition proves the algebraic and topological statements printed below. It does not assert historical novelty, independent external certification, automatic discovery of useful packet systems, nonlinear obstruction theory, multilevel refinement, arithmetic congruences, quantum gravity, automorphy, or local or global Langlands reciprocity.

Formal correspondence. scope boundary. Scope exclusion, not an additional positive theorem.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 25–28.

Statement SHA-256. `de436ff66bb1b236ea21bf9d3cf19c10b67981488cc3ab97eadc5b05708a39ba`

4. Typed operator grammar

Stable ID. `PSC-I-D-TYPED-GRAMMAR`

Kind. definition

Statement.

Let $Q = (Q_0, Q_1, s, t)$ be a quiver with finite vertex set. A typed operator grammar over $\Bbbk$ is a pair

$$\mathfrak{G} = (Q, I),$$

where $I \lhd \Bbbk Q$ is an ideal on both sides generated by linear combinations over $\Bbbk$ of paths having common source and common target. Write

$$\Lambda_{\mathfrak{G}} := \Bbbk Q / I.$$

A realization of $\mathfrak{G}$ is a family $(X_v)_{v \in Q_0}$ and linear maps

$$X_a : X_{s(a)} \longrightarrow X_{t(a)} \qquad (a \in Q_1)$$

that annihilate every relation in I. A morphism $f : X \to Y$ of realizations is a family of linear maps $f_v : X_v \to Y_v$ satisfying

$$f_{t(a)} X_a = Y_a f_{s(a)} \qquad (a \in Q_1).$$

Formal correspondence. definition represented. Finite vertex set, arbitrary arrow set, source/target maps, independent vector spaces and typed arrow maps; relations are finite linear combinations of paths with fixed endpoints. The more general free-algebra relation format is specialized both to homogeneous typed path relations and to all representatives of an actual TwoSidedIdeal.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 37–57.

Statement SHA-256. `282b22656cc22122458c5c399315c5468190e48cc5578ef5258b9a5246a905c9`

5. Collapsed one-space realization

Stable ID. `PSC-I-D-COLLAPSED-REALIZATION`

Kind. definition

Statement.

For a typed realization X, define its realization on a single space by

$$|X| := \bigoplus_{v \in Q_0} X_v.$$

Every vertex idempotent acts as a coordinate projector on $|X|$, and every path acts as a block operator from its source space to its target space.

Formal correspondence. definition represented. Total space is the finite product, canonically the finite direct sum. Vertex operators are single-after-projection maps and arrows are single-after-arrow-after-projection. Induction on the genuinely source/target-indexed TypedPath proves the actual block-composition action, including the zero-length vertex path.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 60–67.

Statement SHA-256. `79fcb85b9e889dae8d8305bb688123c8a54c9d9a18a5b86d37765b76b25a82aa`

6. Typed realization and module equivalence

Stable ID. `PSC-I-T-TYPED-MODULE-EQUIVALENCE`

Kind. theorem

Statement.

The category of realizations of $\mathfrak{G}$ is equivalent to the category of unital left modules over $\Lambda_{\mathfrak{G}}$. Explicitly, a realization X determines the collapsed space $|X|$ of `PSC-I-D-COLLAPSED-REALIZATION` with the vertex idempotent e_v acting as the coordinate projector onto X_v and each arrow acting in the block between its declared source and target. Conversely, a unital module M over $\Lambda_{\mathfrak{G}}$ determines the realization

$$M_v = e_v M, \qquad M_a(x) = ax.$$

The two constructions are inverse up to canonical natural isomorphism.

Proof. Because Q_0 is finite, $1 = \sum_{v \in Q_0} e_v$ in $\Bbbk Q$, the e_v are pairwise orthogonal, and the same identities hold in $\Lambda_{\mathfrak{G}}$. Given a realization, define the action of a path by composition of its arrow maps and extend linearly. Every element of I acts as zero, so the action factors through $\Lambda_{\mathfrak{G}}$. The vertex idempotents give

$$|X| = \bigoplus_v e_v|X| = \bigoplus_v X_v.$$

Conversely, if M is unital, then

$$M = 1M = \sum_v e_v M.$$

Orthogonality makes the sum direct. For an arrow $a : v \to w$, the identities $a = e_w a e_v$ imply

$$a(e_v M) \subseteq e_w M.$$

The relations in I act as zero because M is a module over $\Lambda_{\mathfrak{G}}$. Applying both constructions returns the original vertex spaces and arrow maps, or the original module decomposition, through the evident identity maps. These identifications commute with morphisms, giving an equivalence of categories. □

Formal correspondence. covered. The grammar algebra is constructed by FreeAlgebra and RingQuot, with complete orthogonal vertex idempotents and exact source/target arrow corners. Collapse is full, faithful and essentially surjective, using actual vertex ranges and their analysis/synthesis equivalence. Action objects are then proved equivalent to ordinary ModuleCat for all unital left modules; the coefficient action is recovered through algebraMap. A separate quotient comparison uses the actual TwoSidedIdeal ring congruence and proves both inverse identities. No category equivalence, split decomposition, path action or module structure is supplied as an assumption.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 70–80; proof lines 84–98.

Statement SHA-256. `a7fb9fcf8a2ff9a5b6ca94fba965afd801c3acb93f1fe6e0323b9fd3fab8470b`

7. Realized operator algebra

Stable ID. `PSC-I-D-REALIZED-ALGEBRA`

Kind. definition

Statement.

For a realization X, the realized operator algebra is

$$\mathcal{A}_X := \mathrm{im}(\Lambda_{\mathfrak{G}} \longrightarrow \mathrm{End}_{\Bbbk}(|X|)) .$$

It records the actual operators in the realization and may be a proper quotient of the abstract grammar algebra.

Formal correspondence. definition represented. The realized algebra is literally the range of the constructed algebra homomorphism into Module.End. It is not a supplied equivalent algebra or an abstract surrogate.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 114–121.

Statement SHA-256. `43b505da15a63ccf3534f295a12aaadd6cd3d7d4f7e2ab5dba25d3d5cf63d0bc`

8. Action factorization and hull invariance

Stable ID. `PSC-I-P-ACTION-FACTORIZATION`

Kind. proposition

Statement.

Let $S \subseteq |X|$. The generated submodule under the grammar algebra equals the generated submodule under the realized operator algebra:

$$\Lambda_{\mathfrak{G}} S = \mathcal{A}_X S.$$

Consequently, every statement about seed rank depends only on the realized action, not on redundant relations in a chosen presentation of the grammar.

Proof. The action map $\rho : \Lambda_{\mathfrak{G}} \twoheadrightarrow \mathcal{A}_X$ is surjective by definition and satisfies $\lambda s = \rho(\lambda)s$. Hence every grammar orbit vector lies in $\mathcal{A}_X S$. The reverse inclusion holds because every element of $\mathcal{A}_X$ is $\rho(\lambda)$ for some λ. □

Formal correspondence. covered. The two actual spans are compared by span induction and range-surjectivity. The cardinal seed ranks are equal via the identity semilinear bijection into the actual image algebra. Arbitrary seed sets and zero modules are included; there is no finite-generation assumption.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 124–131; proof lines 135–137.

Statement SHA-256. `472b9117cf7ed5ed76713d4b131141c2e9f00b9b6dd827bcb2515705d21e94f1`

9. Linear seed system

Stable ID. `PSC-I-D-SEED-SYSTEM`

Kind. definition

Statement.

A linear seed system is a tuple

$$\mathfrak{S} = (X, \mathcal{A}, S, \mathcal{P}, \tau),$$

where X is a unital left module over $\mathcal{A}$, $\mathcal{A}$ is fixed independently of the target element, $S = (s_1, \dots, s_r)$ is a finite distinguished seed family, $\mathcal{P}$ is either empty or a declared packet system, and τ is either the algebraic convention or a specified Hausdorff topology in which the declared operator action is continuous.

Formal correspondence. documentary. Algebraic and continuous packet cases are represented by concrete operator algebras, packet objects and arbitrary seed sets, which include every finite distinguished family after passage to its range. The record is a regime/data definition, not an assertion that one bundled structure covers the optional packet-free and topological regimes. Optional fields are represented in separate structures.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 145–152.

Statement SHA-256. `f1b9660868ad56e506bd33c2ab474312509199727cc8c23a64d4334641974e26`

10. Generated hull

Stable ID. `PSC-I-D-GENERATED-HULL`

Kind. definition

Statement.

For $S \subseteq X$, define

$$\mathrm{Hull}_{\mathcal{A}}(S) := \sum_{s \in S} \mathcal{A}s.$$

In the topological regime define

$$\mathrm{Hull}_{\mathcal{A},\tau}(S) := \overline{\mathrm{Hull}_{\mathcal{A}}(S)}^{\tau}.$$

For a singleton $S = \{s\}$, write $\mathrm{Hull}_{\mathcal{A}}(s)$.

Formal correspondence. definition represented. The scalar span of algebra-orbit vectors is proved equal as a set to the module span. The general topological operator hull is an actual Submodule and its topologicalClosure is used in the topological development.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 155–166.

Statement SHA-256. `859743fdac21ebb8ba120148cbf03f5511974f6e3356b5f733a3beea316b55f5`

11. Natural presentation

Stable ID. `PSC-I-D-NATURAL-PRESENTATION`

Kind. definition

Statement.

A seed presentation is natural relative to a declared grammar when the primitive operators and relations are fixed independently of the target, the relation system is finite or effectively enumerable, the topology is intrinsic to the realization, no primitive operator directly stores the complete target, and the presentation exposes a reusable invariant, theorem, or computation not encoded by a primitive chosen for the target.

Formal correspondence. documentary. A methodological criterion rather than a decidable Lean predicate.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 171–174.

Statement SHA-256. `94104ee5b6710359c3fa14a5febde34de8455668f83dfc5f49cf3e5028770033`

12. Algebra generation and module generation are distinct

Stable ID. `PSC-I-P-ALGEBRA-MODULE-GENERATION`

Kind. proposition

Statement.

Every nonzero unital algebra A, regarded as a left module over itself, has

$$\operatorname{srank}_A(A) = 1,$$

with cyclic seed 1_A. This conclusion is independent of the number of algebra generators required to present A as an algebra.

Proof. For every $a \in A$, one has $a = a1_A$. Hence $A1_A = A$. The number of operations needed to generate A as an algebra is a different invariant and does not enter the module calculation. □

Formal correspondence. covered. The regular action is multiplication on A. The singleton unit is proved generating by surjectivity of scalar evaluation; the nontrivial regular module then has seedRank exactly one. No assertion about algebra presentations is used as a premise.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 177–184; proof lines 188–190.

Statement SHA-256. `9ba2f9c1f32694b86a7d9ac63ef11d2b3c46ee5c38307f3abcc3c12048cf91d0`

13. Target-dependent operators

Stable ID. PSC-I-B-TARGET-DEPENDENT-OPERATORS

Kind. boundary

Statement.

For a fixed seed s and target x, the existence of a specially defined operator A_x satisfying $A_x s = x$ does not establish a natural seed calculus unless A_x belongs to a grammar fixed independently of the target satisfying PSC-I-D-NATURAL-PRESENTATION.

Formal correspondence. scope boundary. Target-independence restriction remains documentary.

Source locator. editable/traditional/02_foundations.tex; statement lines 192–195.

Statement SHA-256. aece204c76d6b378ec937375eebd02a43d0a48dbed1f94054b4ed514ef573dd1

14. Seed evaluation map

Stable ID. PSC-I-D-SEED-EVALUATION

Kind. definition

Statement.

Let A be a unital ring, let M be a left module over A, and let $S = (s_1, \dots, s_r) \in M^r$. Define the linear map over A

$$\varepsilon_S : A^{\oplus r} \longrightarrow M, \qquad (a_1, \dots, a_r) \longmapsto \sum_{j=1}^{r} a_j s_j.$$

Formal correspondence. definition represented. multiSeedMap is the actual Finsupp linear combination map; finite families give the stated finite free module.

Source locator. editable/traditional/02_foundations.tex; statement lines 215–223.

Statement SHA-256. db3e882c18dfdf5770d2779811295f6d287e9ffa95dbfb79bec513f96cba185d

15. Finite free presentation

Stable ID. PSC-I-T-FREE-PRESENTATION

Kind. theorem

Statement.

For the map in PSC-I-D-SEED-EVALUATION,

$$\operatorname{im} \varepsilon_S = \operatorname{Hull}_A(S), \qquad N_S := \operatorname{Ker} \varepsilon_S \leq A^{\oplus r},$$

and the induced map is an isomorphism of left modules over A

$$\boxed{A^{\oplus r} / N_S \cong \operatorname{Hull}_A(S).}$$

Consequently, S generates M if and only if ε_S is surjective.

Proof. The image consists exactly of finite sums $\sum_j a_j s_j$, which is $\operatorname{Hull}_A(S)$. Because ε_S is linear over A, its kernel is a left submodule. The first isomorphism theorem gives

$$A^{\oplus r} / N_S \cong \operatorname{im} \varepsilon_S = \operatorname{Hull}_A(S).$$

The final equivalence is the equality $\operatorname{im} \varepsilon_S = M$. □

Formal correspondence. covered. Actual range/span equality, quotient equivalence and generation/-surjectivity equivalence are present.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 226–239; proof lines 244–250.

Statement SHA-256. `6e2db91e9df6b69a04e531d9b552fe7148f878663bcd3600c36c94ac62592ef8`

16. Minimal free-cover characterization

Stable ID. `PSC-I-C-MINIMAL-FREE-COVER`

Kind. corollary

Statement.

For every finitely generated left module M over A,

$$\boxed{\operatorname{srank}_A(M) = \min\{r \geq 0 : \text{there exists a surjection } A^{\oplus r} \twoheadrightarrow M\}.}$$

Proof. A seed family of size r gives a surjection by `PSC-I-T-FREE-PRESENTATION`. Conversely, the images of the standard basis vectors under any surjection $A^{\oplus r} \twoheadrightarrow M$ form a generating family of size at most r. □

Formal correspondence. covered. seedFinrank_isLeast_free_surjection proves the finite minimum, not an executable basis algorithm.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 267–275; proof lines 279–281.

Statement SHA-256. `8e4ae31565265679e9c8bf397291baf65b396ad21bb88e7f00b8d17328b1cb00`

17. One-seed presentation

Stable ID. `PSC-I-C-ONE-SEED-PRESENTATION`

Kind. corollary

Statement.

For $s \in M$, the annihilator

$$\operatorname{Ann}_A(s) := \{a \in A : as = 0\}$$

is a left ideal and

$$\boxed{A/\operatorname{Ann}_A(s) \cong \operatorname{Hull}_A(s).}$$

Proof. The evaluation map for one seed is $a \mapsto as$. Its kernel is $\operatorname{Ann}_A(s)$, which is therefore a left ideal, and `PSC-I-T-FREE-PRESENTATION` gives the quotient isomorphism. □

Formal correspondence. covered. oneSeedMap has the stated annihilator kernel and its quotient is the literal cyclic range.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 283–293; proof lines 297–299.

Statement SHA-256. `92a43462490ec1465fe4129738284f9c3f53e2d8bb7b63f980c1d03a0fbbb2ed`

18. Two-sided annihilator criterion

Stable ID. `PSC-I-P-ANNIHILATOR-TWO-SIDED`

Kind. proposition

Statement.

For $s \in M$, the left ideal $L = \mathrm{Ann}_A(s)$ is an ideal on both sides if and only if

$$L\ \mathrm{Hull}_A(s) = 0.$$

If s is cyclic, these conditions are equivalent to

$$\mathrm{Ann}_A(s) = \mathrm{Ann}_A(M).$$

Proof. The left ideal L is an ideal on both sides exactly when $ab \in L$ for every $a \in L$ and $b \in A$. This is equivalent to

$$0 = (ab)s = a(bs) \qquad (a \in L,\ b \in A).$$

By additivity, the last identity is equivalent to $L\,\mathrm{Hull}_A(s) = 0$.

If s is cyclic, then $\mathrm{Hull}_A(s) = M$. Hence the preceding condition is $L \subseteq \mathrm{Ann}_A(M)$. The reverse inclusion always holds because an operator annihilating all of M annihilates s. Thus equality follows. Conversely, $\mathrm{Ann}_A(M)$ is an ideal on both sides, so equality implies that L is an ideal on both sides. □

Formal correspondence. covered. vectorAnnihilator is the actual kernel of a↦a•s. Right multiplication closure is equivalent to annihilating Submodule.span A {s}; Ideal.IsTwoSided supplies the standard two-sided-ideal interface. Under singleton generation, the actual ideal equals Module.annihilator A M. Noncommutative order is a*b and (a*b)•s=a•(b•s).

Source locator. `editable/traditional/02_foundations.tex`; statement lines 302–312; proof lines 316–325.

Statement SHA-256. `dd991bd6ce28ee7f94302ed9dd3fb00719cf26de3b6ccf740f441b118bdd8e54`

19. Completion of a dense free presentation

Stable ID. `PSC-I-T-COMPLETED-PRESENTATION`

Kind. theorem

Statement.

Let X be a complete Hausdorff locally convex space, let $\mathcal{A} \subseteq \mathrm{End}(X)$ act continuously, and let $S = (s_1, \dots, s_r)$. Put

$$E := \mathcal{A}^{\oplus r} / N_S$$

algebraically and let $j : E \to X$ be the injective map induced by ε_S. Give E the locally convex topology transported from $j(E)$, equivalently the topology generated by

$$\widetilde{p}(e) := p(j(e))$$

for the continuous seminorms p on X. Every $a \in \mathcal{A}$ acts continuously on E in the transported topology and therefore extends to $\widehat{E}$. If $\mathrm{Hull}_{\mathcal{A}}(S)$ is dense in X, then j extends uniquely to a topological isomorphism of modules over $\mathcal{A}$

$$\boxed{\widehat{E} \cong X.}$$

Proof. By PSC-I-T-FREE-PRESENTATION, j is an algebraic isomorphism of modules over $\mathcal{A}$ from E onto $\mathrm{Hull}_{\mathcal{A}}(S)$. The transported seminorms make it a topological isomorphism onto that subspace. For $a \in \mathcal{A}$ and a continuous seminorm p on X, continuity of $a : X \to X$ supplies continuous seminorms controlling $p(aj(e))$, so the induced action on E is continuous and extends uniquely to $\widehat{E}$. The subspace is dense by hypothesis. A Cauchy net in E is mapped to a Cauchy net in X, which converges because X is complete. This defines a continuous extension $\widehat{j} : \widehat{E} \to X$. For any $x \in X$, choose a net (e_λ) in E with $j(e_\lambda) \to x$. The transported topology makes (e_λ) Cauchy, so it converges to some $\xi \in \widehat{E}$, and continuity gives $\widehat{j}(\xi) = x$. Thus $\widehat{j}$ is surjective. If $\widehat{j}(\xi) = 0$, represent ξ by a Cauchy net (e_λ). Then $j(e_\lambda) \to 0$, so every defining seminorm $\widetilde{p}(e_\lambda)$ tends to zero. Thus $e_\lambda \to 0$ in the completion and $\xi = 0$. Hence $\widehat{j}$ is bijective. Its inverse is continuous by the universal property of completion, or directly because the topology on E was transported from X. □

Formal correspondence. covered. The actual finite free evaluation A^(Fin r)→X is used, its actual kernel is quotiented, and UniformSpace.comap pulls back the target uniformity to that quotient. Dense range is derived from dense module span. AbstractCompletion.compareEquiv supplies a uniform equivalence, linearity over A is proved by completion density, and uniqueness follows from equality on the dense image. Constant action uniform continuity is inherited through the actual quotient embedding; scalar action on Completion is the usual extension. The local-convexity pullback lemma uses ordered scalars (in particular ℝ, including underlying real spaces for complex spaces); the stronger uniform-module completion proof does not require local convexity.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 333–347; proof lines 351–353.

Statement SHA-256. `23708a85485e7162e31b64ee0a8fb316bec231a1aadaa0e00f0a08f70dfe1721`

20. Seed rank

Stable ID. PSC-I-D-SEED-RANK

Kind. definition

Statement.

For a unital left module M over A, define

$$\mathrm{srank}_A(M) := \min\{|S| : AS = M\}.$$

For a topological module (X, τ), define

$$\mathrm{srank}_{\mathcal{A},\tau}(X) := \min\{|S| : \overline{AS}^{\tau} = X\}.$$

Set $\mathrm{srank}_A(0) = 0$. When the value is finite, it is the minimal number of module generators.

Formal correspondence. definition represented. The operator hull is the scalar span of actual action values; for an acting algebra this is AS. The cardinal infimum ranges over all densely generating subsets, and existence of a minimum is proved from identity membership and cardinal well ordering.

Empty generators and infinite cardinals are included. The direct moduleSeedRank definition uses Dense of the literal acting-ring module span, and a proved equality identifies it with the integer-linear operator-family definition even for a nonfaithful action.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 370–381.

Statement SHA-256. `81a23b39cf2b6194ae8b0bc84ac270ee5ef86e4703b5fb5411f5fa9519aafae9`

21. Cyclic characterization

Stable ID. `PSC-I-P-CYCLIC-CHARACTERIZATION`

Kind. proposition

Statement.

For $M \neq 0$,

$$\operatorname{srank}_A(M) = 1 \quad \Longleftrightarrow \quad M \text{ contains a cyclic vector.}$$

Proof. Both conditions say that there is $m \in M$ with $Am = M$. □

Formal correspondence. covered. The nontriviality hypothesis agrees with the current publication.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 384–392; proof lines 396–398.

Statement SHA-256. `de62f3fddcf5cefb429536723a8933a119585faa47b6f2e51745ea055ae6a9cc`

22. Monotonicity under enlargement of the acting algebra

Stable ID. `PSC-I-P-ACTING-ALGEBRA-MONOTONICITY`

Kind. proposition

Statement.

Let $B \subseteq A \subseteq \operatorname{End}_{\mathbb{k}}(X)$ be unital operator algebras with the same identity. Then

$$\boxed{\operatorname{srank}_A(X) \leq \operatorname{srank}_B(X).}$$

The same statement holds for topological seed rank when both algebras act continuously.

Proof. For every $S \subseteq X$, one has $BS \subseteq AS$. Hence every generating family over B is also a generating family over A. Taking closures gives the topological statement. □

Formal correspondence. covered. For unital operator algebras, actual family inclusion implies operator-hull inclusion. Closure monotonicity transports a minimum generating subset. This exactly supplies the topological clause, combined with the previously mapped algebraic semilinear rank theorem.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 400–407; proof lines 411–413.

Statement SHA-256. `115d0049078122c1d6c43bb8ec53237a6efae32ef13330b8e31d8bf77e68eb56`

23. Quotient monotonicity

Stable ID. `PSC-I-T-QUOTIENT-MONOTONICITY`

Kind. theorem

Statement.

Let $\varphi : A \to B$ be a unital ring homomorphism and let

$$\Phi : M \twoheadrightarrow N$$

be a surjective additive map satisfying

$$\Phi(am) = \varphi(a)\Phi(m) \qquad (a \in A,\ m \in M).$$

Then

$$\boxed{\operatorname{srank}_B(N) \le \operatorname{srank}_A(M).}$$

If M and N are topological modules, Φ is continuous and surjective, and the actions are continuous, then

$$\operatorname{srank}_{B,\tau_N}(N) \le \operatorname{srank}_{A,\tau_M}(M).$$

Proof. Let S generate M. For every $n \in N$, choose $m \in M$ with $\Phi(m) = n$ and write $m = \sum_i a_i s_i$. Then

$$n = \sum_i \varphi(a_i)\Phi(s_i),$$

so $\Phi(S)$ generates N.

For the topological statement, let S generate M densely. Given $n = \Phi(m)$, choose a net $m_\lambda \in AS$ converging to m. Continuity gives

$$\Phi(m_\lambda) \longrightarrow n,$$

and every $\Phi(m_\lambda)$ lies in $B\Phi(S)$. Thus $B\Phi(S)$ is dense in N. □

Formal correspondence. covered. The new theorem starts with the printed arbitrary unital ring homomorphism, additive map, scalar compatibility, continuity, and surjectivity. Span induction maps the actual source module span into the target module span; continuous surjectivity transports density. An attained minimum generating set maps to an image of no larger cardinality. No ring-homomorphism surjectivity or faithfulness is assumed. The direct module-span rank is proved equal to the earlier operator-family rank using integer-linear acting operators. This supplies the exact topological clause alongside the separately accepted algebraic theorem.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 421–440; proof lines 445–457.

Statement SHA-256. `ccde1353d26e9f7bc7aef341c35be5304729daa69f8f42274ab70e2f9d7016a7`

24. Isomorphism invariance

Stable ID. PSC-I-C-ISOMORPHISM-INVARIANCE

Kind. corollary

Statement.

An intertwining module isomorphism preserves algebraic seed rank. A topological intertwining isomorphism preserves topological seed rank.

Proof. Apply PSC-I-T-QUOTIENT-MONOTONICITY to the isomorphism and its inverse. □

Formal correspondence. covered. A continuous semilinear module equivalence with continuous inverse preserves the direct module-span cardinal rank, by applying the exact semilinear surjection inequality in both directions. The same-ring case uses identity ring maps. The earlier bidirectional operator-family theorem covers intertwining operator-algebra isomorphisms, and the new rank equality bridges these definitions. This supplies the exact topological clause alongside separately accepted algebraic invariance.

Source locator. editable/traditional/02_foundations.tex; statement lines 464–467; proof lines 471–473.

Statement SHA-256. fc01d1773cdeebcaba8346b323df6df33d48e0f6f7adda763b14307b2e902ca1

25. Short exact sequence bounds

Stable ID. PSC-I-T-EXACT-SEQUENCE-BOUNDS

Kind. theorem

Statement.

Let

$$0 \longrightarrow L \xrightarrow{\iota} M \xrightarrow{\pi} N \longrightarrow 0$$

be a short exact sequence of left modules over A. Then

$$\boxed{\operatorname{srank}_A(N) \leq \operatorname{srank}_A(M) \leq \operatorname{srank}_A(L) + \operatorname{srank}_A(N).}$$

Proof. The lower inequality is quotient monotonicity. For the upper inequality, choose generating families $(\ell_i)_{i\in I}$ of L and $(n_j)_{j\in J}$ of N with the least possible cardinalities. Choose a lift $m_j \in M$ of each n_j. For any $m \in M$, a finite subset $F \subseteq J$ and coefficients $a_j \in A$ give

$$\pi(m) = \sum_{j\in F} a_j n_j.$$

The vector $m - \sum_{j\in F} a_j m_j$ belongs to $\iota(L)$, so it is a finite linear combination of the $\iota(\ell_i)$. The union of the lifted family and the image of the generating family of L therefore generates M. Its cardinality is at most $|I| + |J|$, giving the upper bound. This argument uses finite sums for each vector even when either generating family is infinite. □

Formal correspondence. covered. Actual linear f,g with injectivity, range f=ker g and surjectivity; canonical seedRank=top.spanRank. Minimum generators of N are lifted and combined with images of

minimum generators of L. The proof derives generation of M and the cardinal upper bound; the lower bound is surjective monotonicity. No splitting, finite generation or desired bound is assumed.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 475–488; proof lines 492–498.

Statement SHA-256. `2e4e5af8593f49860709b8eb0b2d2b88577c0bc765a8b9e0c086441aaf142348`

26. Shared direct-sum bounds

Stable ID. `PSC-I-P-SHARED-DIRECT-SUM`

Kind. proposition

Statement.

If one algebra A acts diagonally on $M \oplus N$, then

$$\boxed{\max\{\operatorname{srank}_A(M), \operatorname{srank}_A(N)\} \le \operatorname{srank}_A(M \oplus N) \le \operatorname{srank}_A(M) + \operatorname{srank}_A(N).}$$

Proof. The coordinate projections are intertwining quotients and give the lower bound. For the upper bound, embed minimal generating families of M as $(m_i, 0)$ and of N as $(0, n_j)$. Their union generates by finite sums and has cardinality at most the sum of the two seed ranks. □

Formal correspondence. covered. The actual diagonal A-action on M×N realizes the binary direct sum. Projection surjectivity gives both lower bounds; inclusion of generating sets in the two factors yields cardinal addition for the upper bound.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 506–516; proof lines 520–522.

Statement SHA-256. `613d0bed5e9f4890c069d8d37670d0b8c9cb3a981df5bceb95686c08dc5638c6`

27. Independent direct-sum formula

Stable ID. `PSC-I-T-INDEPENDENT-DIRECT-SUM`

Kind. theorem

Statement.

Let M be a left module over A and N a left module over B. Under the action of the product algebra

$$(a, b)(m, n) = (am, bn),$$

one has

$$\boxed{\operatorname{srank}_{A\times B}(M \oplus N) = \max\{\operatorname{srank}_A(M), \operatorname{srank}_B(N)\}.}$$

Proof. The coordinate projections give the lower bound. Let r be the maximum on the right, regarded as a cardinal, and choose an index set I of cardinality r. Choose minimal generating families for M and N, index them by subsets of I, and fill any unused positions with zeros. Write the resulting families as $(m_i)_{i\in I}$ and $(n_i)_{i\in I}$. For any $m \in M$ and $n \in N$, their finite expressions involve a common finite subset $F \subseteq I$ after zero coefficients have been added. Thus

$$m = \sum_{i\in F} a_i m_i, \qquad n = \sum_{i\in F} b_i n_i,$$

and

$$(m, n) = \sum_{i \in F} (a_i, b_i)(m_i, n_i).$$

The family of paired vectors generates and has cardinality at most r. The empty family handles the case in which both modules are zero. □

Formal correspondence. covered. Actual product-algebra action and the maximum formula are proved.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 524–538; proof lines 542–554.

Statement SHA-256. `b6f497941ccc0be69e3780d70cd1d79cb39363dedb591b81527183724fc58748`

28. Tensor-product bound

Stable ID. `PSC-I-P-TENSOR-BOUND`

Kind. proposition

Statement.

Let A and B be unital algebras over $\mathbb{k}$, let M be a left module over A, and let N be a left module over B. Under the natural $A \otimes_{\mathbb{k}} B$ action,

$$\boxed{\operatorname{srank}_{A \otimes B}(M \otimes_{\mathbb{k}} N) \leq \operatorname{srank}_A(M) \operatorname{srank}_B(N).}$$

Proof. Choose minimal generating families $(m_i)_{i \in I}$ for M and $(n_j)_{j \in J}$ for N. Each vector in either module is a finite linear combination of its generators. Bilinearity therefore expresses every simple tensor as a finite sum of terms

$$(am_i) \otimes (bn_j) = (a \otimes b)(m_i \otimes n_j).$$

Simple tensors span the algebraic tensor product, so the family $(m_i \otimes n_j)_{(i,j) \in I \times J}$ generates it. This family has cardinality at most $|I||J|$, which is the claimed bound. The proof also covers an empty generating family, when the corresponding module and tensor product are zero. □

Formal correspondence. covered. The genuine tensor-product action and cardinal product upper bound are proved.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 557–567; proof lines 571–577.

Statement SHA-256. `b1b31d79b3ffc3d73319922c4a3f2f1dde12a0f774ceda1ae29227e9c63a6d4e`

29. Tensor rank is not generally multiplicative

Stable ID. PSC-I-B-TENSOR-NONEQUALITY

Kind. boundary

Statement.

The inequality in PSC-I-P-TENSOR-BOUND can be strict. Equality requires additional hypotheses on the acting algebras and their module multiplicities and is not exported as a universal law.

Formal correspondence. scope boundary. No universal tensor equality is exported. This boundary is not counted as a positive theorem.

Source locator. editable/traditional/02_foundations.tex; statement lines 584–587.

Statement SHA-256. 9328501ddd219b9e0defabc4233a3e0c6437a8890f6920385de876bc5223e204

30. Scalar-extension monotonicity

Stable ID. PSC-I-P-SCALAR-EXTENSION-MONOTONICITY

Kind. proposition

Statement.

Let $K/\Bbbk$ be a field extension, let A be a unital algebra over $\Bbbk$, and let M be a finitely generated left module over A. Set

$$A_K := K \otimes_{\Bbbk} A, \qquad M_K := K \otimes_{\Bbbk} M.$$

Then

$$\boxed{\operatorname{srank}_{A_K}(M_K) \le \operatorname{srank}_A(M).}$$

Every generating family $S \subseteq M$ extends to the generating family $1 \otimes S \subseteq M_K$.

Proof. Let $S = \{s_1, \dots, s_r\}$ generate M. Every pure tensor $\lambda \otimes m \in M_K$ has an expression

$$m = \sum_{i=1}^{r} a_i s_i,$$

so

$$\lambda \otimes m = \sum_{i=1}^{r} (\lambda \otimes a_i)(1 \otimes s_i).$$

Pure tensors span M_K, hence $1 \otimes S$ generates M_K over A_K. Taking the minimum over S proves the inequality. □

Formal correspondence. covered. The source constructs the natural (K⊗k A)-action on K⊗k M using commuting tensor-factor actions and proves (c⊗a)•(d⊗m)=(c*d)⊗(a•m). Tensor and span induction prove the literal image (1⊗-) of any generating set generates. Minimum-cardinality generation plus cardinality of an image gives the rank inequality.

Source locator. editable/traditional/02_foundations.tex; statement lines 592–607; proof lines 612–624.

Statement SHA-256. 89013f407adf17424cd55db8a6f59a4a9141e34d39a1d350731d9e18d542a3e4

Stable ID. `PSC-I-D-SEED-RANK-WITNESS`

Kind. definition

Statement.

A surjective intertwiner $\Phi : M \twoheadrightarrow N$ is a witness for seed rank of order r when $\operatorname{srank}(N) = r$. It certifies $\operatorname{srank}(M) \geq r$.

Formal correspondence. documentary. A named use of the quotient lower bound, not a new proof target.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 632–635.

Statement SHA-256. `81381ceea3d420ff6ba2f0b9378863598308dc392cf597cc1dc0b4d7f84f7cc0`

32. Scalar quotient witness

Stable ID. `PSC-I-P-SCALAR-QUOTIENT-WITNESS`

Kind. proposition

Statement.

Let M be a module over A with coefficient field $\Bbbk$. Suppose M has a quotient N of dimension r on which A acts through a character

$$\chi : A \longrightarrow \Bbbk.$$

Then

$$\boxed{\operatorname{srank}_A(M) \geq r.}$$

Proof. For every $n \in N$, the cyclic submodule An is contained in the scalar span $\Bbbk n$. Therefore q seed images span a subspace of dimension at most q. Generating the quotient of dimension r requires at least r seeds. Quotient monotonicity transfers the lower bound to M. □

Formal correspondence. covered. The character, surjective semilinear map and finite scalar dimension match the printed hypotheses.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 638–648; proof lines 652–654.

Statement SHA-256. `92e35ac7e226b34fce4aa0e1e40a198c1273cc439ac42a8ea2f437f75965a632`

33. Nakayama lemma

Stable ID. `PSC-I-CI-NAKAYAMA`

Kind. classicalinput

Statement.

Let A be a unital ring, let $J \subseteq \mathrm{Jac}(A)$, and let M be a finitely generated left module over A. If $M = N + JM$ for a submodule $N \leq M$, then $M = N$.

Formal correspondence. classical input integrated. The noncommutative input is integrated at the printed finitely generated left-module scope. For any left ideal I contained in Ring.jacobson R, the actual submodule equality N ⊔ I • top = top implies N = top. No commutativity, Noetherian, semisimplicity, finite length, or two-sidedness of I is required for this lifting theorem. The proof derives the radical lifting result from maximal submodules and the ring-radical action inclusion, rather than assuming the desired conclusion.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 669–672.

Statement SHA-256. `68901a557c34762568711f0e6c8b400485a0c4b66477b8f231e899d9a48f5878`

34. Generator number is detected modulo the Jacobson radical

Stable ID. `PSC-I-T-MODULE-TOP`

Kind. theorem

Statement.

Let A be a unital ring, let $J = \mathrm{Jac}(A)$, and let M be a finitely generated left module over A. A family $S \subseteq M$ generates M if and only if its image generates M/JM as a module over A/J. When A/J is semisimple Artinian, this quotient is the usual semisimple top. No semisimplicity of A/J is required for the general equality. Consequently,

$$\boxed{\mathrm{srank}_A(M) = \mathrm{srank}_{A/J}(M/JM).}$$

Proof. If S generates M, its image generates every quotient. Conversely, suppose the image of S generates M/JM and put $N = AS$. Then

$$M = N + JM.$$

Nakayama's lemma gives $M = N$. Thus the same finite families generate before and after passage to the top, and the minimal cardinalities agree. □

Formal correspondence. covered. The complete generating-set/family equivalence and canonical cardinal seedRank equality are proved for arbitrary unital rings and finitely generated left modules using the literal M / (Jac(R) • top), its actual scalar action over R / Jac(R), and an exact quotient-map kernel. Any lifts of a generating quotient family generate upstairs, and both minimum-cardinality inequalities are established. The natural seedFinrank equality is proved as well. No semisimplicity hypothesis is needed. The descriptive semisimple-top sentence is covered by the pinned general IsSemisimpleRing.isSemisimpleModule instance applied to this actual quotient module. This is not an algorithm for computing the radical or finding generators.

Kind. corollary

Statement.

Let A be a local ring with Jacobson radical J and residue division ring $D = A/J$. For every finitely generated left module M over A,

$$\boxed{\operatorname{srank}_A(M) = \dim_D(M/JM),}$$

where the dimension is that of a left vector space over D.

Proof. The module M/JM over A/J is a left vector space over D. Its minimal number of generators is its dimension over D. □

Formal correspondence. covered. The local formula is proved for noncommutative local rings and finitely generated left modules. From IsLocalRing R the source proves uniqueness of the maximal left ideal, identifies the actual Jacobson radical as maximal, constructs DivisionRing (R / Jac(R)) internally, and proves the canonical seedRank equals the left vector-space Module.rank of the actual radical quotient. The natural finite-rank equality is also proved. No commutative residue-field surrogate or caller-supplied division-ring certificate is used.

Statement SHA-256. `50bd885a16ef40862a42e9ddd15b7dd03758b5ee514ee98aab28acf22c1e26ed`

36. Wedderburn–Artin decomposition

Stable ID. `PSC-I-CI-WEDDERBURN-ARTIN`

Kind. classicalinput

Statement.

Every semisimple Artinian ring is isomorphic to a finite product

$$A \cong \prod_{i=1}^{q} M_{d_i}(D_i)$$

of full matrix rings over division rings.

Formal correspondence. classical input integrated. The actual arbitrary-division-ring Wedderburn-Artin existence theorem is now integrated at its semisimple-ring scope. The finite-algebra radical quotient is proved semisimple and its actual decomposition is constructed. These depend on proved pinned Mathlib results, not a custom existence axiom. Compatible finite module decompositions are separately constructed in ProductPresentation and SemisimpleExistence.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 727–734.

Statement SHA-256. `effdfe288b991fcc5cdf7549800403bbb6fd698be57f017880428042cc23a058`

37. Regular-module multiplicities

Stable ID. `PSC-I-L-REGULAR-MODULE-MULTIPLICITIES`

Kind. lemma

Statement.

Let

$$A = \prod_{i=1}^{q} M_{d_i}(D_i)$$

and let $S_i = D_i^{d_i}$ denote the natural simple left module for the ith factor, extended by zero across the other factors. Then, as a left module over A,

$$\boxed{A \cong \bigoplus_{i=1}^{q} S_i^{\oplus d_i}.}$$

Proof. For one factor $M_d(D)$, let e_{jj} be the diagonal matrix units. The left regular module decomposes as

$$M_d(D) = \bigoplus_{j=1}^{d} M_d(D)e_{jj}.$$

Each minimal left ideal $M_d(D)e_{jj}$ is isomorphic to the natural column module D^d. Taking the direct product of factors gives the stated decomposition. □

Formal correspondence. covered. The actual left regular module is explicitly equivalent to its natural columns, then to the displayed finite direct sum of natural-module copies over arbitrary division rings. Coordinate ring homomorphisms define the inflated actions, other factors act by zero, and positive-dimensional natural factors are proved simple. No transpose-as-ring-map or commutative-scalar shortcut is used. Finite products for the inner repeated copies are the canonical finite direct-sum model.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 737–747; proof lines 751–757.

Statement SHA-256. `cd1bf9aa7ec7ad71f24491e1969c318f330a268fb73a29873ff2e9494eb91799`

38. Semisimple seed-rank formula over arbitrary division rings

Stable ID. PSC-I-T-SEMISIMPLE-SEED-RANK

Kind. theorem

Statement.

Let

$$A \cong \prod_{i=1}^{q} M_{d_i}(D_i)$$

be semisimple Artinian and let

$$M \cong \bigoplus_{i=1}^{q} S_i^{\oplus m_i}$$

be a finitely generated left module over A. Then

$$\boxed{\operatorname{srank}_A(M) = \max_{1 \le i \le q} \left\lceil \frac{m_i}{d_i} \right\rceil .}$$

If A is any algebra of finite dimension over a field, the same formula applied to the decomposition of $M/\operatorname{Jac}(A)M$ over $A/\operatorname{Jac}(A)$ computes $\operatorname{srank}_A(M)$.

Proof. By PSC-I-C-MINIMAL-FREE-COVER, M is generated by r elements exactly when it is a quotient of $A^{\oplus r}$. By PSC-I-L-REGULAR-MODULE-MULTIPLICITIES,

$$A^{\oplus r} \cong \bigoplus_{i} S_i^{\oplus r d_i}.$$

Every short exact sequence of modules over a semisimple ring splits. Therefore a quotient isomorphic to M exists if and only if

$$m_i \le r d_i \qquad \text{for every } i.$$

The smallest such r is the displayed maximum. For a nonsemisimple algebra of finite dimension, PSC-I-T-MODULE-TOP reduces the calculation to the semisimple module $M/\operatorname{Jac}(A)M$ over $A/\operatorname{Jac}(A)$. □

Formal correspondence. covered. Actual product matrix ring with left multiplication and natural column modules acted on through the matching factor. Semilinear eM along eR enforces compatibility. DivisionRows proves left generation iff row spanning and m<=r*d; standard rows prove sufficiency. Product assembly, column rearrangement and seed-rank invariance prove the formula. RadicalTop is literally M/(Jac(R) smul top); existence constructs decompositions.

Source locator. editable/traditional/02_foundations.tex; statement lines 759–779; proof lines 784–795.

Statement SHA-256. c604c6473ceeb6b651f37301bd3e719d69a555f04c9e4aea5fa6ad49bcd35de4

39. Algebraically closed multiplicity formula

Stable ID. PSC-I-C-ALGEBRAICALLY-CLOSED-FORMULA

Kind. corollary

Statement.

Let $\Bbbk$ be algebraically closed, let A be a unital algebra of finite dimension over $\Bbbk$, put $J = \mathrm{Jac}(A)$, and let M be a finitely generated left module over A. Assume compatible decompositions indexed by an integer $q \geq 0$:

$$A/J \cong \prod_{i=1}^{q} M_{d_i}(\Bbbk), \qquad M/JM \cong \bigoplus_{i=1}^{q} (\Bbbk^{d_i})^{\oplus m_i},$$

where the d_i are positive integers and the m_i are nonnegative integers. The first isomorphism is an isomorphism of algebras over $\Bbbk$. The second is an isomorphism of left modules over A/J, using the natural column module for each matrix factor and zero action from the other factors. Then

$$\mathrm{srank}_A(M) = \max_{1 \leq i \leq q} \left\lceil \frac{m_i}{d_i} \right\rceil,$$

with $\max \varnothing = 0$ when $q = 0$.

Proof. By PSC-I-T-MODULE-TOP, $\mathrm{srank}_A(M) = \mathrm{srank}_{A/J}(M/JM)$. Apply PSC-I-T-SEMISIMPLE-SEED-RANK to the displayed decompositions of A/J and M/JM, with every $D_i = \Bbbk$. This gives the stated maximum. If $q = 0$, the unital A/J-module M/JM is zero, and PSC-I-T-MODULE-TOP gives seed rank zero. □

Formal correspondence. covered. Correct public map uses decomposition of A/J, not A. The supplied algebra equivalence forgets to a ring equivalence, and the module decomposition stays compatible. Specializing the exact radical-top theorem to all D_i=k gives the current statement.

Source locator. editable/traditional/02_foundations.tex; statement lines 809–822; proof lines 826–828.

Statement SHA-256. 20c07c2db5ab4c4a956355fe5e45008edff100a4b279dd27a37ddff90871fcbf

40. Full matrix algebra

Stable ID. PSC-I-C-FULL-MATRIX

Kind. corollary

Statement.

For the natural module $S = D^d$ over $M_d(D)$,

$$\mathrm{srank}_{M_d(D)}(S) = 1.$$

More strongly, every nonzero vector of S is cyclic.

Proof. The formula gives $\lceil 1/d \rceil = 1$. Directly, let $v \neq 0$ and choose a coordinate $v_j \neq 0$. For any target $w = (w_i)$, the matrix whose jth column has entries $w_i v_j^{-1}$ and whose other columns vanish sends v to w. □

Formal correspondence. covered. For every division ring and positive matrix size, the natural module has canonical seed rank one and every nonzero vector generates. The proof uses entries w_i / v_j with the inverse on the correct right side. The positive-size convention of the surrounding natural-simple-module discussion is essential: size zero has seed rank zero. This guard remains explicit in Lean and is tested, not silently discarded.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 830–837; proof lines 841–843.

Statement SHA-256. `f22f88ae7b9fe79b50f6c82420d301d784c941d6340fc700723841d724826055`

41. Multiplicity obstruction

Stable ID. `PSC-I-C-MULTIPLICITY-OBSTRUCTION`

Kind. corollary

Statement.

For the diagonal action of $M_d(D)$ on $S^{\oplus m}$,

$$\boxed{\operatorname{srank}_{M_d(D)}(S^{\oplus m}) = \left\lceil \frac{m}{d} \right\rceil .}$$

Proof. Apply `PSC-I-T-SEMISIMPLE-SEED-RANK` to the single simple type with multiplicity m. □

Formal correspondence. covered. For arbitrary division rings and positive block size, the actual shared matrix action on m natural-module copies has canonical rank ceil(m/d). The rectangular-matrix, natural-column-product and finite-direct-sum formulations are connected by actual module equivalences. Zero multiplicity is included. This is not the independent-factor action, whose bound is a maximum across distinct factors.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 845–855; proof lines 859–861.

Statement SHA-256. `df87d9465fd05e359ca1a96ba5b69e501f5e6b9b93b2d4e1b555a84476ec84ef`

42. Primary decomposition for polynomial modules

Stable ID. `PSC-I-CI-PID-PRIMARY-DECOMPOSITION`

Kind. classicalinput

Statement.

Every module X over $\mathbb{k}[t]$ with finite dimension over the coefficient field decomposes as

$$X = \bigoplus_{p \in \operatorname{Irr}(\mathbb{k}[t])} X_p,$$

where $\operatorname{Irr}(\mathbb{k}[t])$ denotes the monic irreducible polynomials, only finitely many components are nonzero, and every nonzero X_p is a finite direct sum of modules $\mathbb{k}[t]/(p^e)$.

Formal correspondence. classical input integrated. For an existing polynomial module, multiplication by X constructs its evaluation operator and an actual polynomial-linear equivalence; finite coefficient dimension gives torsion. PID decomposition constructs positive elementary divisors, while actual

intrinsic primary submodules are proved equal to ideal primary components. PolynomialMonic proves a bijection between monic irreducibles and nonzero prime ideals via p↦(p), deriving injectivity from monicity and surjectivity from a normalized PID prime generator. It reindexes the internal sum and finite nonzero support to precisely the manuscript index set. intrinsic_primary_finite_power_sum is a literal finite DirectSum of k[X]/(p^e), with positive e, for each specified irreducible p.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 883–890.

Statement SHA-256. `446dc677476b213cc4daac554de2b3f15ab816c9d0d6eeff98a67965eea843a9`

43. Single-operator seed rank

Stable ID. `PSC-I-T-SINGLE-OPERATOR`

Kind. theorem

Statement.

Let X have finite dimension over $\mathbb{k}$ and let $T \in \mathrm{End}_{\mathbb{k}}(X)$. Regard X as a module over $\mathbb{k}[t]$ by $t \cdot x = Tx$. For every monic irreducible p, let X_p be the primary component for p and set

$$\mu_p(T) := \dim_{\mathbb{k}[t]/(p)}(X_p / p(T)X_p).$$

Then

$$\boxed{\mathrm{srank}_{\mathbb{k}[T]}(X) = \max_p \mu_p(T).}$$

Moreover, $\mu_p(T)$ is the number of cyclic primary summands for p in the decomposition into elementary divisors of X_p.

Proof. Let the minimal polynomial be

$$m_T(t) = \prod_p p(t)^{e_p}.$$

The acting algebra is

$$\mathbb{k}[T] \cong \mathbb{k}[t]/(m_T) \cong \prod_p R_p, \qquad R_p := \mathbb{k}[t]/(p^{e_p}),$$

by the Chinese remainder theorem. The factor R_p acts on X_p and annihilates every other primary component. Hence the formula for a direct sum with independent actions gives

$$\mathrm{srank}_{\mathbb{k}[T]}(X) = \max_p \mathrm{srank}_{R_p}(X_p).$$

Each R_p is local with maximal ideal generated by the class of p and residue division field $K_p = \mathbb{k}[t]/(p)$. By `PSC-I-C-LOCAL-ALGEBRA-FORMULA`,

$$\mathrm{srank}_{R_p}(X_p) = \dim_{K_p} X_p / p(T)X_p = \mu_p(T).$$

Finally, every summand $\mathbb{k}[t]/(p^e)$ contributes one copy of K_p after quotienting by p, so the dimension equals the number of summands in the elementary divisor decomposition. □

Formal correspondence. covered. The full printed statement is now mapped. The actual power-annihilation submodule is proved equal to the ideal primary component. Its inclusion into V/pV

has exact kernel pX_p and is onto from the internally discharged Artinian hypothesis. The induced quotient equivalence is residue-field linear. Every intrinsic multiplicity is identified with every actual presentation fibre. The grouped factors are proved to be the literal X_p, and any positive primary decomposition of X_p has the same intrinsic count. The presentation-free maximum over all monic irreducibles is proved bounded and attained, and equals both natural-valued and cardinal-valued seed rank. No caller-supplied decomposition or seed-count conclusion is needed by the public maximum theorem. These are noncomputable mathematical constructions. The printed proof uses a different route through local-module/Nakayama machinery; that separately listed machinery is not thereby marked complete.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 893–907; proof lines 914–939.

Statement SHA-256. `e96051e5d8333ea1ba1efe94f70b260ad356a41bc5ecad49525ec1df9c759967`

44. Invariant-factor count

Stable ID. `PSC-I-C-INVARIANT-FACTOR-COUNT`

Kind. corollary

Statement.

If $X \neq 0$ and the rational canonical decomposition is written with nonconstant invariant factors

$$X \cong \bigoplus_{j=1}^{r} \mathbb{k}[t]/(f_j), \qquad f_1 \mid f_2 \mid \cdots \mid f_r,$$

then

$$\boxed{\operatorname{srank}_{\mathbb{k}[T]}(X) = r.}$$

Proof. For each irreducible p, the number of invariant factors divisible by p equals the number of elementary divisors for p. Because $f_1 \mid \cdots \mid f_r$ and $f_1 \neq 1$ after zero summands are removed, some irreducible divisor of f_1 divides all r invariant factors. Hence $\max_p \mu_p(T) = r$. □

Formal correspondence. covered. Complete at the displayed conditional scope: an actual polynomial-module equivalence to the finite product of nonconstant factors and their divisibility chain imply least seed number, natural seed rank and cardinal seed rank equal the factor count. The theorem also handles the empty product. Finite products and finite direct sums represent the same finite decomposition. Existence of an ordered invariant-factor presentation is not asserted by this declaration, and is not an additional hypothesis-free claim of the printed conditional corollary.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 951–963; proof lines 967–969.

Statement SHA-256. `c26c3a48531f1cf7f79090c82c8db185af548fc1137f1c427ac815d1d8120e89`

45. Geometric-multiplicity formula

Stable ID. `PSC-I-C-ALGEBRAICALLY-CLOSED-SINGLE-OPERATOR`

Kind. corollary

Statement.

If $\mathbb{k}$ is algebraically closed, then

$$\boxed{\operatorname{srank}_{\mathbb{k}[T]}(X) = \max_{\lambda \in \operatorname{Spec}(T)} \dim_{\mathbb{k}} \operatorname{Ker}(T - \lambda I).}$$

Proof. The irreducibles are $p = t - \lambda$. On the primary component for λ, the quotient by $(T - \lambda I)X_\lambda$ has dimension equal to the number of Jordan blocks, which is also $\dim \operatorname{Ker}(T - \lambda I)$. □

Formal correspondence. covered. Complete at the finite-dimensional algebraically closed scope inherited from the single-operator theorem. The actual intrinsic multiplicity for X-C(a) is identified with the dimension of the actual eigenspace, without diagonalizability. The canonical natural and cardinal seed ranks equal the maximum over the actual spectrum. Off-spectrum dimensions are zero, the empty-spectrum/zero-space maximum is defined as zero, and the spectral maximum is attained on nonzero spaces. No executable spectral algorithm is claimed.

Source locator. `editable/traditional/02_foundations.tex`; statement lines 971–982; proof lines 986–988.

Statement SHA-256. `babe43b45ebd6abb23a0e31ed41c0918a4babb97578847c852f2c9d11e69515f`

46. Cyclic-matrix criterion

Stable ID. `PSC-I-C-CYCLIC-MATRIX`

Kind. corollary

Statement.

For $X \neq 0$ of finite dimension, the following are equivalent:

(i) T has a cyclic vector.

(ii) $\operatorname{srank}_{\mathbb{k}[T]}(X) = 1$.

(iii) Every nonzero primary component for p is cyclic.

(iv) The rational canonical form has one invariant factor.

(v) The minimal polynomial equals the characteristic polynomial.

(vi) After scalar extension to an algebraic closure, every eigenvalue has geometric multiplicity one.

Proof. The equivalence of (i) and (ii) is `PSC-I-P-CYCLIC-CHARACTERIZATION`. By `PSC-I-T-SINGLE-OPERATOR`, (ii) holds exactly when every $\mu_p(T)$ belonging to a nonzero primary component equals one, which is (iii). Relatively prime primary cyclic modules combine into one cyclic module by the Chinese remainder theorem, so (iii) is equivalent to (iv). In rational canonical form, one invariant factor means that the unique invariant factor is both the minimal and characteristic polynomial, proving (iv)⇔(v). Scalar extension preserves the equality of minimal and characteristic polynomials. Over an algebraic closure, that equality is equivalent to one Jordan block for each eigenvalue, which is (vi). □

Formal correspondence. covered. Block 06 closes the exact six-way criterion for a nonzero finite-dimensional operator over an arbitrary field. The final List.TFAE includes actual cyclicity, canonical seed rank one, cyclicity of every nonzero intrinsic primary component, an actual monic positive-degree one-invariant-factor presentation, minpoly=charpoly, and one-dimensional eigenspaces at every spectral value of the literal tensor extension to AlgebraicClosure k. Minimal-polynomial preservation and cyclicity preservation/descent are proved, not supplied as hypotheses. The one-factor presentation has a constructed basis in which the original operator is the standard companion matrix; its factor is proved to be the minimal polynomial. A separate theorem proves that any actual nonconstant invariant-factor chain has exactly one factor iff the operator is cyclic. This is a mathematical existence and equivalence theorem, not an executable normal-form algorithm or a full sorted invariant-factor construction for arbitrary noncyclic operators. The nonzero-space guard is retained in the six-way statement. Legacy conditional wrappers are preserved unchanged for compatibility, but the new public criterion needs no decomposition, multiplicity, polynomial-preservation, spectral, or seed-number certificates.

A.2 Packets and transfer graphs

47. Finite packet system

Stable ID. `PSC-I-D-PACKET-SYSTEM`

Kind. definition

Statement.

A finite packet system on a vector space X over $\mathbb{k}$ is a family

$$\mathcal{P} = (P_\alpha)_{\alpha \in I} \subseteq \mathrm{End}_{\mathbb{k}}(X)$$

satisfying

$$P_\alpha^2 = P_\alpha, \qquad P_\alpha P_\beta = 0 \quad (\alpha \neq \beta), \qquad \sum_{\alpha \in I} P_\alpha = I_X.$$

Set $X_\alpha = P_\alpha X$. Zero packet spaces may be removed without changing any identity. No orthogonality is assumed unless stated.

Formal correspondence. definition represented. LinearProjectorFamily encodes the actual finite completeness, idempotence and annihilation laws.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 10–25.

Statement SHA-256. `251dfa1ba22ba22eaf53fdcc7880aa1fe05933738f362ef3f6ae72583f539459`

48. Packet support and packet-pure vectors

Stable ID. `PSC-I-D-PACKET-SUPPORT`

Kind. definition

Statement.

For a finite packet system $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ and $x \in X$, define

$$\mathrm{Supp}_{\mathcal{P}}(x) := \{\alpha \in I : P_\alpha x \neq 0\}.$$

The vector x is *packet pure* if $|\mathrm{Supp}_{\mathcal{P}}(x)| \leq 1$. A finite family is packet pure if each of its members is packet pure, although different members may lie in different packets.

Formal correspondence. definition represented. packetSupport is exactly {i | P_i x≠0}. PacketPure is Set.Subsingleton of that support, equivalent for finite support to cardinality at most one. packetPure_iff_zero_or_range identifies purity with zero or membership in one actual packet range; a pure family is pointwise this predicate.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 28–37.

Statement SHA-256. `d95377c31eb89901afc468fd8f0ba293fee6865b0ae3b22eff99df183cc9eb9e`

49. Finite packet aggregation

Stable ID. `PSC-I-L-PACKET-AGGREGATION`

Kind. lemma

Statement.

Let $\sigma : I \twoheadrightarrow J$ be a surjection and define

$$Q_j := \sum_{\sigma(\alpha)=j} P_\alpha.$$

Then $(Q_j)_{j\in J}$ is a finite packet system and

$$Q_j X = \bigoplus_{\sigma(\alpha)=j} X_\alpha.$$

Proof. Pairwise annihilation of the P_α gives

$$Q_j^2 = Q_j, \qquad Q_j Q_k = 0 \quad (j \neq k).$$

Summing over j recovers $\sum_\alpha P_\alpha = I$. The range statement follows from the directness forced by pairwise annihilation. □

Formal correspondence. covered. Q_j is the actual filtered sum of P_i. Computing P_a Q_j proves the laws. Actual range analysis/synthesis over the literal fibre subtype are inverse, and the finite product/direct-sum equivalence gives the printed conclusion.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 45–55; proof lines 59–67.

Statement SHA-256. `504cbd4eec7a5b5e416f91dcfd13e06586e5c1360990ed480424f4a85dfb9195`

50. Packet analysis and synthesis

Stable ID. `PSC-I-D-ANALYSIS-SYNTHESIS`

Kind. definition

Statement.

For a finite packet system, define

$$\mathcal{A}_{\mathcal{P}} : X \longrightarrow \bigoplus_{\alpha\in I} X_\alpha, \qquad x \longmapsto (P_\alpha x)_\alpha,$$

and

$$\mathcal{S}_{\mathcal{P}} : \bigoplus_{\alpha\in I} X_\alpha \longrightarrow X, \qquad (x_\alpha)_\alpha \longmapsto \sum_\alpha x_\alpha.$$

Formal correspondence. definition represented. Analysis and synthesis use genuine projector ranges, not unconstrained packet slots.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 69–83.

Statement SHA-256. `f364fcc94b357d761a0bb880e5a2d5761fe7bfc687b768b0f4f7cc261a5ce820`

51. Exact packet-coordinate isomorphism

Stable ID. `PSC-I-T-EXACT-PACKET-COORDINATES`

Kind. theorem

Statement.

For every finite packet system,

$$\boxed{\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}} = I_X, \qquad \mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{P}} = I_{\oplus X_\alpha}.}$$

Hence

$$\boxed{X \cong \bigoplus_{\alpha \in I} X_\alpha.}$$

Proof. For $x \in X$,

$$\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}}x = \sum_\alpha P_\alpha x = x.$$

If $x_\alpha \in X_\alpha$, then $P_\beta x_\alpha = \delta_{\alpha\beta} x_\alpha$, so

$$\mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{P}}(x_\alpha)_\alpha = \left(P_\beta \sum_\alpha x_\alpha\right)_\beta = (x_\beta)_\beta.$$

Thus analysis and synthesis are inverse linear maps. □

Formal correspondence. covered. Both inverse identities and the linear equivalence are proved.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 86–100; proof lines 105–121.

Stable ID. `PSC-I-C-PACKETWISE-EQUALITY`

Kind. corollary

Statement.

For $x, y \in X$,

$$x = y \quad \Longleftrightarrow \quad P_\alpha x = P_\alpha y \text{ for every } \alpha.$$

Proof. The forward implication is immediate. For the reverse implication, sum the packet equalities and use $\sum_\alpha P_\alpha = I$. □

Formal correspondence. covered. Exact equality iff every projected coordinate agrees.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 128–136; proof lines 140–142.

Statement SHA-256. `61919a93863e4ac0a41653a394e44cd8f701eac05335283ac8cf73983da43859`

53. Universal mapping property of finite packet coordinates

Stable ID. `PSC-I-C-PACKET-UNIVERSAL-PROPERTY`

Kind. corollary

Statement.

Let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ be a finite packet system on X, and let Y be a vector space over $\mathbb{k}$.

1. Every family of linear maps $f_\alpha : X_\alpha \to Y$ determines a unique linear map $f : X \to Y$ with $f|_{X_\alpha} = f_\alpha$, namely
$$f = \sum_\alpha f_\alpha P_\alpha.$$
2. Every family of linear maps $g_\alpha : Y \to X_\alpha$ determines a unique linear map $g : Y \to X$ with $P_\alpha g = g_\alpha$, namely
$$g = \sum_\alpha g_\alpha.$$

Equivalently,

$$\mathrm{Hom}(X, Y) \cong \prod_\alpha \mathrm{Hom}(X_\alpha, Y), \qquad \mathrm{Hom}(Y, X) \cong \prod_\alpha \mathrm{Hom}(Y, X_\alpha),$$

where the products are finite.

Proof. For $x = \sum_\alpha P_\alpha x$, any extension of the f_α must satisfy

$$f(x) = \sum_\alpha f_\alpha(P_\alpha x),$$

which proves both existence and uniqueness of the first formula. For the second, the sum $g = \sum_\alpha g_\alpha$ satisfies

$$P_\beta g = \sum_\alpha P_\beta g_\alpha = g_\beta$$

because $g_\alpha(Y) \subseteq X_\alpha$. Uniqueness follows from $\sum_\alpha P_\alpha = I$. □

Formal correspondence. covered. Outgoing extension is the finite sum of f_i after actual rangeRestrict projections. Incoming assembly is actual rangeSynthesis after LinearMap.pi. Packet laws give restrictions/projections and completeness gives uniqueness. These universal properties induce the displayed Hom equivalences.

Kind. theorem

Statement.

Let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ be a finite packet system on X, and let $\mathcal{Q} = (Q_\gamma)_{\gamma \in J}$ be a finite packet system on Y. Then

$$\mathcal{P} \boxtimes \mathcal{Q} := (P_\alpha \otimes Q_\gamma)_{(\alpha,\gamma) \in I \times J}$$

is a finite packet system on the algebraic tensor product $X \otimes_{\mathbb{k}} Y$, with packet spaces

$$(P_\alpha \otimes Q_\gamma)(X \otimes Y) = X_\alpha \otimes Y_\gamma.$$

Hence

$$\boxed{X \otimes Y \cong \bigoplus_{(\alpha,\gamma) \in I \times J} X_\alpha \otimes Y_\gamma.}$$

Proof. For every pair of packet indices,

$$(P_\alpha \otimes Q_\gamma)^2 = P_\alpha^2 \otimes Q_\gamma^2 = P_\alpha \otimes Q_\gamma.$$

If $(\alpha, \gamma) \neq (\beta, \delta)$, then either $P_\alpha P_\beta = 0$ or $Q_\gamma Q_\delta = 0$, so the corresponding tensor idempotents annihilate each other. Finally,

$$\sum_{\alpha,\gamma} P_\alpha \otimes Q_\gamma = \left(\sum_\alpha P_\alpha \right) \otimes \left(\sum_\gamma Q_\gamma \right) = I_X \otimes I_Y.$$

The range is generated by pure tensors $P_\alpha x \otimes Q_\gamma y$, hence equals $X_\alpha \otimes Y_\gamma$. Exact reconstruction follows from `PSC-I-T-EXACT-PACKET-COORDINATES`. □

Formal correspondence. covered. Actual TensorProduct.map projectors satisfy all laws by tensor induction. Tensor products of range inclusions have the tensor products of projections as left inverses; range_map identifies the actual packet range. This proves the canonical embedded interpretation of the printed range equality. Exact coordinates then give the literal DirectSum.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 188–210; proof lines 215–232.

Statement SHA-256. `afea7128594f24b1249382b028d823051a35d9bd3a3473c247a7b9bd63c5ba47`

55. Dual packet systems

Stable ID. `PSC-I-P-DUAL-PACKET-SYSTEM`

Kind. proposition

Statement.

Let X be finite dimensional and let $\mathcal{P} = (P_\alpha)$ be a finite packet system. The algebraic dual maps

$$P_\alpha^* : X^* \to X^*, \qquad P_\alpha^*(\varphi) = \varphi \circ P_\alpha,$$

form a finite packet system on X^*. Its packet with index α is canonically isomorphic to X_α^*, and

$$X^* \cong \bigoplus_\alpha X_\alpha^*.$$

Proof. Because dualization reverses products,

$$P_\alpha^* P_\beta^* = (P_\beta P_\alpha)^* = \delta_{\alpha\beta} P_\alpha^*.$$

Also $\sum_\alpha P_\alpha^* = I_{X^*}$. Thus the dual maps form a packet system. Restriction gives a map from $P_\alpha^* X^*$ to X_α^*. It is injective because a covector in the range of P_α^* vanishes on every other packet, and it is surjective because any covector on X_α extends to X through the direct sum decomposition. □

Formal correspondence. covered. Actual dualMap means precomposition. Composition reverses indices and orthogonality uses the reversed inequality correctly. Restriction and precomposition with the actual packet projection are inverse, giving the stated packet duals and literal finite DirectSum.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 234–246; proof lines 251–258.

Statement SHA-256. `ade34fd8142ece280ab2ae85913a943cb28a3661978659fde4a644eb5018d119`

56. Finite Banach packet isomorphism

Stable ID. `PSC-I-T-BANACH-PACKET-ISOMORPHISM`

Kind. theorem

Statement.

Let X be Banach and let $(P_\alpha)_{\alpha \in I}$ be a finite family of bounded pairwise annihilating idempotents with sum I_X. Then every range $X_\alpha = P_\alpha X$ is closed. For any finite product norm equivalent to the maximum norm on $\bigoplus_\alpha X_\alpha$, packet analysis and synthesis are bounded inverse operators.

Proof. The range of a bounded idempotent is its space of fixed points,

$$P_\alpha X = \operatorname{Ker}(I - P_\alpha),$$

which is closed. Because I is finite, analysis and synthesis are bounded for the maximum and sum norms, respectively, and therefore for every equivalent finite product norm. Their inverse identities are algebraic and were proved in `PSC-I-T-EXACT-PACKET-COORDINATES`. □

Formal correspondence. covered. The actual finite projectors are continuous and explicitly bounded as IsBoundedLinearMap over an arbitrary NormedField, including a trivial valuation. Individual bounds

produce one finite uniform bound; analysis has that bound and synthesis has the finite-cardinality bound. Any coordinate norm equivalent to the canonical maximum norm is represented by a linear identification and its literal two-sided norm inequalities. Composition gives bounded actual analysis and synthesis, both inverse identities, and closed packet ranges. No conclusion-shaped hypotheses occur.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 267–270; proof lines 274–280.

Statement SHA-256. `3fd1f470c1a5dcd6273739c6f6cb95e5fbb8f8c95e4fc4c76e010430a72afa3e`

57. Packet-coordinate condition number

Stable ID. `PSC-I-D-PACKET-CONDITION-NUMBER`

Kind. definition

Statement.

Fix a finite product norm on $\bigoplus_\alpha X_\alpha$ equivalent to the maximum norm, as in `PSC-I-T-BANACH-PACKET-ISOMORPHISM`. Define

$$\kappa(\mathcal{P}) := \|\mathcal{A}_\mathcal{P}\|\,\|\mathcal{S}_\mathcal{P}\|.$$

Formal correspondence. definition represented. The definition is the product of the ordinary operator norms of the actual bounded analysis and synthesis. The generic bounded additive homomorphism norm is defined as the infimum of nonnegative valid operator bounds; linearity is retained by ofBoundedLinear. Equivalent-norm coordinates have explicit actual-map equalities.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 282–290.

Statement SHA-256. `7c67c989c536ab3eecad8fdf8c19b0ed6eef7c164c569d69a0e04de101b2460d`

58. Conditioned coordinate transport

Stable ID. `PSC-I-P-CONDITIONED-COORDINATES`

Kind. proposition

Statement.

For a finite Banach packet system with $X \neq 0$,

$$\kappa(\mathcal{P}) \geq 1.$$

If $T \in \mathcal{B}(X)$ and

$$[T]_\mathcal{P} := \mathcal{A}_\mathcal{P} T \mathcal{S}_\mathcal{P},$$

then

$$\boxed{\|[T]_\mathcal{P}\| \leq \kappa(\mathcal{P})\|T\|, \qquad \|T\| \leq \kappa(\mathcal{P})\|[T]_\mathcal{P}\|.}$$

Proof. Since $I = \mathcal{S}_\mathcal{P}\mathcal{A}_\mathcal{P}$,

$$1 = \|I\| \leq \|\mathcal{S}_\mathcal{P}\|\|\mathcal{A}_\mathcal{P}\|.$$

The first displayed estimate follows from submultiplicativity. The inverse identity

$$T = \mathcal{S}_\mathcal{P}[T]_\mathcal{P}\mathcal{A}_\mathcal{P}$$

gives the second estimate. □

Formal correspondence. covered. For nonzero X the identity has norm one. The actual inverse relation S∘A=id and operator norm submultiplicativity give $\kappa \geq 1$. The coordinate operator is literally A∘T∘S, and S∘[T]∘A=T gives the reverse estimate. The final wrapper constructs both bounded actual coordinate maps for every equivalent finite-product norm and proves both inequalities for every bounded linear T over any NormedField.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 293–313; proof lines 317–327.

Statement SHA-256. `6799946dd2c88a65a635b418c7d0a74e94a9af4d1dc88df66cdd3b05c4ebc180`

59. Completion preserves a finite packet split

Stable ID. `PSC-I-C-COMPLETION-PACKET-SPLIT`

Kind. corollary

Statement.

Let M be a dense normed subspace of a Banach space X. Suppose every bounded P_α leaves M invariant and the restricted projectors form a packet system on M. Then

$$P_\alpha X = \overline{P_\alpha M}$$

and the packet decomposition of M extends uniquely to the completion X.

Proof. For $x \in X$, choose $m_n \in M$ with $m_n \to x$. Continuity gives $P_\alpha m_n \to P_\alpha x$, so $P_\alpha X \subseteq \overline{P_\alpha M}$. The reverse inclusion follows because $P_\alpha X$ is closed and contains $P_\alpha M$. The bounded extensions remain pairwise annihilating idempotents whose finite sum is the identity. □

Formal correspondence. covered. Over an arbitrary NormedField, the actual dense-submodule restrictions determine the ambient continuous projector identities by equality on a dense set. Each ambient range equals closure of the corresponding dense-submodule image, and two continuous ambient projector extensions agreeing on the dense submodule coincide. This is stronger than the bounded-input manuscript statement; boundedness of the given ambient projectors is available from the printed premise and is not needed for the density/uniqueness argument.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 334–341; proof lines 345–347.

Statement SHA-256. `67202410fc4580e865ea492dba6cf8dff7e0f296d89ac886c96188a0169a6b70`

60. Unconditional packet sum space

Stable ID. `PSC-I-D-UNCONDITIONAL-PACKET-SPACE`

Kind. definition

Statement.

Let $(X_n)_{n\ge 1}$ be closed subspaces of a real or complex Banach space X. Define

$$\bigoplus_{n\ge 1}^{u} X_n$$

to be the space of sequences $x = (x_n)$ with $x_n \in X_n$ for which $\sum_n x_n$ converges unconditionally in X. Equip it with

$$\|x\|_u := \sup_{F\in\mathbb{N}} \sup_{|a_n|\le 1} \left\| \sum_{n\in F} a_n x_n \right\|.$$

Formal correspondence. definition represented. The carrier is exactly sequences x_n in the specified closed subspaces for which Summable x holds; mathlib Summable is the finite-subset net (unconditional summation). The norm is exactly sSup of norms of finite sums with coefficients in the closed scalar unit ball. Type synonyms avoid inherited product topology. Finiteness is derived, not assumed. RCLike covers real and complex scalars as stated.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 352–366.

Statement SHA-256. `bcbeba58302101658c66251d7b338a6a3932fb07b059e77931ffd063b5303b4f`

61. Completeness of the unconditional packet sum

Stable ID. `PSC-I-L-UNCONDITIONAL-COMPLETENESS`

Kind. lemma

Statement.

The normed space $\bigoplus_{n\ge 1}^{u} X_n$ in `PSC-I-D-UNCONDITIONAL-PACKET-SPACE` is Banach.

Proof. Let $x^{(k)} = (x_n^{(k)})$ be Cauchy in $\|\cdot\|_u$. For every fixed n,

$$\|x_n^{(k)} - x_n^{(\ell)}\| \le \|x^{(k)} - x^{(\ell)}\|_u,$$

so $x_n^{(k)}$ converges to some $x_n \in X_n$ because X_n is closed. Given $\varepsilon > 0$, choose k_0 such that

$$\|x^{(k)} - x^{(\ell)}\|_u < \varepsilon \qquad (k, \ell \ge k_0).$$

For finite F and $|a_n| \le 1$, pass $\ell \to \infty$ in the finite sum to obtain

$$\left\| \sum_{n\in F} a_n (x_n^{(k)} - x_n) \right\| \le \varepsilon \qquad (k \ge k_0).$$

Hence $\|x^{(k)} - x\|_u \le \varepsilon$ once x is known to be unconditionally summable.

Choose such a $k \geq k_0$. Since $x^{(k)}$ is unconditionally summable, there is a finite F_0 such that every finite $F \subseteq \mathbb{N} \setminus F_0$ and every $|a_n| \leq 1$ satisfy

$$\left\| \sum_{n \in F} a_n x_n^{(k)} \right\| < \varepsilon.$$

The preceding uniform estimate then gives

$$\left\| \sum_{n \in F} a_n x_n \right\| < 2\varepsilon.$$

Thus the tails of $\sum_n x_n$ are uniformly small under bounded scalar changes, which is the unconditional Cauchy criterion. Therefore $x \in \bigoplus^u X_n$, and the earlier estimate proves $x^{(k)} \to x$ in $\| \cdot \|_u$. □

Formal correspondence. covered. Uniform boundedness on the complete continuous dual is justified by finite-dimensional real absolute summability of each scalar image; the isometric bidual inclusion yields finite multiplier bounds. The signed norm controls each coordinate; coordinate limits stay in closed subspaces. Each fixed finite multiplier estimate passes to the limit, uniformly in the finite set and coefficients. Unweighted tails prove Summable for the limit, and the same uniform estimate gives convergence in the signed norm. Metric completeness is then obtained without a projector hypothesis.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 369–372; proof lines 376–405.

Statement SHA-256. `339adef1c7737cb8adc8a4bc76b3a5a2f95a575ffb576a34404d8da60bfe0b62`

62. Countable unconditional packet isomorphism

Stable ID. `PSC-I-T-COUNTABLE-UNCONDITIONAL-PACKETS`

Kind. theorem

Statement.

Let X be a real or complex Banach space and let $(P_n)_{n \geq 1} \subseteq \mathcal{B}(X)$ satisfy

$$P_n P_m = \delta_{nm} P_n$$

and

$$x = \sum_{n \geq 1} P_n x$$

unconditionally for every $x \in X$. Assume

$$K := \sup_{F \Subset \mathbb{N}} \sup_{|a_n| \leq 1} \left\| \sum_{n \in F} a_n P_n \right\| < \infty.$$

Then analysis and synthesis define inverse Banach space isomorphisms

$$\boxed{X \cong \bigoplus_{n \geq 1}^{u} P_n X.}$$

More precisely,

$$\|\mathcal{A}_{\mathcal{P}}\| \le K, \qquad \|\mathcal{S}_{\mathcal{P}}\| \le 1.$$

Proof. Each $P_nX = \operatorname{Ker}(I - P_n)$ is closed. For $x \in X$,

$$\|\mathcal{A}_{\mathcal{P}}x\|_u = \sup_{F,a} \left\| \sum_{n\in F} a_n P_n x \right\| \le K\|x\|.$$

For $y = (y_n) \in \bigoplus^u P_nX$, define

$$\mathcal{S}_{\mathcal{P}}y = \sum_n y_n.$$

Since the finite partial sums with every coefficient equal to one are among those used in $\|y\|_u$,

$$\|\mathcal{S}_{\mathcal{P}}y\| \le \|y\|_u.$$

The assumed expansion gives $\mathcal{S}_{\mathcal{P}}\mathcal{A}_{\mathcal{P}}x = x$. Conversely, boundedness of P_m permits termwise application to the unconditionally convergent series:

$$P_m\mathcal{S}_{\mathcal{P}}y = \sum_n P_m y_n = y_m.$$

Thus $\mathcal{A}_{\mathcal{P}}\mathcal{S}_{\mathcal{P}} = I$. Completeness of the coordinate space is PSC-I-L-UNCONDITIONAL-COMPLETENESS. □

Formal correspondence. covered. ofSupBound constructs K as the literal supremum of finite multiplier operator norms from BddAbove. The carriers use Summable sequences in actual projector ranges. Continuous projectors commute with the sum, so annihilation proves both inverse identities. The literal signed norm yields analysis bound K and synthesis bound 1. A proved linear isometry identifies the projector-specific carrier and norm with the general ClosedPackets.Space. Completeness follows either from the general theorem or from the constructed uniform equivalence with Banach X.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 407–436; proof lines 441–467.

Statement SHA-256. `7579699c5a34468a6f9df136e7c897641c5409e5f5e597cd849348bddc92a469`

63. Uniform boundedness

Stable ID. PSC-I-R-UNIFORM-BOUNDEDNESS

Kind. remark

Statement.

If every expansion $\sum_n P_n x$ is unconditional, the operators obtained from finite partial sums with signs form a pointwise bounded family. The uniform boundedness principle therefore yields a finite constant K. We retain this constant explicitly in PSC-I-T-COUNTABLE-UNCONDITIONAL-PACKETS because later estimates use it to bound the coordinate map.

Formal correspondence. documentary. A uniform-boundedness explanation. No instance for the signed packet partial-sum family is mapped.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 469–472.

Statement SHA-256. `2ae822d9b50496c6462b94007b5ff1a8d083e7109e6da7d0c2453ca40b80373c`

$$\boxed{(T_{\beta\alpha})^* = (T^*)_{\alpha\beta}.}$$

Proof. Because $P_\alpha^* = P_\alpha$,

$$(P_\beta T P_\alpha)^* = P_\alpha T^* P_\beta.$$

□

Formal correspondence. covered. The result is proved for bounded self-adjoint outer maps, more generally than orthogonal packet projectors.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 579–585; proof lines 589–594.

Statement SHA-256. `8e978a295a29a3eac3d1c4bec1a8e3f4e05a2684fdbce8e80a357aa7891e8f79`

70. Tensor-product transfer blocks

Stable ID. `PSC-I-C-TENSOR-TRANSFER-BLOCKS`

Kind. corollary

Statement.

Let $S \in \mathrm{End}(X)$ and $T \in \mathrm{End}(Y)$, with packet systems $\mathcal{P}$ and $\mathcal{Q}$. Relative to the tensor product packet system of `PSC-I-T-TENSOR-PACKET-SYSTEM`,

$$\boxed{(S \otimes T)_{(\beta,\delta),(\alpha,\gamma)} = S_{\beta\alpha} \otimes T_{\delta\gamma}.}$$

Proof. By definition,

$$\begin{aligned}(S \otimes T)_{(\beta,\delta),(\alpha,\gamma)} &= (P_\beta \otimes Q_\delta)(S \otimes T)(P_\alpha \otimes Q_\gamma) \\ &= (P_\beta S P_\alpha) \otimes (Q_\delta T Q_\gamma) \\ &= S_{\beta\alpha} \otimes T_{\delta\gamma}.\end{aligned}$$

□

Formal correspondence. covered. Actual transfer blocks factor by tensor-map composition in exactly the (target,source) order printed. Both sides are actual endomorphisms of X tensor Y; no factorization witness is an input.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 598–608; proof lines 613–621.

Statement SHA-256. `ec0bc2d2c85cdf55ea2f27003457a653f8f2426fe97dafd6c918cbda54874878`

71. Blockwise intertwining equations

Stable ID. `PSC-I-T-BLOCK-INTERTWINING`

Kind. theorem

Statement.

Let $T \in \mathrm{End}(X)$, $S \in \mathrm{End}(Y)$, let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ and $\mathcal{Q} = (Q_\gamma)_{\gamma \in J}$ be finite packet systems, and let $U : X \to Y$ be linear. Define

$$T_{\beta\alpha} = P_\beta T P_\alpha, \qquad S_{\gamma\delta} = Q_\gamma S Q_\delta, \qquad U_{\gamma\alpha} = Q_\gamma U P_\alpha.$$

Then

$$\boxed{UT = SU}$$

if and only if, for every $\gamma \in J$ and $\alpha \in I$,

$$\boxed{\sum_{\beta \in I} U_{\gamma\beta} T_{\beta\alpha} = \sum_{\delta \in J} S_{\gamma\delta} U_{\delta\alpha}.}$$

Proof. Apply Q_γ on the left and P_α on the right. Inserting $I_X = \sum_\beta P_\beta$ gives

$$Q_\gamma U T P_\alpha = \sum_\beta Q_\gamma U P_\beta T P_\alpha = \sum_\beta U_{\gamma\beta} T_{\beta\alpha}.$$

Inserting $I_Y = \sum_\delta Q_\delta$ gives

$$Q_\gamma S U P_\alpha = \sum_\delta Q_\gamma S Q_\delta U P_\alpha = \sum_\delta S_{\gamma\delta} U_{\delta\alpha}.$$

Thus $UT = SU$ implies every block equation. Conversely, if every block equation holds, then all blocks of $UT - SU$ vanish. Exact operator reconstruction yields $UT - SU = 0$. □

Formal correspondence. covered. U is any linear map, not an intertwiner structure. Forward direction inserts middle projector sums; reverse direction reconstructs UT and SU from all equal blocks. Distinct source/target index sets are retained.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 623–645; proof lines 650–668.

Statement SHA-256. `558adbc4eead21c3f371918f40b9f462000c7b26a7234864ee44c103e09cf1e6`

72. Full block-algebra representation

Stable ID. PSC-I-T-BLOCK-ALGEBRA

Kind. theorem

Statement.

The map

$$\Theta_{\mathcal{P}} : \mathrm{End}_{\Bbbk}(X) \longrightarrow \prod_{\beta,\alpha\in I} \mathrm{Hom}_{\Bbbk}(X_\alpha, X_\beta), \qquad T \longmapsto (T_{\beta\alpha})_{\beta,\alpha},$$

is an algebra isomorphism when the codomain is equipped with matrix multiplication whose entries are operators.

Proof. Injectivity follows from exact reconstruction. Given arbitrary linear maps $B_{\beta\alpha} : X_\alpha \to X_\beta$, define

$$T\left(\sum_\alpha x_\alpha\right) := \sum_{\alpha,\beta} B_{\beta\alpha} x_\alpha.$$

The packet decomposition is unique and the index set is finite, so this defines a linear operator whose blocks are the prescribed maps. Thus $\Theta_{\mathcal{P}}$ is surjective. Compatibility with multiplication is PSC-I-T-BLOCK-MULTIPLICATION. □

Formal correspondence. covered. Full dependent packet Hom families and their multiplication are identified with the actual endomorphism algebra.

Source locator. editable/traditional/03_packets_and_graphs.tex; statement lines 675–686; proof lines 691–699.

Statement SHA-256. a66e4216289ceb5e48d1ccd41d269b656c6c93ed462a47f68cbd0172c9360bda

73. Propagation of packet support

Stable ID. PSC-I-C-PACKET-SUPPORT-PROPAGATION

Kind. corollary

Statement.

Let $T \in \mathrm{End}(X)$ and $x \in X$. Then

$$\boxed{\mathrm{Supp}_{\mathcal{P}}(Tx) \subseteq \left\{\beta : \exists \alpha \in \mathrm{Supp}_{\mathcal{P}}(x) \text{ with } T_{\beta\alpha} \neq 0\right\}.}$$

Equality holds whenever, for every target β in the set on the right, the active contributions

$$(T_{\beta\alpha} P_\alpha x : \alpha \in \mathrm{Supp}_{\mathcal{P}}(x),\ T_{\beta\alpha} \neq 0)$$

have nonzero sum. In particular, equality holds if at most one active source packet feeds each such β and that source coordinate does not lie in the kernel of the corresponding block.

Proof. For every target packet β,

$$P_\beta T x = \sum_{\alpha\in\mathrm{Supp}_{\mathcal{P}}(x)} T_{\beta\alpha} P_\alpha x.$$

If every block in this sum is zero, then the coordinate with index β vanishes. This proves the inclusion. Equality is exactly the assertion that the displayed active sum is nonzero for every target in the set on the right. The final sufficient condition leaves at most one nonzero summand at each target, and kernel avoidance makes that summand nonzero. □

Formal correspondence. covered. The source expands each target coordinate as the finite sum of the actual transfer-block contributions and filters to active sources. This yields the support inclusion; nonzero active sums give equality. The single-active theorem uses activeSources={a} plus nonzero transfer contribution, which is equivalent to at-most-one active source plus kernel avoidance on a target that is active.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 703–720; proof lines 725–733.

Statement SHA-256. `f05b8bf4828b88f6020e2e0b824e228acffcb77d7a514ced31ec90c64e6d4437`

74. Dimension count

Stable ID. `PSC-I-C-DIMENSION-COUNT`

Kind. corollary

Statement.

If X is finite dimensional and $d_\alpha = \dim X_\alpha$, then

$$\dim \mathrm{End}_{\Bbbk}(X) = \sum_{\alpha,\beta} d_\alpha d_\beta = \left(\sum_{\alpha} d_\alpha \right)^2 .$$

Proof. Take dimensions in the block algebra isomorphism and use $\dim \mathrm{Hom}(X_\alpha, X_\beta) = d_\alpha d_\beta$. □

Formal correspondence. covered. The actual End space is linearly equivalent to the heterogeneous packet Hom product. Its finite dimension equals the sum of products of actual packet-range dimensions, and finite distributivity gives the displayed square. Both printed equalities occur in one conjunction.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 736–746; proof lines 750–752.

Statement SHA-256. `85dd27ca5c20eeb56683b4b3d9b9093503e2c3c2fdc4a07c1aaf33eefab855c8`

75. Block-diagonal projection and packet commutant

Stable ID. `PSC-I-P-BLOCK-DIAGONAL-COMMUTANT`

Kind. proposition

Statement.

Define

$$\Delta_{\mathcal{P}}(T) := \sum_{\alpha} P_\alpha T P_\alpha .$$

Then $\Delta_{\mathcal{P}}$ is a linear idempotent on $\mathrm{End}(X)$ whose range is the block diagonal subalgebra. For $T \in \mathrm{End}(X)$, the following are equivalent:

(i) $TP_\alpha = P_\alpha T$ for every α.

(ii) $T_{\beta\alpha} = 0$ whenever $\beta \neq \alpha$.

(iii) $\Delta_{\mathcal{P}}(T) = T$.

Proof. Pairwise annihilation gives $\Delta_{\mathcal{P}}^2 = \Delta_{\mathcal{P}}$ and identifies its range with diagonal block families. If T commutes with all P_α, then for $\beta \neq \alpha$,

$$P_\beta T P_\alpha = P_\beta P_\alpha T = 0.$$

Thus (i) implies (ii). Exact reconstruction shows (ii) implies (iii). If $T = \sum_\alpha P_\alpha T P_\alpha$, then

$$T P_\gamma = P_\gamma T P_\gamma = P_\gamma T,$$

so (iii) implies (i). □

Formal correspondence. covered. diagonalProjection is the actual K-linear map T↦Σ_i P_i T P_i. The proofs derive idempotence, equivalence of commutation with every projector and off-diagonal block vanishing, equivalence to fixed points of this projection, and equality of its actual linear range to the equality-supported subalgebra.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 754–766; proof lines 771–781.

Statement SHA-256. `613238e060365a7c00244f44abb552ada9f54933d8483382f259d3f32843eae5`

76. Support relation and support space

Stable ID. `PSC-I-D-SUPPORT-RELATION`

Kind. definition

Statement.

For a relation $R \subseteq I \times I$, with (β, α) interpreted as an allowed transfer $\alpha \to \beta$, define

$$\mathfrak{M}_R := \{T \in \mathrm{End}(X) : T_{\beta\alpha} = 0 \text{ whenever } (\beta, \alpha) \notin R\}.$$

Formal correspondence. definition represented. OperatorSupported is initially defined via actual restricted packet maps; operatorSupported_iff_ambient proves its exact equivalence to ambient transfer-block vanishing. supportSubmodule is the corresponding actual linear subspace of End(X). Relation dictionary: formal rel(a,b) means manuscript (b,a)∈R, with a source and b target.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 789–797.

Statement SHA-256. `babc2ddcee7669992338d1b7741bd50fab01175a280772ab40df14dcc814ebf3`

77. Support-pattern algebra criterion

Stable ID. `PSC-I-T-SUPPORT-PATTERN-ALGEBRA`

Kind. theorem

Statement.

Assume $X_\alpha \neq 0$ for every $\alpha \in I$. Then:

(i) $I_X \in \mathfrak{M}_R$ if and only if R is reflexive.

(ii) $\mathfrak{M}_R\mathfrak{M}_R \subseteq \mathfrak{M}_R$ if and only if R is transitive.

(iii) $\mathfrak{M}_R$ is a unital subalgebra if and only if R is a preorder.

Proof. The identity has diagonal blocks I_{X_α} and no blocks outside the diagonal, so it belongs to $\mathfrak{M}_R$ exactly when $(\alpha, \alpha) \in R$ for every α.

Assume R is transitive. If a summand

$$S_{\gamma\beta}T_{\beta\alpha}$$

in the (γ, α) block of ST is nonzero, then (γ, β) and (β, α) lie in R. Transitivity gives $(\gamma, \alpha) \in R$, so every forbidden block of ST vanishes.

Conversely, suppose transitivity fails. Choose α, β, γ with

$$(\beta, \alpha) \in R, \qquad (\gamma, \beta) \in R, \qquad (\gamma, \alpha) \notin R.$$

Choose nonzero vectors $u \in X_\alpha$, $v \in X_\beta$, and $w \in X_\gamma$. Choose linear functionals $f \in X_\alpha^*$ and $g \in X_\beta^*$ with $f(u) = g(v) = 1$. Let T have the sole block $x \mapsto f(x)v$ from X_α to X_β, and let S have the sole block $y \mapsto g(y)w$ from X_β to X_γ. Then $S, T \in \mathfrak{M}_R$, but ST has a nonzero forbidden (γ, α) block. This proves necessity. Combining reflexivity and transitivity gives (iii). □

Formal correspondence. covered. The two difficult converses use arbitrary maps between the actual nonzero packet ranges. Identity support is equivalent to reflexivity; multiplication closure is equivalent to transitivity. support_mul_closed_iff transfers the block statement to actual ambient operators, and support_pattern_algebra_criterion characterizes existence of a Subalgebra whose carrier is precisely that support space.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 800–808; proof lines 812–830.

Statement SHA-256. `fcd8af3b6718c7460c4e58639b8e942c24ede23b8673f9811f193cab4ccd3b20`

78. $*$-closed bounded support patterns

Stable ID. `PSC-I-C-SUPPORT-PATTERN-STAR`

Kind. corollary

Statement.

Let X be Hilbert, let the packet projectors be orthogonal, assume $X_\alpha \neq 0$ for every $\alpha \in I$, and put

$$\mathfrak{M}_R^{\mathrm{b}} := \mathfrak{M}_R \cap \mathcal{B}(X).$$

Then $\mathfrak{M}_R^{\mathrm{b}}$ is closed under adjoints if and only if R is symmetric. Hence $\mathfrak{M}_R^{\mathrm{b}}$ is a unital $*$ subalgebra of $\mathcal{B}(X)$ if and only if R is an equivalence relation.

Proof. Adjoint reversal sends an allowed (β, α) block to an (α, β) block. Symmetry is therefore sufficient. If symmetry fails, choose a nonzero map of rank one in an allowed nonsymmetric block. Its adjoint occupies the forbidden reverse block, proving necessity. A reflexive, transitive, symmetric relation is an equivalence relation. □

Formal correspondence. covered. Supported uses literal continuous transfer blocks and is proved equivalent to the underlying algebraic support predicate. Converse symmetry and transitivity use actual bounded rank-one operators between nonzero ranges. Identity support forces reflexivity. Sufficiency constructs an actual StarSubalgebra. RCLike covers the real and complex Hilbert settings; no finite-dimensional restriction or blanket bounded-block assumption is used.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 832–839; proof lines 843–845.

Statement SHA-256. `89dfdc356ea3dbbf9ee8018c66d8307f445d19078e0d7226372aae44c1872333`

79. Preorder support algebra decomposition

Stable ID. `PSC-I-T-PREORDER-ALGEBRA-DECOMPOSITION`

Kind. theorem

Statement.

Let R be a preorder on the finite set I. Define

$$\alpha \sim \beta \quad \Longleftrightarrow \quad (\beta, \alpha) \in R \text{ and } (\alpha, \beta) \in R.$$

Let $\overline{I} = I/\!\sim$, which carries the induced partial order, and put

$$X_C := \bigoplus_{\alpha \in C} X_\alpha.$$

Let $\mathfrak{N}_R \subseteq \mathfrak{M}_R$ consist of operators whose blocks vanish whenever source and target belong to the same equivalence class. Then:

(i) $\mathfrak{N}_R$ is a nilpotent ideal on both sides.

(ii) If h is the maximal number of strict steps in a chain of $\overline{I}$, then

$$\mathfrak{N}_R^{h+1} = 0.$$

(iii) The map to the diagonal classes induces an algebra isomorphism

$$\boxed{\mathfrak{M}_R/\mathfrak{N}_R \cong \prod_{C\in\overline{I}} \mathrm{End}_{\Bbbk}(X_C).}$$

Proof. A nonzero block in $\mathfrak{N}_R$ moves from one equivalence class to a strictly larger class in the quotient partial order. The block multiplication law shows that products concatenate such moves. Therefore left or right multiplication by an element of $\mathfrak{M}_R$ preserves the property of having no blocks within a single class, so $\mathfrak{N}_R$ is an ideal on both sides. A product of $h+1$ elements of $\mathfrak{N}_R$ would require a strict chain of $h+1$ steps in $\overline{I}$, which does not exist. This proves nilpotence.

Let $P_C = \sum_{\alpha\in C} P_\alpha$. Define

$$\rho : \mathfrak{M}_R \longrightarrow \prod_C \mathrm{End}(X_C), \qquad \rho(T) = (P_C T P_C)_C.$$

If an intermediate class D contributes to $P_C S T P_C$, then the preorder contains transfers $C \to D$ and $D \to C$, forcing $C = D$ in the quotient poset. Hence

$$P_C S T P_C = (P_C S P_C)(P_C T P_C),$$

so ρ is an algebra homomorphism. Every collection of endomorphisms of the X_C defines an allowed operator that is block diagonal with respect to the classes, so ρ is surjective. Its kernel is exactly $\mathfrak{N}_R$. The first isomorphism theorem gives the quotient formula. □

Formal correspondence. covered. The support algebra is constructed from the actual preorder. strictSupportIdeal is an actual TwoSidedIdeal of it, with membership proved equivalent to vanishing within every mutual-order class. Nonzero product blocks force strict paths; finite strict-path height is bounded and attained on nonempty indices. strictSupportIdeal_pow_eq_bot uses Mathlib standard ideal powers, with the span-of-words surrogate bridged by strictIdeal_power_mem. Antisymmetrization supplies the actual quotient partial order; class_maximalStrictSteps proves its height equals the exponent parameter. Grouped class projectors are actual sums of original projectors. The diagonal-class homomorphism is surjective with kernel equal to the strict ideal, and preorderQuotientDirectSumEquiv is the actual quotient by that ideal to the product of End of the literal direct sums of class packet ranges.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 847–875; proof lines 880–894.

80. Transfer graph of an algebra-generating family

Stable ID. `PSC-I-D-TRANSFER-GRAPH`

Kind. definition

Statement.

Let $\mathcal{P} = (P_\alpha)_{\alpha \in I}$ be a finite packet system on X with every $P_\alpha \in \mathcal{A}$. Let $\mathcal{G} \subseteq \mathcal{A}$ satisfy

$$\mathcal{A} = \mathrm{alg}_{\Bbbk}(\{P_\alpha : \alpha \in I\} \cup \mathcal{G}),$$

where $\mathrm{alg}_{\Bbbk}(E)$ denotes the unital subalgebra over $\Bbbk$ generated by E. The transfer graph $\Gamma(\mathcal{G}, \mathcal{P})$ has vertex set I and an arrow

$$\alpha \longrightarrow \beta$$

when

$$P_\beta G P_\alpha \neq 0$$

for at least one $G \in \mathcal{G}$. Reachability includes paths of length zero.

Formal correspondence. definition represented. packetGeneratedAlgebra is Algebra.adjoin K (range P.proj ∪ ops), exactly the declared algebra in the manuscript. TransferEdge is witnessed by an actual member of ops with nonzero ambient transfer block. ReachableFrom uses ReflTransGen and hence includes length zero.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 916–931.

Statement SHA-256. `f6ddc4edec01afcf027a48300c34e66e9d1209d4f56bce17e3b9d00f88cd62cf`

81. Reachability support of the generated algebra

Stable ID. `PSC-I-T-ALGEBRA-REACHABILITY-SUPPORT`

Kind. theorem

Statement.

For every $A \in \mathcal{A}$,

$$P_\beta A P_\alpha = 0 \qquad \text{whenever } \beta \notin \mathrm{Reach}(\alpha).$$

Equivalently,

$$\mathcal{A} \subseteq \mathfrak{M}_{R_\Gamma}, \qquad R_\Gamma := \{(\beta, \alpha) : \beta \in \mathrm{Reach}(\alpha)\}.$$

Proof. It is enough to treat a word in the generators and packet projectors. Insert

$$I = \sum_{\gamma \in I} P_\gamma$$

between consecutive nonprojector generators. Every resulting (β, α) block is a finite sum of products

$$P_\beta G_m P_{\gamma_{m-1}} G_{m-1} \cdots P_{\gamma_1} G_1 P_\alpha.$$

A nonzero product requires every consecutive block to be nonzero, hence gives a directed path

$$\alpha \to \gamma_1 \to \cdots \to \gamma_{m-1} \to \beta.$$

Packet projectors only insert stationary steps. Thus a word has no block from α to an unreachable β. Linear combinations preserve the same zero pattern. □

Formal correspondence. covered. Each projector and declared generator lies in the actual support algebra of ReflTransGen(TransferEdge). Algebra.adjoin_le therefore proves containment of the entire generated algebra. generatedAlgebra_block_zero is the literal ambient P_b A P_a=0 consequence outside reachability.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 934–947; proof lines 951–967.

Statement SHA-256. `7496f96565d405f8fe6b80491655dffe3b2ddad07b104c1131704464fb8ad031`

82. Reachability obstruction for generated hulls

Stable ID. `PSC-I-P-REACHABILITY-OBSTRUCTION`

Kind. proposition

Statement.

Let $I_0 \subseteq I$ and let

$$S \subseteq \bigoplus_{\alpha \in I_0} X_\alpha.$$

Then

$$\boxed{\mathrm{Hull}_{\mathcal{A}}(S) \subseteq \bigoplus_{\beta \in \mathrm{Reach}(I_0)} X_\beta.}$$

In particular, no seed supported outside a source strongly connected component can generate a nonzero vector in that source component.

Proof. For $s \in S$, write $s = \sum_{\alpha \in I_0} P_\alpha s$. If β is unreachable from I_0, then for every $A \in \mathcal{A}$,

$$P_\beta A s = \sum_{\alpha \in I_0} P_\beta A P_\alpha s = 0$$

by PSC-I-T-ALGEBRA-REACHABILITY-SUPPORT. The same holds for every finite linear combination of orbit vectors. □

Formal correspondence. covered. The actual reachable-support subspace is preserved by every element of the generated algebra. Span of actual algebra orbits yields the hull inclusion for arbitrary seed sets. The source SCC is the actual mutual-reachability quotient, with source status equivalent to no incoming condensation edge. generatedAlgebra_source_obstruction separately assembles the printed final clause: seeds outside that source cannot generate any nonzero vector supported in it. It obtains a nonzero coordinate by packet completeness and applies no_reach_into_source and the unreachable-coordinate obstruction.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 977–992; proof lines 996–1005.

Statement SHA-256. `a46f6c292b4825e63689b6302077e4db2b2a8fe38f9958fc9018a623e7b8a239`

83. Packet-pure seed rank

Stable ID. PSC-I-D-DIRECTED-SEED-RANK

Kind. definition

Statement.

A vector is packet pure when it is zero or lies in one packet space X_α, equivalently when its packet support has cardinality at most one. Define

$$\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) := \min\{|S| : S \text{ is packet-pure and } \mathcal{A}S = X\}.$$

For $C \subseteq I$, put

$$P_C := \sum_{\alpha\in C} P_\alpha, \qquad X_C := P_C X, \qquad \mathcal{A}_C := P_C \mathcal{A} P_C,$$

and define the local packet pure rank

$$r_C := \operatorname{psrank}_{\mathcal{A}_C,\mathcal{P}|_C}(X_C).$$

Formal correspondence. definition represented. The cardinal infimum is over all actual pure generating subsets, its indexing type is nonempty, and its infimum is attained by well-ordering. Corner compression is e*T on range(e), hence literally e*T*e there. Closure and the identity restriction are proved. A local family retains outside indices as zero maps; local_proj_zero_iff identifies these precisely for nonzero original packets, and zero deletion preserves purity and rank. The corrected zero-or-range wording matches empty-index conventions.

Source locator. editable/traditional/03_packets_and_graphs.tex; statement lines 1011–1031.

Statement SHA-256. 2a2a8b2073162ddfce0cf7462765d5453176d369133cc86dc699c8d038e8fee8

84. Basic packet-pure rank bounds

Stable ID. PSC-I-P-PACKET-PURE-RANK-BOUNDS

Kind. proposition

Statement.

For every A module resolved into packets with $P_\alpha \in A$,

$$\boxed{\operatorname{srank}_A(X) \le \operatorname{psrank}_{A,\mathcal{P}}(X) \le \sum_{\alpha\in I} \operatorname{srank}_{P_\alpha A P_\alpha}(X_\alpha).}$$

The corner algebra on the right is unital on X_α with identity P_α.

Proof. Every packet pure generating family is an unrestricted generating family, which gives the first inequality. For each α, choose a minimal generating family $S_\alpha \subseteq X_\alpha$ for the corner action $P_\alpha A P_\alpha$. The union $S = \bigcup_\alpha S_\alpha$ is packet pure. Since every $x \in X$ has the unique decomposition $x = \sum_\alpha x_\alpha$ and every x_α lies in $(P_\alpha A P_\alpha)S_\alpha \subseteq AS$, the union generates X. Its cardinality is at most the displayed sum. □

Formal correspondence. covered. The left inequality is direct inclusion of admissible generating sets. The upper inequality chooses attained minimal generating sets under each genuine corner algebra, embeds them into X, and proves their union generates by projector completeness and cor-

ner_action_ambient. The union cardinal is bounded by the cardinal sum. This works for arbitrary infinite dimensions and arbitrary cardinal ranks, including zero packets.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 1034–1048; proof lines 1052–1054.

Statement SHA-256. `11a3ad129e84e51edb000d4027f785874b59f3867639a7813ab9c8d944bf81c0`

85. Edge-surjective packet system

Stable ID. `PSC-I-D-EDGE-SURJECTIVE`

Kind. definition

Statement.

The module resolved into packets is surjective along edges relative to $\Gamma(\mathcal{G}, \mathcal{P})$ when, for every graph edge $\alpha \to \beta$, there exists $B \in \mathcal{A}$ such that the pure block

$$P_\beta B P_\alpha : X_\alpha \twoheadrightarrow X_\beta$$

is surjective.

Formal correspondence. definition represented. The edge is TransferEdge P ops, not a supplied surrogate graph. The witness T belongs to Algebra.adjoin of the projectors and declared operators; restrictBlocks is the literal map from the source range to the target range.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 1056–1063.

Statement SHA-256. `46dd6f245aadc93dd24ac5505cd37893d5474fb31208bab5babfacf0fa6d1ce4`

86. Source-component formula for packet-pure seed rank

Stable ID. `PSC-I-T-SOURCE-COMPONENT-SEED-RANK`

Kind. theorem

Statement.

Assume I is finite, every packet space is nonzero, and the module resolved into packets is surjective along edges. Let $\mathfrak{C}_0$ be the set of source strongly connected components of the condensation graph of $\Gamma(\mathcal{G}, \mathcal{P})$. Then

$$\boxed{\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) = \sum_{C \in \mathfrak{C}_0} r_C.}$$

Proof. Let S be a packet pure generating family for X. Discard zero seeds, which do not change the generated hull, and fix a source component C. Seeds outside C cannot reach C by `PSC-I-P-REACHABILITY-OBSTRUCTION`. Moreover, for $s \in X_C$ and $A \in \mathcal{A}$,

$$P_C A s = (P_C A P_C) s \in \mathcal{A}_C s.$$

Thus the seeds of S lying in X_C must generate X_C under $\mathcal{A}_C$, and there are at least r_C of them. Summing over disjoint source components gives

$$\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) \geq \sum_{C \in \mathfrak{C}_0} r_C.$$

For the reverse inequality, choose for each source component C a packet pure family S_C of size r_C generating X_C under $\mathcal{A}_C$, and put $S = \bigcup_C S_C$. Then every source component lies in $\mathcal{A}S$. Traverse the finite condensation graph in a topological order. Suppose all components preceding a component D that is not a source have already been shown to lie in $\mathcal{A}S$. Choose an incoming condensation edge from such a component to D, represented by a graph edge $\alpha \to \beta$ with α already generated and $\beta \in D$. Surjectivity along edges gives a pure block

$$B_{\beta\alpha} : X_\alpha \twoheadrightarrow X_\beta.$$

Because $X_\alpha \subseteq \mathcal{A}S$ and $\mathcal{A}S$ is invariant under $\mathcal{A}$, surjectivity implies $X_\beta \subseteq \mathcal{A}S$. For any other vertex $\gamma \in D$, choose a directed path inside the strongly connected component from β to γ. Successive surjective edge blocks propagate the full packet space along the path, so $X_\gamma \subseteq \mathcal{A}S$. Hence $X_D \subseteq \mathcal{A}S$. Induction over the condensation graph gives $X = \mathcal{A}S$, proving the upper bound. □

Formal correspondence. covered. SCC is the quotient by mutual reflexive-transitive reachability. Source is proved equivalent to absence of incoming condensation edges. Finite minimality proves every vertex is reached from a source. Generated-algebra support proves source projection compression. The lower bound removes zero seeds, proves those actually lying in each source generate its corner module, and injects the dependent union of these nonzero seed sets into the original generating set. The upper bound chooses attained local minima; actual surjective blocks propagate range containment along actual paths. No source coverage, compression identity, generating conclusion, or graph certificate is assumed in the final theorem. The theorem in fact does not require nonzero original packets, so it includes the printed hypotheses.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 1066–1076; proof lines 1081–1098.

Statement SHA-256. `0be97dd456719faad7e8e6ba4091ee877f58e7c7c900c8ae79a7b8385c19daea`

87. Packet-propagating system

Stable ID. `PSC-I-D-PACKET-PROPAGATING`

Kind. definition

Statement.

A packet system that is surjective along edges is called packet propagating when every packet space X_α is cyclic under its diagonal corner algebra

$$P_\alpha \mathcal{A} P_\alpha.$$

Formal correspondence. definition represented. Cyclicity is the existing module Cyclic predicate for the genuine packetCornerAlgebra acting on its actual range. There are no extra local-rank-one certificates supplied.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 1105–1111.

Statement SHA-256. `4e9bfc875f14eeec60ebfab1d4906a00230861dfe0e37ea46c90639653fbc111`

88. Unweighted source-component count

Stable ID. `PSC-I-C-SOURCE-COMPONENT-COUNT`

Kind. corollary

Statement.

Assume the module resolved into packets is packet propagating and $X_\alpha \neq 0$ for every $\alpha \in I$. If c_0 denotes the number of source strongly connected components, then

$$\boxed{\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) = c_0.}$$

Proof. Fix a source component C and a vertex $\alpha \in C$. Choose a cyclic vector $s \in X_\alpha$ for $P_\alpha \mathcal{A} P_\alpha$. It generates all of X_α. Strong connectivity and surjectivity along edges then propagate the whole packet space to every vertex of C. Thus $r_C = 1$ for every source component. Apply `PSC-I-T-SOURCE-COMPONENT-SEED-RANK`. □

Formal correspondence. covered. The upper bound chooses a cyclic vector at one actual representative vertex of each source SCC and propagates full packet ranges to every vertex. The lower bound proves every generating set has a nonzero source projection, then uses purity and orthogonality to inject Sources into the chosen pure generating set. Nonzero packet range hypotheses are explicit. The finite cardinal-number form is proved; no finite generation or dimension assumption is introduced.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 1114–1122; proof lines 1126–1128.

Statement SHA-256. `f7d07d0e6a080b4b92c8a401d9663246fb377ecc6d930b8ecdb94ec07ea7e5dc`

89. Mixed-support seeds can merge source requirements

Stable ID. `PSC-I-B-PACKET-PURE-BOUNDARY`

Kind. boundary

Statement.

The source component formulas concern packet pure seeds. They do not give the unrestricted seed rank. For example, let

$$\mathcal{A} = \mathbb{k} \times \mathbb{k}, \qquad X = \mathbb{k} \oplus \mathbb{k}$$

with the coordinate action and the two coordinate packet projectors. The transfer graph has two source components and

$$\operatorname{psrank}_{\mathcal{A},\mathcal{P}}(X) = 2,$$

but the mixed vector $(1, 1)$ is cyclic, so

$$\operatorname{srank}_{\mathcal{A}}(X) = 1.$$

Formal correspondence. scope boundary. The unrestricted mixed-seed example is consistent with the proved product-algebra formula. The packet-pure rank calculation is not separately formalized.

Source locator. `editable/traditional/03_packets_and_graphs.tex`; statement lines 1130–1146.

Statement SHA-256. `a3610fb8adcedb4fb91006a77f357f3f18c57678d044c21b8522730a456b0006`

A.3 Transport and realization

90. Coordinate transport

Stable ID. `PSC-I-T-COORDINATE-TRANSPORT`

Kind. theorem

Statement.

Let $U : X \to Y$ be a vector space isomorphism and let $\mathcal{P} = (P_\alpha)$ be a packet system on X. Define

$$Q_\alpha := UP_\alpha U^{-1}.$$

Then $\mathcal{Q} = (Q_\alpha)$ is a packet system on Y. For $\widetilde{T} = UTU^{-1}$,

$$\boxed{Q_\beta \widetilde{T} Q_\alpha = U(P_\beta T P_\alpha)U^{-1}.}$$

Hence packet dimensions, zero patterns, and support preorders are invariant under coordinate transport. If a declared algebra generating family $\mathcal{G}$ is transported to $U\mathcal{G}U^{-1}$, then its transfer graph and reachability relation are also preserved.

Proof. Conjugation preserves products and sums, so

$$Q_\alpha Q_\beta = UP_\alpha P_\beta U^{-1} = \delta_{\alpha\beta} Q_\alpha, \qquad \sum_\alpha Q_\alpha = I_Y.$$

The block identity is direct multiplication:

$$Q_\beta \widetilde{T} Q_\alpha = UP_\beta T P_\alpha U^{-1}.$$

All listed invariants are determined by these transported blocks. □

Formal correspondence. covered. conjugate constructs the actual family U P_i U^{-1} and proves all projector identities. conjugate_transferBlock proves the exact displayed equality. packetRangeEquiv restricts U to each actual packet range and yields cardinal dimension equality with explicit universe lifts. support_pattern_invariant proves preservation for every relation. TransferEdge and ReachableFrom are unchanged when the actual generator set is transported by conjugation.

Statement SHA-256. `ae5e550ba65822235a1f8ab84c76a5a3ac876b28334523c9d845ece2af2d2d5a`

91. Packet-compatible operator morphism

Stable ID. `PSC-I-D-PACKET-MORPHISM`

Kind. definition

Statement.

Let $(X, \mathcal{A}, \mathcal{P})$ and $(Y, \mathcal{B}, \mathcal{Q})$ be packet resolved operator modules with packet index sets I and J. A packet compatible operator morphism is a triple

$$(\Phi, \varphi, \sigma)$$

consisting of a unital algebra homomorphism $\varphi : \mathcal{A} \to \mathcal{B}$, a linear map $\Phi : X \to Y$ satisfying

$$\Phi(Ax) = \varphi(A)\Phi(x),$$

and a map $\sigma : I \to J$ satisfying

$$Q_j \Phi = \Phi P_{\sigma^{-1}(j)}, \qquad P_{\sigma^{-1}(j)} := \sum_{\sigma(\alpha)=j} P_\alpha.$$

An empty fiber is interpreted as the zero projector.

Formal correspondence. definition represented. The source and target have actual concrete unital operator subalgebras and nonzero complete orthogonal packet projectors. The linear map, unital algebra map and entirely arbitrary index map are separately retained. Fiber projectors are literal finite sums; no injectivity or surjectivity condition is imposed on the index map.

Source locator. `editable/traditional/04_transport.tex`; statement lines 48–68.

Statement SHA-256. `e0e522a401795ef9ecf2497c058baf522801bf33dd581a837deaabd9cbe887bf`

92. Morphism of seeded systems

Stable ID. `PSC-I-D-SEED-MORPHISM`

Kind. definition

Statement.

A morphism

$$(X, \mathcal{A}, S, \mathcal{P}) \longrightarrow (Y, \mathcal{B}, S', \mathcal{Q})$$

is a packet compatible operator morphism satisfying the seed condition

$$\Phi(S) \subseteq \mathrm{Hull}_{\mathcal{B}}(S').$$

In the topological category all maps and actions are required to be continuous and the seed condition uses the topological hull when declared.

Formal correspondence. definition represented. The algebraic condition uses the actual target algebra span, with arbitrary seed sets. The continuous variant separately retains Hausdorff topological vector-space structure, actual continuity of every algebra operator and packet projector, and actual continuity of the carrier morphism. Its seed condition is membership in the literal topologicalClosure of AlgebraGeneratedHull. The paper specifies an algebra of continuous operators, not a separate topology on that algebra, and the code states this convention explicitly.

Source locator. `editable/traditional/04_transport.tex`; statement lines 73–84.

Statement SHA-256. `88c7e9a865f68bac1df1727bd7cfc8c66e5b11d2e8be77ada048a83aaafd5637`

93. Naturality of generated hulls and transfer blocks

Stable ID. `PSC-I-T-NATURALITY`

Kind. theorem

Statement.

Let (Φ, φ, σ) be a packet compatible operator morphism. For every subset $S \subseteq X$,

$$\boxed{\Phi(\mathrm{Hull}_{\mathcal{A}}(S)) = \mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi(S)) \subseteq \mathrm{Hull}_{\mathcal{B}}(\Phi(S)).}$$

For $T \in \mathcal{A}$ and $i, j \in J$,

$$\boxed{Q_j \varphi(T) Q_i \Phi = \sum_{\substack{\sigma(\beta)=j \\ \sigma(\alpha)=i}} \Phi P_\beta T P_\alpha.}$$

If Φ is surjective and S generates X, then $\Phi(S)$ generates Y under $\varphi(\mathcal{A})$ and hence under $\mathcal{B}$. If, in addition, the morphism is seeded, then S' generates Y.

Proof. Every element of $\Phi(\mathrm{Hull}_{\mathcal{A}}(S))$ is a finite sum of vectors

$$\Phi(As) = \varphi(A)\Phi(s),$$

so it belongs to $\mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi(S))$. Conversely, every generator $\varphi(A)\Phi(s)$ equals $\Phi(As)$, giving equality.

For the block formula, use intertwining and packet compatibility twice:

$$\begin{aligned} Q_j \varphi(T) Q_i \Phi &= Q_j \varphi(T) \Phi P_{\sigma^{-1}(i)} \\ &= Q_j \Phi T P_{\sigma^{-1}(i)} \\ &= \Phi P_{\sigma^{-1}(j)} T P_{\sigma^{-1}(i)} \\ &= \sum_{\substack{\sigma(\beta)=j \\ \sigma(\alpha)=i}} \Phi P_\beta T P_\alpha. \end{aligned}$$

If Φ is surjective and $\mathrm{Hull}_{\mathcal{A}}(S) = X$, the hull equality gives $Y = \mathrm{Hull}_{\varphi(\mathcal{A})}(\Phi(S))$. If $\Phi(S) \subseteq \mathrm{Hull}_{\mathcal{B}}(S')$, then $\mathrm{Hull}_{\mathcal{B}}(\Phi(S)) \subseteq \mathrm{Hull}_{\mathcal{B}}(S')$, so S' generates Y. □

Formal correspondence. covered. Hull naturality is actual Submodule.map equality with the span of image-algebra orbits; target-algebra inclusion is derived. The block formula is the exact double sum over possibly many-to-one fibers, at the level of actual linear maps. Surjective generation is derived from the map of top, then the seeded condition implies generation by the target seeds.

Source locator. `editable/traditional/04_transport.tex`; statement lines 87–109; proof lines 114–131.

Statement SHA-256. `e7fb174db6031054bdf06996ebad915dfaf307ad38b27fceb17442c46128863b`

94. Category of seeded packet systems

Stable ID. PSC-I-P-SEED-SYSTEM-CATEGORY

Kind. proposition

Statement.

Packet compatible operator morphisms compose, seeded morphisms compose, and identity morphisms satisfy both definitions. Thus packet resolved operator modules form a category **PktMod** and seeded packet systems form a category **SeedSys**.

Proof. Let $(\Phi, \varphi, \sigma) : (X, \mathcal{A}, \mathcal{P}) \to (Y, \mathcal{B}, \mathcal{Q})$ and $(\Psi, \psi, \tau) : (Y, \mathcal{B}, \mathcal{Q}) \to (Z, \mathcal{C}, \mathcal{R})$ be morphisms. Intertwining is preserved because

$$\Psi\Phi(Ax) = \Psi(\varphi(A)\Phi x) = (\psi \circ \varphi)(A)\Psi\Phi x.$$

For k in the target packet set,

$$\begin{aligned} R_k \Psi\Phi &= \Psi Q_{\tau^{-1}(k)}\Phi \\ &= \Psi\Phi \sum_{\tau(\sigma(\alpha))=k} P_\alpha. \end{aligned}$$

Thus the composite packet map is $\tau \circ \sigma$. If the morphisms are seeded, then

$$\Phi(S) \subseteq \mathrm{Hull}_{\mathcal{B}}(S'), \qquad \Psi(S') \subseteq \mathrm{Hull}_{\mathcal{C}}(S'').$$

By PSC-I-T-NATURALITY,

$$\Psi\Phi(S) \subseteq \Psi(\mathrm{Hull}_{\mathcal{B}}(S')) \subseteq \mathrm{Hull}_{\mathcal{C}}(\Psi(S')) \subseteq \mathrm{Hull}_{\mathcal{C}}(S'').$$

Identity maps satisfy the definitions with identity algebra and packet maps. □

Formal correspondence. covered. Composition explicitly aggregates composite fibers by a finite-sum rearrangement and composes operator intertwiners. Algebraic seed closure is proved using span transport. The continuous variant proves invariance of the actual closed algebraic hull from individual operator continuity, maps the source algebraic hull into the target closed hull, then derives map_closedHull from carrier continuity and closure minimality. Seeded composition applies this proved closure transport; identity seed membership and all category laws are proved. The actual algebraic and topological Category instances therefore cover the full stated category claim.

Source locator. `editable/traditional/04_transport.tex`; statement lines 138–141; proof lines 147–180.

Statement SHA-256. `3cc5c23c5df9094cc9c18b7b9539bf0cadbbe2e74dd249651920fd5034f347a1`

95. Packet exact sequence for an invariant subspace

Stable ID. `PSC-I-T-PACKET-EXACT-SEQUENCE`

Kind. theorem

Statement.

Let $K \leq X$ satisfy $P_\alpha K \subseteq K$ for every α. Define

$$K_\alpha := P_\alpha K = K \cap X_\alpha$$

and

$$\overline{P}_\alpha(x + K) := P_\alpha x + K.$$

Then:

(i) The nonzero restrictions $P_\alpha|_K$ form a packet system on K.

(ii) The nonzero $\overline{P}_\alpha$ form a packet system on X/K.

(iii) For every α there is a short exact sequence

$$0 \longrightarrow K_\alpha \longrightarrow X_\alpha \longrightarrow \overline{P}_\alpha(X/K) \longrightarrow 0,$$

and

$$\overline{P}_\alpha(X/K) \cong X_\alpha/(X_\alpha \cap K) \cong (X_\alpha + K)/K.$$

(iv) The full exact sequence decomposes packetwise as the direct sum of these short exact sequences.

Proof. Restriction preserves idempotency, pairwise annihilation, and the identity sum on K. If $x \in K \cap X_\alpha$, then $x = P_\alpha x \in P_\alpha K$, proving $K_\alpha = K \cap X_\alpha$.

The quotient operator is well defined because replacing x by $x + k$ changes $P_\alpha x$ by $P_\alpha k \in K$. The idempotent and annihilation identities descend, and the sum is the identity on X/K. The map $X_\alpha \to X/K$ has image $(X_\alpha + K)/K$ and kernel $X_\alpha \cap K$, giving the short exact sequence and the quotient isomorphisms. Exact packet coordinates identify the original sequence with the direct sum over α. □

Formal correspondence. covered. K is an actual invariant submodule. Restriction/quotient projectors are constructed; restricted range equals K intersect X_i. Actual packet inclusion is injective, its range equals the actual quotient-map kernel, and quotient map is onto. First/second quotient isomorphisms use denominator comaps in the correct ambient type. Pointwise coordinate maps intertwine with original inclusion/quotient and form a short exact sequence; exact direct-sum coordinates give the full decomposition.

Source locator. `editable/traditional/04_transport.tex`; statement lines 185–216; proof lines 221–225.

Statement SHA-256. `7311937b07e98adf3e6f91ad665358380cab6ce26e3daeffdbf4787d7a01de56`

96. Packet descent through an invariant quotient

Stable ID. PSC-I-T-QUOTIENT-PACKET-DESCENT

Kind. theorem

Statement.

Under the hypotheses of PSC-I-T-PACKET-EXACT-SEQUENCE, the operators

$$\overline{P}_\alpha(x+K) = P_\alpha x + K$$

are well defined pairwise annihilating idempotents with sum $I_{X/K}$, and the quotient map satisfies

$$\boxed{\pi P_\alpha = \overline{P}_\alpha \pi.}$$

After zero packets are removed, they form the canonical quotient packet system.

Proof. All assertions are the quotient part of PSC-I-T-PACKET-EXACT-SEQUENCE. The intertwining identity follows directly from the definition:

$$\overline{P}_\alpha \pi(x) = P_\alpha x + K = \pi P_\alpha(x).$$

□

Formal correspondence. covered. Actual mapQ uses invariance of K. Quotient representative calculations prove the laws and commuting identity. Zero removal preserves completeness. Quotient surjectivity proves uniqueness of every descended operator, so canonicity is established.

Source locator. editable/traditional/04_transport.tex; statement lines 232–243; proof lines 247–252.

Statement SHA-256. b51391a00350d220fc92610f351826489ca69d166e27e266a1ecc6ecc7a2ffc7

97. Restriction and quotient of transfer blocks

Stable ID. PSC-I-C-QUOTIENT-PACKET-DESCENT

Kind. corollary

Statement.

Under the hypotheses of PSC-I-T-PACKET-EXACT-SEQUENCE, let $T \in \mathrm{End}(X)$ preserve K. Then every block $T_{\beta\alpha}$ maps K_α into K_β, and the induced quotient operator $\overline{T}$ satisfies

$$\boxed{\overline{T}_{\beta\alpha}\,\pi = \pi T_{\beta\alpha},}$$

where $\pi : X \twoheadrightarrow X/K$.

Proof. If $x \in K_\alpha$, then $Tx \in K$, so

$$T_{\beta\alpha}x = P_\beta T x \in K \cap X_\beta = K_\beta.$$

On the quotient,

$$\overline{T}_{\beta\alpha}\pi = \overline{P}_\beta \overline{T} \overline{P}_\alpha \pi = \pi P_\beta T P_\alpha.$$

□

Formal correspondence. covered. Invariance under P_i,T,P_j proves preservation of K and membership in the target packet. Tbar is actual K.mapQ K T hT, and representative calculation proves the quotient-block identity. Lean orientation is the symmetric equality of the printed formula.

Source locator. `editable/traditional/04_transport.tex`; statement lines 254–265; proof lines 269–282.

Statement SHA-256. `4fa0ae8effe1e5472dcde2be67829cba4ae586df9853d252baff055f3ee7fd46`

98. Topological packet exact sequence

Stable ID. `PSC-I-C-TOPOLOGICAL-PACKET-EXACT-SEQUENCE`

Kind. corollary

Statement.

If X is Banach, the P_α are bounded, and K is closed and packet invariant, then every packet sequence in `PSC-I-T-PACKET-EXACT-SEQUENCE` is a short exact sequence of Banach spaces with bounded maps, and the quotient projectors are bounded.

Proof. Closedness of K makes X/K Banach. The restricted projectors are bounded, and the quotient projectors are bounded because

$$\|\overline{P}_\alpha(x+K)\|_{X/K} \le \|P_\alpha\|\,\|x+K\|_{X/K}.$$

The packet spaces are closed ranges of bounded idempotents. □

Formal correspondence. covered. The generic theorem works over any NormedField, including a trivial valuation, with explicit boundedness of the original projectors. Restriction and quotient CLMs are the actual algebraic packet maps. Near-minimal quotient representatives transfer every original bound to the quotient; the norm bound uses the usual infimum-of-bounds norm of the bounded additive projector. Actual packet inclusion and quotient maps are bounded with constant one and retain injectivity, exactness, and surjectivity. Closed K and closed bounded-idempotent ranges make all three terms complete.

Source locator. `editable/traditional/04_transport.tex`; statement lines 284–287; proof lines 292–300.

Statement SHA-256. `2590b3fce057e3d054522a58a728f46dbf3c609c95ff6ab061ff654ffd72fee1`

99. Dense realization theorem

Stable ID. `PSC-I-T-DENSE-REALIZATION`

Kind. theorem

Statement.

Let X and Y be Hausdorff topological vector spaces, let $\Phi : X \to Y$ be continuous, surjective, and intertwining with respect to φ, and let S topologically generate X. Then $\Phi(S)$ topologically generates Y. If finite continuous packet systems satisfy

$$Q_j \Phi = \Phi P_{\sigma^{-1}(j)},$$

then

$$\boxed{Q_j Y = \Phi(P_{\sigma^{-1}(j)} X)}$$

for every j.

Proof. Given $y = \Phi(x)$, choose a net $x_\lambda \in \mathrm{Hull}_{\mathcal{A}}(S)$ converging to x. Then

$$\Phi(x_\lambda) \to y,$$

and naturality places every $\Phi(x_\lambda)$ in $\mathrm{Hull}_{\mathcal{B}}(\Phi(S))$. Hence the latter hull is dense. For packets, one inclusion follows from compatibility. Conversely, if $y = Q_j y$, choose x with $\Phi(x) = y$. Then

$$y = Q_j \Phi(x) = \Phi P_{\sigma^{-1}(j)} x.$$

□

Formal correspondence. covered. For the actual continuous linear intertwiner in the packet-morphism convention, the image of the source algebraic operator hull is contained in the target hull, and continuous surjectivity transports density. The actual finite grouped projector is the sum over the σ-fibre, including empty fibres. Surjectivity and the given intertwining identity prove exact equality of image and target range. No norm or metrizability assumptions occur.

Source locator. `editable/traditional/04_transport.tex`; statement lines 305–318; proof lines 322–331.

Statement SHA-256. `58bf2b9bfb4ab3ae9f3309b03cc231e0b59c81b7fe2b6c99e4b74884aaf15bca`

100. Quotient topology and completed realization

Stable ID. `PSC-I-T-QUOTIENT-TOPOLOGY-COMPLETION`

Kind. theorem

Statement.

Let $\Phi : X \twoheadrightarrow Y$ be a continuous linear quotient map between Hausdorff topological vector spaces, and put $K = \operatorname{Ker} \Phi$. Then the induced map

$$\widetilde{\Phi} : X/K \longrightarrow Y$$

is a topological isomorphism. If $D \subseteq X$ is a linear subspace whose image $\Phi(D)$ is dense in a complete space Y, then the completion of

$$D/(D \cap K)$$

in the topology transported from Y is canonically isomorphic to Y.

Proof. The algebraic first isomorphism theorem gives a bijection $\widetilde{\Phi}$. By definition of the quotient topology, a set $U \subseteq X/K$ is open exactly when its preimage in X is open. Because Φ is a quotient map, this is equivalent to $\widetilde{\Phi}(U)$ being open in Y. Thus $\widetilde{\Phi}$ is a homeomorphism. The second statement applies the dense completion argument of PSC-I-T-COMPLETED-PRESENTATION to the injective map $D/(D \cap K) \to Y$. □

Formal correspondence. covered. The actual first-isomorphism linear equivalence is continuous both ways using IsQuotientMap, not continuity plus surjectivity alone. The restriction to D uses its actual kernel, definitionally comap(D inclusion,ker Φ); density is exactly Φ(D). The same explicit transported-uniformity quotient completion gives the canonical target equivalence and agrees with Φ on represented classes. No original-domain quotient topology is silently substituted for the printed transported topology.

Source locator. `editable/traditional/04_transport.tex`; statement lines 333–344; proof lines 348–350.

Statement SHA-256. `2e986d76e93d67446708502bfae8275f63d8ab0eaf8dcc3e3630ee7f6b3fa077`

101. Continuous surjections and quotient topology

Stable ID. PSC-I-B-TOPOLOGICAL-QUOTIENT

Kind. boundary

Statement.

Continuity and surjectivity transport density as in PSC-I-T-DENSE-REALIZATION. They do not by themselves identify the given topology on Y with the quotient topology from X. The stronger conclusion in PSC-I-T-QUOTIENT-TOPOLOGY-COMPLETION requires the quotient map hypothesis or an equivalent open mapping condition.

Formal correspondence. scope boundary. The quotient-map requirement is preserved; no open-map theorem is inferred from continuity alone.

Source locator. `editable/traditional/04_transport.tex`; statement lines 352–355.

Statement SHA-256. `855989a0fadfaf7174d83889d9a2c4208bc722f866b35c5da99de3e7ecf1b9f7`

102. Realization functor and preservation profile

Stable ID. `PSC-I-D-REALIZATION-FUNCTOR`

Kind. definition

Statement.

Let $\mathbf{SeedSys}_{\mathrm{abs}}$ be an abstract category of seed systems and let $\mathbf{C}_D$ be a domain category. A realization functor is a functor

$$\mathsf{Ev}_D : \mathbf{SeedSys}_{\mathrm{abs}} \longrightarrow \mathbf{C}_D$$

with a declared preservation profile specifying which of the following structures are preserved:

$$0,\ I,\ \text{finite sums},\ \text{composition},\ \text{biproducts},$$
$$\text{kernels},\ \text{cokernels},\ \text{quotients},\ \text{tensor products},$$
$$\text{packet idempotents},\ \text{transfer blocks},\ \text{topological completions}.$$

Preservation of a structure means preservation of its defining identity or universal property, not merely a similarity of notation.

Formal correspondence. documentary. The profile is represented by actual additive/linear functor and PreservesLimit/PreservesColimit instances, with typed syntax for equational operations. Universal constructions also use explicit structured categories, an induced functor, an underlying comparison isomorphism, and actual initial/terminal preservation. No Boolean profile field is accepted in place of preservation evidence.

Source locator. `editable/traditional/04_transport.tex`; statement lines 382–397.

Statement SHA-256. `152d8ee6b5bb1735f7655c6eeee72210d213959c00c9e6168d554eee25b7c5fe`

103. Equational realization principle

Stable ID. `PSC-I-T-REALIZATION-EXPORT`

Kind. theorem

Statement.

Let $F : \mathbf{C} \to \mathbf{D}$ be an additive functor between preadditive categories. Any equality of morphisms constructed from declared generating morphisms by finite sums, additive inverses, identities, zero maps, and composition is preserved by F. Scalar multiplication by a coefficient ring is also preserved when the categories are enriched over that ring and F is linear for the declared enrichment. If a proof additionally uses a chosen biproduct, kernel, cokernel, quotient, tensor product, or completion and F preserves that construction in its declared profile, then the corresponding proof diagram is transported to $\mathbf{D}$.

Proof. Functoriality gives

$$F(I) = I, \qquad F(g \circ f) = F(g) \circ F(f),$$

and additivity gives

$$F(0) = 0, \qquad F(f+g) = F(f) + F(g), \qquad F(-f) = -F(f).$$

If the declared enrichment is present, linearity additionally gives $F(af) = aF(f)$ for every coefficient a. A structural induction on the construction of a morphism expression therefore carries every permitted

equational proof to its image under F. If a step invokes a universal construction, preservation means that the image diagram satisfies the same universal property. The uniquely induced morphism in the source proof is therefore carried to the uniquely induced morphism in the target proof. Repeating this argument through the finite proof diagram transports the conclusion. □

Formal correspondence. covered. Structural induction on well-typed morphism expressions proves transport of identities, zero, addition, negation, scalar multiplication and composition. The additive-only statement uses the canonical integer enrichment, and no extra scalar-linearity assumption is inserted. Actual limit/colimit diagrams are transported under the matching preservation instance. The conditional universal-construction clause is explicit: a declared profile supplies the structured categories of the universal problem, an induced functor, compatibility with the underlying realization functor, and actual initial/terminal preservation. CategoryUniversal derives the mapped initial/terminal property, equality of the uniquely induced arrows, and the underlying commuting comparison squares. Tensor and completion preservation are legitimate conditional inputs, not falsely inferred from additivity.

Source locator. `editable/traditional/04_transport.tex`; statement lines 400–403; proof lines 408–424.

Statement SHA-256. `e0352bdb7ba75e24d4c7e6e0259802f47800c4945c13efe4b3c68edcacef678d`

104. Realization export principle

Stable ID. `PSC-I-P-REALIZATION-EXPORT`

Kind. proposition

Statement.

Every canonical Paper I identity whose proof uses only the operations listed in a realization functor's verified preservation profile remains valid after applying that functor. If the proof uses a domain specific hypothesis not encoded by the functor, that hypothesis must be verified separately before the transported statement is promoted to a theorem.

Proof. The first assertion is `PSC-I-T-REALIZATION-EXPORT`. The second is a logical boundary: a functor transports established identities and preserved universal constructions, but it does not create an unverified analytic, topological, positivity, finiteness, or integrality hypothesis. □

Formal correspondence. covered. This is the methodological specialization of record 103 to already established Paper I identities. The formal equations are transported from a proved source equality, not assumed as the desired target equality. The universal-property step uses the explicit structured-category profile of CategoryUniversal. No new analytic/topological/positivity/finiteness/integrality assumption is generated.

Source locator. `editable/traditional/04_transport.tex`; statement lines 432–435; proof lines 439–441.

Statement SHA-256. `bf39b86447c8332d60216e48d23129b6ae5b096611e3febd9d09a699f1a9a557`

105. Semantic realization criterion

Stable ID. PSC-I-D-SEMANTIC-REALIZATION

Kind. definition

Statement.

A domain theorem is a semantic realization of a canonical seed calculus theorem only when:

(i) An explicit realization functor or intertwining construction is given.

(ii) The preservation profile covers every construction used in the canonical proof.

(iii) Every additional analytic, finiteness, convergence, positivity, or integrality hypothesis is verified in the domain.

(iv) The resulting conclusion is stated in the domain's native objects.

Reuse of the words "seed", "packet", or "transfer" without these data is only syntactic reuse.

Formal correspondence. documentary. A methodology and scope checklist, not automatic formal certification.

Source locator. editable/traditional/04_transport.tex; statement lines 443–453.

D Operation and hypothesis vocabulary

The runtime ontology separates structural operations from hypothesis classes. These names form a controlled vocabulary for profiles and source-derived annotations. They are not a complete formal semantics for every mathematical construction named.

Name	Class
`identity`	structural
`zero`	structural
`finite_sum`	structural
`additive_inverse`	structural
`composition`	structural
`scalar_action`	structural
`direct_sum`	structural
`finite_product`	structural
`biproduct`	structural
`kernel`	structural
`cokernel`	structural
`image`	structural
`quotient`	structural
`tensor_product`	structural
`dual`	structural
`packet_idempotents`	structural
`transfer_blocks`	structural
`support_relation`	structural
`path_composition`	structural
`polynomial_action`	structural
`jacobson_radical`	structural
`semisimple_decomposition`	structural
`primary_decomposition`	structural
`universal_property`	structural
`functoriality`	structural
`exact_sequence`	structural
`closure`	structural
`completion`	structural
`topology`	structural
`norm`	structural
`adjoint`	structural
`dimension`	structural
`finite_indexing`	hypothesis
`surjectivity`	hypothesis
`injectivity`	hypothesis
`isomorphism`	hypothesis
`continuity`	hypothesis
`boundedness`	hypothesis
`closedness`	hypothesis
`density`	hypothesis
`orthogonality`	hypothesis
`self_adjointness`	hypothesis
`positivity`	hypothesis
`integrality`	hypothesis

Name	Class
unconditional_convergence	hypothesis
hausdorff	hypothesis
complete_field	hypothesis
invariant_subspace	hypothesis
commutation	hypothesis
transitivity	hypothesis
edge_surjectivity	hypothesis
packet_propagation	hypothesis
nonzero_packet_spaces	hypothesis

E Runtime Lean record map

This is the eight-entry mapping attached to the archived runtime. The evidence descriptions and source-match categories are reproduced from that map. A fresh build performed elsewhere must be documented separately.

Finite packet system

PSC-I-D-PACKET-SYSTEM

Source match. `structural_exact`

Stored certificate status. `compiled_in_verified_tranche`

Declarations. `Komorebi.Foundation.LinearProjectorFamily`

In the runtime formalization, ProjectorCore.lean supplies structure axioms for idempotence, pairwise annihilation, and completeness.

Packet analysis and synthesis

PSC-I-D-ANALYSIS-SYNTHESIS

Source match. `stronger_typed_realization`

Stored certificate status. `kernel_accepted`

Declarations. `Komorebi.Foundation.LinearProjectorFamily.PacketSpace`; `Komorebi.Foundation.LinearProjectorFamily.rangeAnalysis`; `Komorebi.Foundation.LinearProjectorFamily.rangeSynthesis`

ExactCoordinates.lean defines the packet space as the product of projector ranges, so both transforms carry range certificates.

Exact packet-coordinate isomorphism

PSC-I-T-EXACT-PACKET-COORDINATES

Source match. `stronger_typed_realization`

Stored certificate status. `kernel_accepted`

Declarations. `Komorebi.Foundation.LinearProjectorFamily.exactPacketCoordinates`

Explicitly listed as Kernel accepted in VERIFICATION_REPORT.md; proves both inverse laws for range-restricted packet coordinates.

Packetwise equality

PSC-I-C-PACKETWISE-EQUALITY

Source match. `one_direction_plus_trivial_reverse`

Stored certificate status. `compiled_in_verified_tranche`

Declarations. `Komorebi.Foundation.LinearProjectorFamily.eq_of_projectors_eq`

The nontrivial direction is proved in ProjectorCore.lean; the reverse direction follows by congruence from equality.

Transfer block

PSC-I-D-TRANSFER-BLOCK

Source match. `generalized_domain_codomain`

Stored certificate status. `compiled_in_verified_tranche`

Declarations. `Komorebi.Foundation.transferBlock`

Definition allows distinct source and target packet systems; the PSC-I endomorphism case is a specialization.

Exact operator reconstruction

PSC-I-T-OPERATOR-RECONSTRUCTION

Source match. `generalized_domain_codomain`

Stored certificate status. `kernel_accepted`

Declarations. `Komorebi.Foundation.transferBlock_reconstruction`

Explicitly listed as Kernel accepted; reconstructs any linear map from all source-target blocks using completeness of both packet families.

Packet matrix multiplication

PSC-I-T-BLOCK-MULTIPLICATION

Source match. `generalized_composition_form`

Stored certificate status. `kernel_accepted`

Declarations. `Komorebi.Foundation.transferBlock_comp`

Explicitly listed as Kernel accepted; inserts the complete middle packet family and yields the local composition sum.

Support-pattern algebra criterion

PSC-I-T-SUPPORT-PATTERN-ALGEBRA

Source match. `partial_sufficient_direction`

Stored certificate status. `kernel_accepted_related`

Declarations. `Komorebi.Algebra.MatrixSupported.mul`

Verified tranche proves multiplicative closure for transitive support relations; it is related evidence, not a source-equivalent certificate for every direction of the PSC-I criterion.

Reading scope

This formal companion connects Chapter I to its Lean sources, correspondence map, and verification evidence. Section 2 identifies the source tree and distinguishes complete correspondences from partial or unmapped records.

> The tutorial and its complete 35-row contract describe the foundational formalization: 20 source files, 84 mapped targets, and 1,126 recorded namespace entries. Those counts belong to that component. The later continuation has a larger source closure and a separate map to the expanded manuscript's 108 records. The two inventories are retained with their exact scopes.

Evidence for the 108-record correspondence is indexed separately from the foundational receipts. Rendering this guide is a presentation check. Compiler acceptance, logical kernel replay, source identity, and source-to-statement correspondence are reported as distinct checks.

1 Reading the mathematical, formal, and computational texts together

The mathematical text develops the language and its examples. The computational companion gives stable records, typed dependencies, semantic profiles, and executable validation interfaces. This guide makes the Lean development usable: where the definitions live, what each theorem actually accepts, how its proof works, and what evidence connects the delivered source to an accepted kernel run.

The foundational formalization in Sections 3–14 has twenty Lean source files.
The source register identifies that formalization. The mathematical text has an expanded core of 108 stable records, an inventory distinct from the 35 foundational Lean contract rows.

> The guide retains both the scope and the exclusions of every contract row. For example, foundational row 10 proves a split-semisimple formula after algebra and module equivalences are supplied. The later continuation constructs compatible decompositions and establishes the general division-ring formula. The new result is documented through its own declarations and evidence. It does not change the inputs of foundational row 10.

1.1 What the numbers count

Quantity	Meaning
20 source files	Local Lean files, including the import aggregator, focused Mathlib import file, and standalone audit.
35 contract rows	Mathematical statement families and specifications in the foundational contract map.
84 mapped targets	Distinct Lean declaration names used by those rows. They include definitions and equivalences as well as theorems.
1,126 entries	Entries in the project namespace inspected by the recorded audit, including generated helpers.
108 stable records	The expanded manuscript inventory. The current correspondence map and the machine payload's separate eight-record map have different evidence scopes.

None of these figures is a count of 1,126 independent new theorems. The useful unit of mathematical coverage is a statement together with its hypotheses, its precise conclusion, its declaration target, and the evidence attached to that target.

1.2 Suggested reading routes

A reader new to Lean can begin with Sections 3–5, which unpack the syntax through exact packet coordinates. A mathematician checking coverage can go directly to the exhaustive map in Section 14, then inspect the relevant source type and proof. A contributor preparing a build should read Sections 10 and 11 before interpreting any successful command.

The displayed Lean listings are excerpts from the preserved source. Their surrounding imports, namespace declarations, and section variables remain in the original files. They are reading excerpts, not advertised standalone files. The editable companion includes their source ranges and hashes in `generated/excerpts.json`.

2 Formal sources, correspondence, and evidence

The mathematical text and both companions share one statement inventory. The traditional manuscript supplies the statements and proofs. The machine catalog reproduces those statements with stable identifiers and source locators. The formal correspondence map records the exact Lean support for each statement. The source archive uses the following stable paths:

File or directory	Purpose
`formal/current/`	Flat formal source closure, including the continuation modules and their earlier dependencies.
`formal/coverage/COVERAGE_108.json`	All 108 statements, source proofs and hashes, declaration mappings, scopes, and record classifications.
`formal/evidence/`	Compiler, replay, audit, identity, and boundary-check receipts, indexed by the verification record.
`editable/traditional/`	Mathematical source, including the stated hypotheses of the split-semisimple corollary.

The inventory has 69 proof-level records. Definitions, classical inputs, boundaries, and documentary records are listed separately in the map and are excluded from this proof-level count.

Status	Covered	Partial	Not mapped
Proof-level records	69	0	0

"Covered" means a complete correspondence at the recorded scope. "Partial" includes substantive missing proofs and consequences not yet assembled from existing declarations. "Not mapped" means that this source closure has no established complete declaration for the record. These statuses are not a percentage of independent theorems: the records differ in scope and may share mathematical dependencies.

2.1 Primary and semisimple constructions

The continuation proves the intrinsic primary quotient and generator count, the geometric formula, scalar extension, and the six-way cyclic criterion. It also proves noncommutative module-top reduction and the nonsplit semisimple formula, including actual compatible decompositions from the Wedderburn–Artin existence theorem. The final existence theorems do not take a desired rank equality or a compatible decomposition as an input. They are noncomputable mathematical constructions, not executable decomposition algorithms.

Source layer	Mathematical entry points
`PaperICompletion/`, `PaperICompletion3/`	Spectral certificates, invariant factors, primary seed formulas, and operator-level bridges.
`PaperICompletion4/`	Intrinsic primary decomposition, residue quotients, and the operator seed formula.
`PaperICompletion5/`	Linear primary eigenspaces, the geometric seed formula, and its cyclic criterion.
`PaperICompletion6/`	Scalar extension, one invariant factor, and the six-way cyclic criterion.
`PaperICompletion7/`	Nakayama, module-top reduction, and the local residue division-ring case.
`PaperICompletion8/`	Division-ring row generation, products, regular multiplicities, compatible presentations, and semisimple existence/-formulas.

The original `KomorebiVerification/` modules remain the foundation for packet coordinates, transport, seed rank, matrix models, and bounded-packet analysis. Their explanations occupy the following tutorial sections. Current declarations may strengthen those earlier results. The original theorem signatures retain their own input boundaries.

2.2 Source modules and presentation conventions

The `PaperIRelease/` layer extends the preceding continuation. Its source files are grouped by mathematical construction:

Source family	Construction
`GrammarAlgebra`, `GrammarTyped`, `GrammarModules`, `GrammarEquivalence`, `GrammarIdeal`	Typed realizations, module categories, comparison functors, and quotient-algebra presentations.
`SeedOperations`, `ExactSequences`, `ScalarExtension`, `PolynomialModule`, `PolynomialMonic`	Generator bounds, exact sequences, scalar extension, and canonical polynomial-module wrappers.
`PacketAggregation`, `PacketDescent`, `PacketExactSequence`, `PacketUniversal`, `TensorPackets`	Actual range packets, quotient and restriction maps, exactness, universal properties, and tensor constructions.
`AlgebraSupport`, `AlgebraPreorder`, `AlgebraQuotient`, `PacketCorners`, `BoundedStar`	Support algebras, diagonal and quotient structure, local actions, and bounded adjoints.
`GraphReachability`, `GraphSources`, `GraphSourceCount`, `PacketPureRank`, `PacketSourceRank`	Transfer reachability, source components, and packet-pure generator counts.
`TopologySeedRank`, `TopologyPresentations`, `TopologyCountablePackets`, `TopologyCategories`	Closed hulls, locally convex presentations, unconditional packets, and continuous categorical maps.
`CategoryPackets`, `CategoryUniversal`, `CategoryExport`	Packet-system categories, naturality, and preservation of equations under functors.

These entries support source navigation. The correspondence map supplies the exact declaration names and hypotheses. Its verification receipt determines the accepted scope.

For the typed-grammar correspondence, the finite-vertex path algebra uses its standard vertex-and-arrow presentation: vertex idempotents are pairwise annihilating and sum to one, and each arrow lies in its target/source corner. The formal `PathAlgebra` names that presentation. `GrammarIdeal` takes an

arbitrary two-sided ideal and constructs the comparison between the iterated ideal quotient and the combined presentation. Its two comparison maps are proved inverse. Thus the presentation convention is explicit when reading the manuscript notation kQ/I. It is not an assumed module-category equivalence or a supplied conclusion about generators.

2.3 Verification scope

The verification receipt reports complete correspondences for all 69 proof-level records in the 108-record inventory. Each conclusion retains the hypotheses and presentation conventions recorded in the correspondence map. Definitions, boundaries, and classical inputs are classified separately. The record includes targeted semantic reviews for 47 proof-level records and accepted predecessor correspondences for 22 others. The total of 69 accepted correspondences does not mean that all records received independent reviews in the same verification event.

The recorded audit checks 116 formal source modules plus the retained boundary suite. Including that suite, it inventories 3513 source-owned entries and checks 3500 logical declarations. Of these, 3499 are checked by logical replay and one declaration sharing an upstream name receives a fresh-name kernel body check after exact type/value comparison. It inventories 13 runtime helpers separately and records 12 rejected negative controls. The allowed transitive axiom set is `Classical.choice`, `Quot.sound`, `propext`. The receipt is `formal/evidence/RELEASE_VERIFICATION.json`. Its detailed compiler and logical-replay evidence is under `formal/evidence/whole_closure/`.

The recorded computational checks pass for 96 exact finite or symbolic visual assertions, 33 companion tests, and 10 regenerated PDF/PNG figure pairs. These bounded computations have their own scope and do not replace the formal declarations.

The pinned upstream dependency cache is reused. Logical replay uses Lean's official kernel. It is not an independently implemented checker. The source-to-manuscript correspondence is a separate reviewed mathematical artifact.

2.4 Proof-level correspondence index

The following index is generated from the correspondence map. The machine companion supplies the source statements, and the JSON map supplies every declaration name and exact scope note. Every covered status must be read with that scope note before reusing a theorem.

Stable record	Recorded status
`PSC-I-T-TYPED-MODULE-EQUIVALENCE`	covered

3 The type system as mathematical bookkeeping

Lean's types carry assumptions that would otherwise be easy to leave implicit. A statement over a semiring and a module is not automatically a statement about a Hilbert space. A linear equivalence is not automatically a continuous linear equivalence. An endomorphism over the ground field is not automatically linear over a larger acting algebra.

Lean expression	Mathematical role
`[SemiringR]`	An instance supplying the semiring laws for the coefficient object. Square brackets request typeclass synthesis.
`[ModuleRM]`	The scalar action and its laws. The module is over the named scalar object, not an unspecified field.
`M→ₗ[R]N`	An R-linear map, with additive and scalar compatibility bundled into the value.
`Module.EndRM`	The endomorphism type $\mathrm{End}_R(M)$.
`M≃ₗ[R]N`	A linear equivalence with inverse laws.
`X→L[k]Y`	A continuous linear map between normed spaces. The uppercase L is significant.
`X≃L[k]Y`	A continuous linear equivalence.
`M→ₛₗ[σ]N`	A semilinear map along the specified scalar homomorphism σ.
`LinearMap.rangef`	The range as a submodule. An element includes a witness that it is attained by f.
`[Fintypeι]`	A finite enumeration of the index type, allowing finite sums over all indices.
`ι→₀A`	Finitely supported coefficient families, the free A-module on the label type.
`IsLeastSR`	Both $R \in S$ and $R \leq r$ for every $r \in S$. This packages upper and lower bounds.

Arguments in braces are implicit parameters inferred from use. Arguments in parentheses are explicit inputs. A section's `variable` declarations can supply parameters to all later declarations that use them. Therefore a theorem copied without its section context can look less constrained than its actual elaborated type. The preserved `mapped_declarations.log` prints every mapped type with universe information and is the right companion when checking the complete signature.

The package disables automatic invention of implicit variables with `autoImplicit=false` and `relaxedAutoImplicit=false`. This makes a misspelled or undeclared variable an error instead of silently introducing a new parameter. It does not remove explicit hypotheses, nor prove that a chosen formal statement is the intended prose statement.

3.1 Proof terms and the tactics used here

`exacth` closes the current goal with an existing proof of its type. `rfl` proves a definitional equality after reduction. `rw` substitutes proved equalities. `simp` applies a collection of simplification lemmas and produces a proof term. `funext` reduces equality of functions to equality at each input. `Subtype.ext` reduces equality of range elements to equality of their underlying vectors.

The command `classical` makes classical instances available during elaboration. It is not a placeholder. Some resulting declarations depend on `Classical.choice`. The audit records this explicitly. A `noncomputabledef` can define a mathematically precise object through choice or noncomputable library constructions. It does not by itself provide executable numerical code.

These distinctions matter particularly for graph rank. A formula defined using a finite exact spectrum may be mathematically well defined and formally verified while still not being an extracted eigensolver.

4 The source architecture

The project is organized around a finite algebraic core, seed generation, concrete matrix models, operator and packet completion, and a separate analytic component. MathlibImports.lean centralizes the focused external imports.

Layer	Main responsibility
Projector core	`ProjectorCore`, `ExactCoordinates`, `FibreRefinement`, and `ResidueProjectors`: finite masks, range coordinates, exact reconstruction, and refinement.
Transport and blocks	`PaperITransport` and `PaperIBlockCompletion`: conjugation, naturality, operator-level block identities, and support patterns.
Seed rank	`SeedRankBasics` and `SeedRankOperations`: generation, free presentations, cardinal minima, semilinear transport, products, tensor bounds, and scalar quotients.
Matrix realizations	`SemisimpleSeedRank`, `FullMatrixCyclicity`, `SemisimpleCompletion`: concrete row-space bounds and their connection to canonical seed rank.
One operator	`PathGraphKrylov` and `SingleOperatorGraph`: polynomial orbits, exact minimum certificates, paths, and cycles.
Packet completion	`PacketNaturalityCompletion`: dependent block algebra, support, reachability, strict morphisms, and the typed-quiver certificate.
Analysis	`TopologicalCompletion`: bounded projectors, closure, dense realization, completion, and the bilateral shift.
Models and specifications	`EllipticAlgorithms`: the elliptic quotient model and the three finite mathematical algorithm specifications.
Audit	`KernelAudit`: concrete instantiations, the exact mapped-target list, and the namespace-wide axiom gate.

The accompanying source records contain the direct-import table. File imports do not identify every logical dependency of each declaration. A declaration's transitive axiom set is obtained separately from the Lean environment.

5 Exact packet coordinates, from assumptions to inverse laws

The starting object is a finite family of linear projectors. Its structure records three separate laws: each map is idempotent, different maps annihilate one another, and their finite sum is the identity.

Source: KomorebiVerification/ProjectorCore.lean.

```
structure LinearProjectorFamily
    (R : Type u) (M : Type v) (ι : Type w)
    [Semiring R] [AddCommMonoid M] [Module R M] [Fintype ι] where
  proj : ι → Module.End R M
  idempotent : ∀ i x, proj i (proj i x) = proj i x
  orthogonal : ∀ {i j}, i ≠ j → ∀ x, proj i (proj j x) = 0
  complete : ∀ x, (∑ i, proj i x) = x
```

Here orthogonality means pairwise annihilation. An inner product is not among the assumptions, so this word is algebraic at this stage. Self-adjointness appears only in the later adjoint result.

Write P_i for the maps. The intended coordinates are

$$\mathcal{P} = \prod_{i \in I} \mathrm{range}(P_i), \qquad \mathsf{A}(x) = (P_i x)_i, \qquad \mathsf{S}((x_i)_i) = \sum_i x_i.$$

The type of the packet space is crucial. It is the product of independently defined ranges. It is not defined as the image of analysis, and synthesis is the ordinary sum. Thus the reverse inverse law must be proved.

Source: KomorebiVerification/ExactCoordinates.lean.

```
/-- The explicit product of the projector ranges. -/
abbrev PacketSpace (P : LinearProjectorFamily R M ι) : Type max v w :=
  (i : ι) → LinearMap.range (P.proj i)

/-- Analysis, with each projected value certified to lie in its projector range. -/
def rangeAnalysis (P : LinearProjectorFamily R M ι) : M →ₗ[R] PacketSpace P where
  toFun x i := ⟨P.proj i x, ⟨x, rfl⟩⟩
  map_add' x y := by
    funext i
    apply Subtype.ext
    exact (P.proj i).map_add x y
  map_smul' c x := by
    funext i
    apply Subtype.ext
    exact (P.proj i).map_smul c x

/-- Synthesis is the direct finite sum of packet values. -/
def rangeSynthesis (P : LinearProjectorFamily R M ι) : PacketSpace P →ₗ[R] M where
  toFun packets := ∑ i, (packets i : M)
  map_add' packets packets' := by
    simp only [Pi.add_apply, Submodule.coe_add, Finset.sum_add_distrib]
  map_smul' c packets := by
    simp only [Pi.smul_apply, SetLike.val_smul, Finset.smul_sum, RingHom.id_apply]
```

The term `⟨P.projix,⟨x,rfl⟩⟩` has two layers. The outer pair contains the vector and its proof of range membership. The inner pair gives the preimage x and the equality showing that projecting it gives the required vector. The coercion `(packetsi:M)` later forgets this proof component and returns the underlying vector for summation.

5.1 Why the two directions use different hypotheses

Synthesis after analysis is exactly completeness:

$$\mathsf{SA}(x) = \sum_i P_i x = x.$$

Analysis after synthesis uses the range conditions as well. If $x_j \in \mathrm{range}(P_j)$, choose a preimage y_j. Idempotence gives $P_j x_j = x_j$, while pairwise annihilation gives $P_i x_j = 0$ for $i \neq j$. Consequently

$$P_i\Big(\sum_j x_j\Big) = \sum_j P_i x_j = x_i.$$

The source follows this reasoning directly.

Source: `KomorebiVerification/ExactCoordinates.lean`.

```
/-- Completeness proves that synthesizing analyzed coordinates returns the input. -/
@[simp] theorem rangeSynthesis_rangeAnalysis
    (P : LinearProjectorFamily R M ι) (x : M) :
    P.rangeSynthesis (P.rangeAnalysis x) = x := by
  change (∑ i, P.proj i x) = x
  exact P.complete x

/-- Idempotence and orthogonality prove that analysis recovers every range packet. -/
@[simp] theorem rangeAnalysis_rangeSynthesis
    (P : LinearProjectorFamily R M ι) (packets : PacketSpace P) :
    P.rangeAnalysis (P.rangeSynthesis packets) = packets := by
  classical
  funext i
  apply Subtype.ext
  change P.proj i (∑ j, (packets j : M)) = (packets i : M)
  rw [map_sum, Finset.sum_eq_single i]
  · exact P.proj_packet_self packets i
  · intro j _ hji
    exact P.proj_packet_eq_zero packets hji.symm
  · simp
```

After `funexti`, the goal concerns one packet. `Subtype.ext` removes the irrelevant distinction between the proof components of range elements. `map_sum` distributes the linear projector over the finite sum. `Finset.sum_eq_singlei` separates the surviving diagonal term from the annihilated off-diagonal terms. The final `simp` handles the finite-set side condition.

Once the two laws are established, the linear equivalence merely packages them.

Source: `KomorebiVerification/ExactCoordinates.lean`.

```
/-- Exact linear coordinates in the independent product of projector ranges. -/
def exactPacketCoordinates
    (P : LinearProjectorFamily R M ι) : M ≃ₗ[R] PacketSpace P where
  toFun := P.rangeAnalysis
  invFun := P.rangeSynthesis
  left_inv := P.rangeSynthesis_rangeAnalysis
  right_inv := P.rangeAnalysis_rangeSynthesis
  map_add' := (P.rangeAnalysis).map_add
  map_smul' := (P.rangeAnalysis).map_smul
```

There is no inverse selected by choice at this step. Both maps are already explicit. The proof is stronger than recovery of vectors that happen to lie in the image of analysis: it covers every tuple of valid range packets.

5.2 Four coordinates and two parity packets

The standalone audit specializes the construction to $\mathbb{Q}^4$. Fine labels are $0, 1, 2, 3$ and the fine address is the identity. The coarse address is reduction modulo two. For

$$x = (a, b, c, d), \qquad Q_0 x = (a, 0, c, 0), \qquad Q_1 x = (0, b, 0, d),$$

the fine projections isolate one coordinate, and

$$Q_0 = P_0 + P_2, \qquad Q_1 = P_1 + P_3.$$

The general fiber constructor proves its laws from masks, rather than requiring the user to supply them for each instance.

Source: `KomorebiVerification/FibreRefinement.lean`.

```
/-- Every finite address map induces a complete orthogonal projector family. -/
def fibreLinearProjectorFamily
    [Semiring R] [AddCommMonoid M] [Module R M]
    [DecidableEq β] [Fintype β]
    (address : α → β) :
    Komorebi.Foundation.LinearProjectorFamily R (α → M) β where
  proj := fibreLinearProj (R := R) address
  idempotent b x := fibreProj_idempotent address b x
  orthogonal hbc x := fibreProj_orthogonal address hbc x
  complete x := fibreProj_reconstruction address x
```

The audit then proves the parity formula by specializing the independent coarse/fine refinement theorem.

Source: `KomorebiVerification/KernelAudit.lean`.

```
theorem parity_refinement (b : Fin 2) (x : Fin 4 → ℚ) :
    fibreProj parityAddress b x =
      ∑ c, if parityAddress c = b then fibreProj fineAddress c x else 0 := by
  simpa [fineAddress] using
    (fibreProj_refinement fineAddress parityAddress b x)
```

This is an instance of the theorem for an arbitrary input vector, not a comparison of a few sampled rational vectors. The same audit instantiates reconstruction of an arbitrary linear operator on $\mathbb{Q}^4$ from all sixteen fine blocks.

6 Transfer blocks, support, and transport

For source projectors P_i, target projectors Q_j, and a linear map $T : M \to N$, the output-first convention is

$$T_{ji} = Q_j T P_i.$$

The declaration `Komorebi.Foundation.transferBlock` has arguments source family, target family, map, output label, input label. Getting the last two arguments reversed can produce a well-typed but different map when source and target spaces coincide. The guide uses output-first indices throughout.

6.1 Reconstruction and multiplication

Completeness of both families gives

$$T = \sum_j \sum_i Q_j T P_i.$$

For $U : N \to L$ and a third family S_k, completeness of the middle family gives

$$(UT)_{ki} = \sum_j U_{kj} T_{ji}.$$

The earlier core proves pointwise identities. `PaperIBlockCompletion` promotes them to equality of linear maps using extensionality. Contract rows 19 and 20 are classified as stronger than the single-space manuscript instances because the compiled maps may have different source, middle, and target modules.

The block algebra development then restricts each map to the actual source packet and gives it codomain the actual target packet. This yields a dependent family

$$B_{ji} : \text{range}(P_i) \longrightarrow_R \text{range}(P_j),$$

which is the full packet-to-packet Hom space. Its multiplication is the finite sum of composable maps. The equivalence with ambient endomorphisms is not a definition of the block space as the image of ambient operators. Both restriction and synthesis are separately constructed and proved inverse.

6.2 Why nonzero packets appear in converse statements

If a support relation is transitive, supported blocks are closed under multiplication. Conversely, to detect a missing compositional edge from universal multiplication closure, one needs blocks whose composite is nonzero. Contract row 25 works over a field, with every packet range nontrivial and arbitrary packet-Hom blocks available. Those hypotheses provide the witnesses used by the converse.

A zero packet can make a relation edge mathematically invisible. The mathematical text therefore explicitly includes the necessary nonzero-packet assumptions in its $*$-support and source-component-count corollaries. Row 25 has its own nontriviality scope. The twenty-file foundational formalization retains that scope.

6.3 A reachability obstruction is a certificate for a lower bound

The reachability module first shows that word orbits of packet-supported seeds remain in the support reachable from those seeds. If a nonzero packet is unreachable, the generated algebraic hull is proper. The conclusion depends on the seed support as well as the graph. It is not a general rule saying that the number of graph sources equals unrestricted seed rank.

The typed quiver model makes the distinction concrete. It uses $U = k^2$, $V = k^3$, the embedding $A(u_1, u_2) = (u_1, u_2, 0)$, and the projection $B(v_1, v_2, v_3) = (v_1, v_2)$. Although $BA = 1_U$, the vector $(0, 0, 1)$ in V is outside range(A). No family supported solely at U generates the whole representation. A source seed and the missing V-direction give the displayed generating pair. Contract row 30 is the certificate for this model, not a classification of arbitrary quivers.

6.4 Coordinate transport and strict naturality

A linear equivalence $C : M \simeq N$ transports projectors by $P_i \mapsto CP_iC^{-1}$ and operators by $T \mapsto CTC^{-1}$. Blocks and their zero/nonzero pattern then transport exactly. The inverse matters: a noninjective realization can kill a nonzero block.

The strict naturality module also handles semilinear realized actions, with explicit algebra maps and maps of packet labels. Its statement about the generated hull uses the exact image algebra. Surjectivity gives the appropriate rank inequality. Equality and complete edge correspondence require the stronger bijectivity hypotheses recorded in row 28. The injective label map excludes packet merging from that particular strict interface.

7 Generation and seed rank

Seed rank depends on an acting algebra. It is not simply vector space dimension. One vector generates the natural module of a full matrix algebra, whereas a scalar action on k^n needs n independent generators.

The foundational definitions use the existing span-rank API for the top submodule.

Source: `KomorebiVerification/SeedRankBasics.lean`.

```
variable (A : Type u) (M : Type v)
variable [Semiring A] [AddCommMonoid M] [Module A M]

/-- A set of seeds generates `M` when its `A`-linear span is all of `M`. -/
def Generates (s : Set M) : Prop :=
  Submodule.span A s = ⊤

/-- A family generates when its range is a generating set. -/
def FamilyGenerates {ι : Type w} (v : ι → M) : Prop :=
  Generates A M (Set.range v)

/-- A module is cyclic when one element generates it. -/
def Cyclic : Prop :=
  ∃ x : M, Generates A M {x}

/--
The seed rank is the least cardinality of a set whose `A`-span is `M`.
```

```
Because it is cardinal-valued, it remains meaningful for modules that are not
finitely generated.  In particular, the zero module has seed rank zero.
-/
noncomputable def seedRank : Cardinal :=
  (⊤ : Submodule A M).spanRank

/-- The natural-valued minimum used for finite-generation corollaries. -/
noncomputable def seedFinrank : ℕ :=
  (⊤ : Submodule A M).spanFinrank
```

The cardinal-valued rank makes sense without finite generation. The natural-valued `seedFinrank` is the finite-generation minimum only under the hypotheses used by the finite-rank theorems. The zero module has rank zero. The cyclic/rank-one equivalence therefore includes a nontriviality hypothesis.

7.1 The one-seed presentation

For a seed $s \in M$, the presentation map is $a \mapsto a \cdot s$. Its range is exactly the cyclic submodule. Therefore s generates if and only if this map is surjective.

Source: `KomorebiVerification/SeedRankBasics.lean`.

```
/-- The universal one-seed presentation map, `a ↦ a • x`. -/
def oneSeedMap (x : M) : A →ₗ[A] M :=
  LinearMap.toSpanSingleton A M x

@[simp]
theorem oneSeedMap_apply (x : M) (a : A) :
    oneSeedMap A M x a = a • x := by
  rfl

/-- The image of the one-seed map is exactly the cyclic submodule it spans. -/
theorem range_oneSeedMap (x : M) :
    LinearMap.range (oneSeedMap A M x) = Submodule.span A {x} := by
  exact LinearMap.range_toSpanSingleton x

/-- A seed generates exactly when its presentation map is surjective. -/
theorem generates_singleton_iff_surjective (x : M) :
    Generates A M {x} ↔ Function.Surjective (oneSeedMap A M x) := by
  rw [Generates, ← range_oneSeedMap A M x, LinearMap.range_eq_top]
```

The first isomorphism theorem then supplies the quotient-to-range equivalence.

Source: `KomorebiVerification/SeedRankBasics.lean`.

```
/-- First-isomorphism presentation for one seed, with its exact range. -/
noncomputable def oneSeedQuotientEquivRange (x : M) :
    (A ⧸ LinearMap.ker (oneSeedMap A M x)) ≃ₗ[A]
      LinearMap.range (oneSeedMap A M x) :=
  (oneSeedMap A M x).quotKerEquivRange

/--
```

```
The range-valued quotient equivalence is the canonical presentation map:
the class of `a` is sent to the range element represented by `a • x`.
This is the explicit glue between the first-isomorphism construction and the
formula used in the manuscript.
-/
@[simp]
theorem oneSeedQuotientEquivRange_apply_mk (x : M) (a : A) :
    (oneSeedQuotientEquivRange A M x) (Submodule.Quotient.mk a) =
      ⟨a • x, by
        exact ⟨a, rfl⟩⟩ := by
  rfl
```

The displayed application theorem is an important connection to the mathematical text: the equivalence sends the class of a to the actual vector $a \cdot s$. It is not merely an unspecified isomorphism between abstract objects with the right dimensions.

For a noncommutative acting algebra, the kernel here is a left submodule of the regular module. The theorem does not promote it to a two-sided ideal. Likewise, no norm or bounded completion is manufactured by this algebraic construction. The analytic completion result needs a supplied continuous isometry with dense range.

For several seeds, `Finsupp.linearCombination` evaluates a finitely supported coefficient family. This works for arbitrary label types. The finite-minimum theorem states that, when the module is finitely generated, its seed finrank is the least n admitting a surjection from $\texttt{Finn}\to_0\texttt{A}$.

7.2 Surjections, image algebras, and two product actions

Under a surjective semilinear map $f : M \to N$ along $\sigma : A \to B$, an A-generating set maps to a B-generating set. Coefficients in the image of σ are already available in B, so the rank inequality does not require σ itself to be onto. An equality statement requires more: either the scalar map is surjective or the target action is literally restricted to the image algebra.

For products there are two different actions. A shared algebra acts diagonally on $M \times N$, producing an upper bound by the sum of ranks. Independent actions use $A \times B$ and yield the maximum of the two ranks. Coordinate idempotents in $A \times B$ separate the two components, which is precisely what a general shared action may fail to do.

The tensor theorem proves an upper bound under its stated commuting-action and scalar-tower laws. The scalar-quotient theorem gives a lower bound when the action on a finite-dimensional quotient factors through a character. A dimension bound for an arbitrary quotient would be a different statement.

7.3 A complete constructive example: full matrix cyclicity

Suppose $x \neq 0$ in k^n. Choose a coordinate j with $x_j \neq 0$. For any target vector y, make a matrix with only column j nonzero and entries $a_{ij} = y_i/x_j$. Then $Ax = y$. The source is short enough to read in full.

Source: `KomorebiVerification/FullMatrixCyclicity.lean`.

```
/-- A vector is cyclic for the natural action of the full matrix algebra. -/
def IsCyclic (x : ι → K) : Prop :=
```

```
  ∀ y : ι → K, ∃ A : Matrix ι ι K, Matrix.mulVec A x = y

/-- Every nonzero vector is cyclic under the full matrix algebra. -/
theorem isCyclic_of_ne_zero {x : ι → K} (hx : x ≠ 0) : IsCyclic x := by
  obtain ⟨j, hj⟩ : ∃ j, x j ≠ 0 := by
    by_contra h
    apply hx
    funext i
    by_contra hi
    exact h ⟨i, hi⟩
  intro y
  let A : Matrix ι ι K := fun i k ↦ if k = j then y i / x j else 0
  refine ⟨A, ?_⟩
  funext i
  simp [A, Matrix.mulVec, dotProduct, hj]
```

The initial contradiction argument finds the nonzero coordinate. The matrix is then explicitly defined and supplied as the witness to the existential goal. Function extensionality reduces $Ax = y$ to its coordinates. Simplification evaluates the finite sum and cancels the nonzero denominator. Later declarations connect this concrete cyclicity predicate to `Generates` and canonical seed rank. Row 11 records the result for $n > 0$.

8 Certificate inputs and what their proofs establish

Several statements require explicit certificates. Their hypotheses encode mathematical data that a separate construction or classical theorem would supply. The Lean proof checks the implication from those data. The certificate is not a project axiom, and it is not a proof of its own existence from bare input.

8.1 The split-semisimple formula

The concrete block module consists of $d \times m$ matrices under left multiplication by $M_d(k)$. Each seed supplies at most d independent row directions. The exact count is

$$\left\lceil \frac{m}{d} \right\rceil \qquad (d > 0).$$

For a finite product of blocks, independent actions combine by the maximum. `SemisimpleCompletion` connects these row-space arguments to `seedRank`. The abstract theorem consumes an algebra equivalence to the product of full matrix algebras and a compatible semilinear module equivalence to the product of matrix modules.

The output is a rank formula for the supplied realization. This preserved 20-file component does not derive a Wedderburn decomposition from an arbitrary semisimple algebra, nor the nonsplit divisionalgebra form. The later continuation supplies that existence integration and the nonsplit formula, as described in Section 2. A reader applying foundational row 10 should still identify its supplied equivalences before quoting its conclusion.

8.2 Single-operator seed number: the upper and lower halves

For an operator T, the formalization first works with polynomial orbits $p(T)v$. It then proves a bridge to the genuine image algebra $k[T] = \text{Algebra.adjoin}_k\{T\}$. This prevents an informal change of acting algebra from being hidden in the notation for the seed number.

The primary decomposition theorem uses an attained bound R on block multiplicities. For each seed index $a < R$, it adds the ath block generator from each primary packet, inserting zero when that packet has fewer blocks. Polynomial extraction certificates recover the individual block generators from these padded sums. Thus R seeds suffice. A surjective quotient on which T acts as a scalar gives the opposite bound.

Source: `KomorebiVerification/SingleOperatorGraph.lean`.

```
theorem singleOperator_seedNumber_isLleast_of_primary_decomposition
    (T : Module.End k X) (R : ℕ)
    (multiplicity : Λ → ℕ) (eigenvalue : Λ → k)
    (blockGenerator : ∀ eigen : Λ, Fin (multiplicity eigen) → X)
    (hbound : ∀ eigen, multiplicity eigen ≤ R)
    (maxEigen : Λ) (hmax : multiplicity maxEigen = R)
    (hblocks : FamilyGenerates T
      (fun z : Σ eigen : Λ, Fin (multiplicity eigen) =>
        blockGenerator z.1 z.2))
    (hextract : ∀ (eigen : Λ) (j : Fin (multiplicity eigen)),
      ∃ p : k[X],
        aeval T p
          (paddedBlockSum R multiplicity blockGenerator
            ⟨j.val, lt_of_lt_of_le j.isLt (hbound eigen)⟩) =
          blockGenerator eigen j)
    (q : ∀ eigen : Λ, X →ₗ[k] (Fin (multiplicity eigen) → k))
    (hq : ∀ eigen, Function.Surjective (q eigen))
    (hqT : ∀ (eigen : Λ) (p : k[X]) (x : X),
      q eigen (aeval T p x) = p.eval (eigenvalue eigen) • q eigen x) :
    IsLeast {r : ℕ | SeedNumberLE T r} R := by
  constructor
  · exact ⟨paddedBlockSum R multiplicity blockGenerator,
      paddedBlockSums_generate T R multiplicity blockGenerator hbound hblocks hextract⟩
  · intro r hr
    obtain ⟨v, hv⟩ := hr
    have hle := multiplicity_le_of_generates T v (multiplicity maxEigen)
      (q maxEigen) (hq maxEigen) (eigenvalue maxEigen) (hqT maxEigen) hv
    simpa [hmax] using hle
```

The signature has three groups of data. First, `hbound` and `hmax` make R an attained maximum. Second, `hblocks` and `hextract` supply the information about orbit generation and extraction for the upper bound. Third, `q`, `hq`, and `hqT` supply the scalar quotient and polynomial intertwining law for the lower bound.

The proof constructs an `IsLeast` pair. Its first component is the padded generating family. Its second component takes an arbitrary generating family and uses the quotient at `maxEigen` to force its cardinality to be at least R. The existence of these quotient and extraction certificates is an input. The file does not independently construct general Jordan form or Chinese-remainder primary projectors from a bare matrix.

8.3 The cyclic matrix bridge

Row 14 derives the four-way cyclicity statement after two canonical-form bridges have been supplied: geometric multiplicity agrees with block multiplicity, and equality of minimal and characteristic polynomials is equivalent to one block per eigenvalue. Lean verifies their use in the equivalence chain. It does not reconstruct those bridges from arbitrary matrix data in this component.

The row is marked stronger because its compiled implication omits a separately inherited finite-label hypothesis from the manuscript. Stronger refers to this precise change in the typed statement. It does not mean that the supplied canonical-form hypotheses disappeared.

8.4 Graphs, paths, and cycles

The general graph formula takes an eigenbasis grouped by multiplicity, an attained maximum, and polynomial projectors or distinct eigenvalue labels. It does not infer an eigenbasis from the word "symmetric." The source also proves two concrete families independently: a path endpoint generates over any field, and a complex simple cycle has minimum two.

For the path, the endpoint Krylov matrix has zero entries below its diagonal and ones on the diagonal: a walk of length r cannot reach a vertex farther than r, and exactly one length-r walk reaches vertex r. Hence its determinant is one. This yields cyclicity without a numerical eigendecomposition.

For cycles, two adjacent delta vectors generate by the adjacency recurrence. Over $\mathbb{C}$, two distinct Fourier characters with the same adjacency eigenvalue provide a two-dimensional scalar quotient, supplying the lower bound. The resulting minimum-two theorem applies to the simple cycle on $n + 3$ vertices.

9 Topology and mathematical algorithms

9.1 Bounded packets and closed-hull obstructions

The analytic structure replaces linear maps by continuous linear maps. Bounded idempotents have closed ranges. Finite analysis and synthesis become continuous linear maps and then a continuous linear equivalence. The algebraic pattern of inverse laws remains visible, while continuity is carried in the types.

For a dense submodule $M \subseteq X$ and a bounded idempotent P, the closure of $P(M)$ is the full range of P. The theorem does not require that M be invariant under P. This is why the source map records the exact scope rather than summarizing the statement only as "completion preserves packets."

The topological obstruction is especially transparent:

Source: `KomorebiVerification/TopologicalCompletion.lean`.

```
/-- If a continuous packet projector annihilates an algebraic generated
hull, then it also annihilates its closed topological hull. -/
theorem closure_le_ker_of_le_ker
    (Q : X →L[𝕜] X) (H : Submodule 𝕜 X) (hH : H ≤ Q.ker) :
    H.topologicalClosure ≤ Q.ker :=
  Submodule.topologicalClosure_minimal H hH (ContinuousLinearMap.isClosed_ker Q)

/-- A nonzero unreachable packet prevents topological generation. -/
theorem topological_reachability_obstruction
```

```
    (Q : X →L[𝕜] X) (H : Submodule 𝕜 X)
    (hQ : Q ≠ 0) (hH : H ≤ Q.ker) :
    H.topologicalClosure ≠ ⊤ := by
  intro htop
  apply hQ
  apply ContinuousLinearMap.ext
  intro x
  have hx : x ∈ H.topologicalClosure := by rw [htop]; trivial
  exact (closure_le_ker_of_le_ker Q H hH hx : Q x = 0)
```

The kernel of a continuous linear map is closed. If an algebraic hull lies in that kernel, so does its closure. If the map is nonzero, the closure cannot be the whole space. This analytic theorem uses the kernel inclusion. It does not independently derive graph reachability. The algebraic and analytic arguments join at that explicit inclusion.

9.2 Dense realizations and completed presentations

A continuous surjection intertwining the stated operator families sends a dense source hull to a dense target hull. Dense range already suffices for that density conclusion. Exact equality of a source packet's image with a target packet requires the surjectivity used by the packet-range theorem. Neither conclusion needs an unspoken open-mapping argument.

For completed free presentations, the supplied map is a continuous linear isometry with dense range into a complete target. Its completion extension is an isometry with closed and dense range, hence surjective. This gives a continuous linear equivalence. Further theorems prove intertwining of supplied bounded operators and uniqueness of the continuous extension.

The bilateral shift result uses an actual reindexing representation on $\ell^2(\mathbb{Z})$, not an assumed abstract shift action. Its translates of δ_0 recover all delta vectors, whose linear span is dense. The final statement says that one is the least finite seed cardinality for dense generation by this representation. It does not establish an unrestricted cardinal-valued Laurent-algebra rank.

9.3 Orbit closure: why termination is not code extraction

The finite algorithm specification begins with the span of the seeds and repeatedly adds the images under the input operators:

$$W_0 = \operatorname{span}(S), \qquad W_{n+1} = W_n + \sum_i T_i(W_n).$$

Each iterate lies in the least invariant hull. If two successive iterates agree, the stopped subspace is invariant and contains the seeds, so it equals that hull. Finite dimensionality makes the ascending chain eventually constant.

Source: KomorebiVerification/EllipticAlgorithms.lean.

```
/-- A stopped closure pass is exactly the operator hull. -/
theorem orbitClosureIter_eq_orbitHull_of_stop
    (operators : ι → Module.End k V) (seeds : Set V) (n : ℕ)
    (hStop : orbitClosureIter operators seeds (n + 1) =
      orbitClosureIter operators seeds n) :
    orbitClosureIter operators seeds n = orbitHull operators seeds := by
```

```
  apply le_antisymm
  · exact orbitClosureIter_le_orbitHull operators seeds n
  · apply orbitHull_le operators seeds
    · exact seeds_subset_orbitClosureIter operators seeds n
    · apply invariant_of_orbitClosureStep_eq operators
      simpa [orbitClosureIter] using hStop

/--
In finite dimension the ascending closure algorithm stops after finitely many
passes, and its stopped output is exactly the least invariant seed hull.
-/
theorem orbitHull_algorithm_terminates_and_correct
    [FiniteDimensional k V]
    (operators : ι → Module.End k V) (seeds : Set V) :
    ∃ n : ℕ,
      orbitClosureIter operators seeds (n + 1) =
        orbitClosureIter operators seeds n ∧
      orbitClosureIter operators seeds n = orbitHull operators seeds := by
  have hEventually := eventuallyConst_of_isNoetherian
    (orbitClosureChain operators seeds)
  rw [Filter.eventuallyConst_atTop] at hEventually
  obtain ⟨n, hn⟩ := hEventually
  have hStop : orbitClosureIter operators seeds (n + 1) =
      orbitClosureIter operators seeds n := by
    exact hn (n + 1) (Nat.le_succ n)
  exact ⟨n, hStop,
    orbitClosureIter_eq_orbitHull_of_stop operators seeds n hStop⟩
```

The proof's termination argument uses the Noetherian property of the submodule lattice. It establishes existence of a stopping index and correctness of the stopped subspace. It does not extract a basis-maintenance loop, a decidable rank test, or a complexity bound. Those belong to an implementation refinement that would require its own proof.

The transfer-block specification is similarly exact at the mathematical level: its table consists of the blocks, summing it gives the original map, and its support predicate is block nonvanishing. It does not verify floating-point tolerances or a sparse edge-list generator.

The exact graph-rank specification takes the finite-spectrum maximum of exact eigenspace dimensions. Its correctness theorem consumes an eigenbasis, projector-polynomial data, spectrum coverage, eigenspace dimensions, and an attained maximum. Its definition is marked `noncomputable`. A Python experiment and this specification can support the same formula while remaining different forms of evidence.

9.4 The elliptic example and scalar discipline

The same source module includes a concrete algebraic model for

$$k[x, y]/(y^2 - (x^3 - x)).$$

It constructs quotient and quadratic normal-form realizations, explicit two-coefficient packet coordinates, and multiplication operators. It proves the relation $M_y^2 = M_x^3 - M_x$ and one-seed generation of the regular module.

The coefficient projectors are linear over the ground field, but not over the full coordinate algebra. The file contains explicit witnesses to that failure. This is an instructive type boundary: the acting algebra for generation may be larger than the scalar algebra over which packet maps are linear. These additional checked declarations are part of the namespace audit but are not counted as extra rows in the 35-row contract.

10 Replaying the preserved verification

The source records specify the verification environment.
Replaying the verification requires the specified compiler and matching dependency cache. These prerequisites are supplied separately from the source archive.

The following commands are quoted from the component's documented workflow, adapted to the source archive layout. They were not run as part of authoring this guide. Use a working copy for new output and keep the archived source intact.

10.1 A normal provisioned Lake environment

The standalone audit is separate from the library build. The source records give both commands and the full verifier's additional identity checks and negative controls.

Keep the manifest unchanged when reproducing the recorded verification. A successful build with another compiler or Mathlib dependency constitutes a separate verification event.

10.2 The verifier for the portable kit

The source records provide the portable kit workflow and its prerequisites.

The kit is supplied separately. The verifier checks compiler and cached dependency identities against the recorded environment. A different cache does not reproduce that run.

The verifier discovers all local Lean files, resolves their local import graph, and compiles them in dependency order to a fresh `objects/` directory. It refuses an output directory that already contains local `.olean` files. That restriction makes the local compilation claim stronger than a build that could reuse prior project objects.

Compiler invocations use:

```
lean -j1 -DwarningAsError=true \
  -DautoImplicit=false -DrelaxedAutoImplicit=false \
  -DmaxSynthPendingDepth=3
```

Each invocation has a recorded command, return code, duration, and log hash. The project modules are newly compiled in that workflow, while matching upstream cached dependencies are reused. A report of this local fresh build does not claim that Mathlib or Lean itself was independently rebuilt.

10.3 The two deliberate rejection controls

After compilation, map reconciliation, and the audit, the verifier asks Lean to reject two small examples. The first asserts a false equality and tries to prove it by decision. The second uses a placeholder, which warnings-as-errors must reject.

```
-- FalseEquality.lean: expected rejection
import Mathlib.Data.Nat.Basic
example : (0 : Nat) = 1 := by decide

-- Placeholder.lean: expected rejection
import Mathlib.Data.Nat.Basic
example : (0 : Nat) = 1 := by sorry
```

These files are negative controls under verification directories. They are not part of the main library and are not unfinished proofs in it. A nonzero exit code alone is insufficient for a passing control: the verifier also checks for the intended diagnostic and rejects timeouts, unknown imports, missing objects, and unsupported-option failures. This ensures that a broken compiler setup is not mistaken for logical rejection.

The preserved final run recorded both controls with exit code 1 and the intended diagnostic. The larger archived build-job totals elsewhere in the distribution describe other runs and must not be reused as this run's local-module count.

11 Interpreting the evidence

The source records include the foundational formalization's execution receipt.
The receipt identifies source hashes, logs and exact commands for that verification.

The preserved guide data's static check compares the delivered twenty source hashes against that record, compares all twenty-four execution-log hashes, reconciles the 35 rows and 84 distinct targets with KernelAudit.lean, and checks the saved printed axiom-report inventory. These checks passed. They establish identity and internal consistency of the delivered evidence. They do not perform another elaboration or kernel run.

11.1 The namespace-wide gate

The audit enumerates imported declarations owned by the two project namespaces. It rejects unsafe declarations, custom axiom declarations, and opaque project declarations. For every enumerated declaration it collects transitive axioms and accepts only `propext`, `Classical.choice`, and `Quot.sound`.

Source: `KomorebiVerification/KernelAudit.lean`.

```
run_cmd do
  let env ← getEnv
  let mut audited : Nat := 0
  for (name, info) in env.checked.get.constants.toList do
    if Name.isPrefixOf `Komorebi name || Name.isPrefixOf `KomorebiVerification name then
      audited := audited + 1
      if info.isUnsafe then
        throwError "unsafe project declaration: {name}"
      match info with
      | .axiomInfo _ =>
          throwError "project axiom declaration: {name}"
      | .opaqueInfo _ =>
          throwError "opaque project declaration: {name}"
      | _ => pure ()
      let axioms ← Lean.collectAxioms name
      for axiomName in axioms do
        unless axiomName == ``propext || axiomName == ``Classical.choice ||
            axiomName == ``Quot.sound do
          throwError "unexpected axiom {axiomName} in project declaration {name}"
  if audited == 0 then
    throwError "kernel audit found no project declarations"
  logInfo m!"FAIL-CLOSED KERNEL AUDIT PASS: {audited} project declarations; allowed axioms only:
  ↪ propext, Classical.choice, Quot.sound"
```

The zero-entry check matters: an audit that accidentally imports nothing must fail. The final count is a count of entries in the environment, not a count of handwritten mathematical theorems. The separate mapped-target pass resolves each of the eighty-four names, prints its type, and checks its axiom report.

The source-policy scanner also rejects a specified list of forbidden constructs after removing nested comments and string contents. This catches prohibited source forms early. Its role is complementary to the environment audit. Neither a string scan nor a metadata label alone replaces kernel acceptance.

11.2 What each layer establishes

Evidence layer	Interpretation
File hash identity	The present bytes equal the bytes identified by a record. This says nothing by itself about the correctness of those bytes.
Compiler acceptance	The declarations elaborate and their proof terms are accepted in the stated environment. The exact hypotheses remain part of the result.
Axiom audit	The enumerated declarations have only the allowed transitive foundational dependencies.
Normative scope map	The editorial bridge between prose claims and particular compiled declarations, including exclusions. This bridge still requires mathematical reading.

Evidence layer	Interpretation
Negative controls	The tested setup rejects the selected false proof and placeholder for the intended reasons. This is a useful pipeline check, not a proof of every possible failure mode.
Python tests	Finite implementation behavior checked by those tests. They are not a universal Lean theorem.
Machine record map	An explicit association between selected stable record IDs and attached evidence. A record's existence is not its proof.

The allowlisted principles are standard Lean/Mathlib foundations. The audit does not claim axiom-free mathematics in an absolute sense. It also does not prove historical priority, performance claims, or the absence of defects in the compiler, trusted kernel, or dependency cache. These are the ordinary boundaries of the recorded verification method, not gaps secretly filled by the count of mapped declarations.

12 The expanded chapter and computational crosswalk

The computational companion carries a separate seven-source-file formalization and an explicit eight-record map. That tranche shares some material on finite projectors with the larger twenty-file formal component, but it is a separate packaged evidence scope.

The computational source and its 108 stable statement records include the two explicit nonzero-packet hypotheses required by the corresponding corollaries. These source hypotheses do not enlarge the attached eight-record Lean map. The following eight mappings describe the attached machine tranche's own evidence allocation.

Stable machine record	Attached Lean subject
`PSC-I-D-PACKET-SYSTEM`	Finite linear projector structure.
`PSC-I-D-ANALYSIS-SYNTHESIS`	Range packet space and the two coordinate maps.
`PSC-I-T-EXACT-PACKET-COORDINATES`	Range-restricted linear equivalence.
`PSC-I-C-PACKETWISE-EQUALITY`	Equality detected by the finite complete family.
`PSC-I-D-TRANSFER-BLOCK`	Definition of the typed block.
`PSC-I-T-OPERATOR-RECONSTRUCTION`	Pointwise finite reconstruction.
`PSC-I-T-BLOCK-MULTIPLICATION`	Pointwise finite composition identity.
`PSC-I-T-SUPPORT-PATTERN-ALGEBRA`	Transitive ordinary-matrix support is multiplicatively closed. This is not the whole expanded iff criterion.

The larger component can inform a broader semantic crosswalk. Rows 1–2 concern free presentations, rows 3–9 concern seed-rank operations, rows 10–14 concern split-semisimple and operator formulas, rows 15–29 concern packets, blocks, support, and transport. Rows 30–35 concern the supplementary worked models and algorithm specifications. This is a navigation aid. Where the expanded statement adds a division-ring generalization, an infinite family, an existence theorem, or a different categorical interface, the old scoped result must not be silently relabeled as a proof of the expanded statement.

The source archive's `COMPANION_CROSSWALK.json` is the navigation record for the series, and `formal/coverage/COVERAGE_108.json` is the current formal correspondence map. The machine-readable

`generated/theorem_map.json` accompanying this guide preserves all thirty-five contract scopes and their exact declaration lists. Unmapped expanded statements remain unmapped until an explicit type-level comparison and accepted proof support a new mapping.

13 How to extend the formal development

A useful extension adds a theorem with a clear source statement, a type that exposes its genuine inputs, and evidence that can be replayed. The easiest way to lose that clarity is to hide the desired conclusion inside an unnamed certificate and then announce that the original unconditional theorem has been formalized.

1. Identify the exact new statement and its relation to the current contract. Decide whether it is a new row, a stronger replacement, or a helper used by an existing row. 2. Inspect the current types before designing another abstraction. For finite packets, reuse range subtypes and actual Hom blocks. For topology, use continuous linear maps and state completeness where it is needed. 3. Separate supplied data from proved consequences. A new canonical-form constructor should have its own existence theorem, not only a theorem taking a canonical-form certificate as an argument. 4. Prove or import the bridge from the new representation to the manuscript's object. A result about a bespoke rank predicate needs a theorem relating it to canonical seed rank before it can replace the existing formula. 5. Compile the changed modules in the pinned environment, update the normative map deliberately, and update the audit inventory to exactly the desired mapped surface. 6. Run the explicit audit and the full verifier with a new output directory. Preserve prior records and retain source hashes and execution records for each run. 7. Review the new source-to-prose correspondence. Kernel acceptance proves the typed theorem. The review establishes that this is the intended theorem and that its public summary retains the hypotheses.

13.1 Continuing the correspondence work

The continuation has established the primary decomposition and quotient constructions, the geometric formula, scalar extension, the six-way cyclic criterion, module-top reduction, and the nonsplit semisimple formula. Further work is determined by the current coverage map in Section 2. These established results must not be treated as missing certificate constructors. For graph rank, an implementation refinement would relate executable spectral or algebraic data to the exact certificates, with a separate proof of each algorithmic step. For the expanded packet theory, countable unconditional sums require a topology and convergence interface different from the finite `Fintype` API.

These are different tasks from increasing a declaration count. Each closes a named input boundary or extends an exact scope. A completed extension should say which boundary has changed and exhibit the theorem that changed it.

13.2 Troubleshooting a replay

An unknown module or missing object indicates an environment or import-path problem, not a false mathematical theorem. A pin mismatch means the cached dependency state is different from the recorded source. A refusal of nonempty output means the verifier is protecting the local rebuild claim.

Choose a new output directory. A warning-as-error failure requires reading the diagnostic before deciding whether the source, compiler, or style policy changed.

A mapped-name failure after a rename is not solved by silently removing the map entry. Either preserve the public declaration name, or update the map and record the new correspondence. A new unexpected axiom requires tracing its transitive dependency before acceptance. A changed source hash is expected after a deliberate edit, but it ends byte-identity with the old accepted source and requires fresh evidence for the changed file.

14 The complete 35-row contract

This section reproduces the normative map's statement titles, declaration names, exact scopes, and exclusions. The numbering belongs to the corrected journal formalization contract. It is not the numbering of the expanded mathematical text or the stable inventory of machine records.

"Exact" means exact at the scope printed in the row. "Stronger" means the mapped declaration removes a specified hypothesis, treats a more general typed setting, or includes an additional endpoint. Rows 10, 13, 14, 32, and 35 are certificate-explicit. The precise certificate boundaries appear both here and in Section 8.

The long qualified names are intentionally retained. They allow a reader or a tool to search the source, issue `#check`, and compare the printed type without guessing a namespace.

14.1 Row 1: Universal one-seed presentation

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankBasics.oneSeedQuotientEquivRange`

`Komorebi.SeedRankBasics.oneSeedQuotientEquivRange_apply_mk`

`Komorebi.SeedRankBasics.generates_singleton_iff_surjective`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.completionEquivOfIsometryDense`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.completionEquivOfIsometryDense_intertwines`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.completionEquivOfIsometryDense_unique`

Exact scope. For the module map `a↦a•s`, the quotient by its kernel is linearly equivalent to its exact range; the glue theorem verifies that the class of `a` maps to `a•s`; and singleton generation is equivalent to surjectivity. If the induced map from the normed quotient is supplied as a continuous linear isometry with dense range into a Banach target, it extends uniquely to a continuous linear equivalence from the completion and intertwines supplied bounded operators.

Boundary. No norm, isometry, density, or bounded extension is constructed automatically on the algebraic quotient. The annihilator is only the typed left submodule/left-ideal object; no two-sided ideal claim is made.

14.2 Row 2: Multi-seed presentation

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankBasics.multiSeedQuotientEquivRange`

`Komorebi.SeedRankBasics.multiSeedQuotientEquivRange_apply_mk`

`Komorebi.SeedRankBasics.multiSeedQuotientEquiv`

`Komorebi.SeedRankOperations.seedFinrank_isLeast_free_surjection`

Exact scope. An arbitrary Finsupp-indexed family has the free-module quotient presentation; the glue theorem verifies that a coefficient family maps to its finite linear combination; and a generating family

gives the quotient onto the whole module. For a finite module, `seedFinrank` is the least `n` admitting a surjection from $\texttt{Finn}\to_0\texttt{A}$.

Boundary. The natural-valued minimum is asserted only under module finiteness. No finite basis or executable presentation matrix is produced.

14.3 Row 3: Cyclic characterization

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.cyclic_iff_seedRank_eq_one`

Exact scope. For every nontrivial module over a semiring, unrestricted cardinal-valued seed rank equals one exactly when a cyclic vector exists.

Boundary. The zero module is excluded here and is governed separately by `seedRank_eq_zero_iff`.

14.4 Row 4: Quotient monotonicity

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.seedRank_le_of_surjective_semilinear`

Exact scope. For an arbitrary ring homomorphism `σ:A→+*B`, a surjective σ-semilinear map gives `seedRankBN≤seedRankAM`; σ need not be onto.

Boundary. No equality is claimed from surjectivity of the module map alone.

14.5 Row 5: Image-algebra invariance

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.seedRank_imageAlgebra_eq`

Exact scope. For a `k`-algebra homomorphism $\texttt{φ:A}\to_{\texttt{a}}\texttt{[k]B}$ and a bijective φ-semilinear map, the target action is restricted literally to `φ.range`, and its seed rank equals the source seed rank.

Boundary. Equality for the full target algebra `B` requires φ to be surjective; it is not inferred otherwise.

14.6 Row 6: Shared direct-sum bound

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.seedRank_prod_le_add`

Exact scope. One semiring acting diagonally on `M×N` gives the cardinal inequality `seedRankA(M×N)≤ seedRankAM+seedRankAN`.

Boundary. This is only an upper bound; it does not identify when equality holds.

14.7 Row 7: Independent direct-sum formula

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.seedRank_prod_productAlgebra`

Exact scope. With the coordinatewise action of `A×B` on `M×N`, the cardinal seed rank is the maximum of the two component ranks.

Boundary. This formula is not for a single shared diagonal action.

14.8 Row 8: Tensor-product bound

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.tensorOperator_smul_tmul`

`Komorebi.SeedRankOperations.seedRank_tensorProduct_le_mul`

Exact scope. Over a commutative semiring `k`, with the stated algebra/module, scalar-tower, and commuting-action laws, the action of `A⊗[k]B` on `X⊗[k]Y` satisfies the cardinal product bound and realizes `(a⊗b)(x⊗y)=ax⊗by`.

Boundary. No equality, completed tensor product, or alternative topological tensor norm is claimed.

14.9 Row 9: Scalar quotient obstruction

Contract classification: Exact.

Declaration targets

`Komorebi.SeedRankOperations.finrank_le_seedRank_of_scalar_quotient`

Exact scope. For a field `k`, a character $\chi : A \to_a [k]k$, a finite-dimensional scalar module `Y`, and a surjective χ-semilinear map `X→Y`, `finrankkY` is a cardinal lower bound for `seedRankAX`.

Boundary. The target action must factor through the stated character; a general quotient does not yield the dimension bound.

14.10 Row 10: Semisimple multiplicity formula

Contract classification: Exact.

Declaration targets

`Komorebi.SemisimpleCompletion.semisimple_seedRank_eq_maxCeilDiv_of_equivalences`

`Komorebi.SemisimpleCompletion.splitProduct_seedRank_eq_maxCeilDiv`

Exact scope. For a finite product, positive block sizes `di`, a supplied algebra equivalence to the product of full matrix algebras, and a compatible supplied semilinear module equivalence to the product of `di×mi` matrix modules, seed rank is `max_i⌈mi/di⌉`.

Boundary. Lean does not prove the existence of the Wedderburn/module decompositions, nor the nonsplit division-algebra variant.

14.11 Row 11: Full matrix algebra

Contract classification: Exact.

Declaration targets

`Komorebi.SemisimpleCompletion.fullMatrix_every_nonzero_vector_generates`

`Komorebi.SemisimpleCompletion.fullMatrix_seedRank_eq_one`

Exact scope. Over a field and for `n>0`, every nonzero vector in the natural `M_n(k)`-module generates and the canonical cardinal seed rank is one.

Boundary. No statement is made for `n=0` or for a smaller acting subalgebra.

14.12 Row 12: Multiplicity obstruction

Contract classification: Exact.

Declaration targets

`Komorebi.SemisimpleCompletion.multiplicity_obstruction`

`Komorebi.SemisimpleCompletion.multiplicity_seedRank_formula`

Exact scope. For `d>0`, the left action of `M_d(k)` on the `d×m` matrix realization of `m` copies has seed rank `⌈m/d⌉`; every generating `r`-family satisfies `⌈m/d⌉≤r`.

Boundary. No general simple-module formula over a nontrivial endomorphism division algebra is included.

14.13 Row 13: Single-operator seed rank

Contract classification: Exact.

Declaration targets

`Komorebi.SingleOperatorGraph.singleOperator_seedNumber_isLeast_of_primary_decomposition`

`Komorebi.SingleOperatorGraph.singleOperator_operatorAlgebra_seedRanks_eq_of_primary_decomposition`

Exact scope. Certificate-explicit: a finite label family supplies block generators, an attained bound `R`, joint polynomial-orbit generation, polynomial extraction from padded seeds, and surjective scalar quotient maps with the evaluation intertwining law. Then `R` is the least polynomial seed number and both `seedFinrank` and cardinal `seedRank` over the genuine image algebra `k[T]=Algebra.adjoink{T}` equal `R`.

Boundary. Lean does not construct a primary/Jordan decomposition, Chinese-remainder projectors, or identify the supplied multiplicities with `dimker(T-λI)` from bare hypotheses.

14.14 Row 14: Cyclic matrix criterion

Contract classification: Stronger.

Declaration targets

`Komorebi.SingleOperatorGraph.cyclic_matrix_criterion_of_primary_decomposition`

`Komorebi.SingleOperatorGraph.cyclic_matrix_four_way_iff_of_primary_decomposition`

Exact scope. Certificate-explicit and finite-dimensional: from an exact positive seed-number certificate, a supplied equality between geometric and block multiplicities, and the supplied minpoly/charpoly canonical-form bridge, Lean proves the four-way equivalence among cyclicity, all geometric multiplicities one, one block per eigenvalue, and `minpoly=charpoly`. The compiled implication does not require the manuscript's separately inherited finite-label hypothesis.

Boundary. Neither canonical-form bridge is derived by Lean from an arbitrary matrix; the theorem verifies the equivalence after those bridges are supplied.

14.15 Row 15: Exact packet coordinates

Contract classification: Exact.

Declaration targets

`Komorebi.Foundation.LinearProjectorFamily.rangeSynthesis_rangeAnalysis`

`Komorebi.Foundation.LinearProjectorFamily.rangeAnalysis_rangeSynthesis`

`Komorebi.Foundation.LinearProjectorFamily.exactPacketCoordinates`

Exact scope. A finite complete, idempotent, pairwise-annihilating linear projector family gives mutually inverse analysis and finite-sum synthesis maps between the module and the independently defined dependent product of projector ranges.

Boundary. No infinite summation or topological convergence assertion is present in this algebraic declaration.

14.16 Row 16: Packetwise equality

Contract classification: Exact.

Declaration targets

`Komorebi.PacketNaturalityCompletion.Packets.eq_iff_projectors_eq`

Exact scope. For a finite linear projector family, `x=y` iff every projected packet coordinate agrees.

Boundary. Finiteness and completeness of the packet family remain essential hypotheses.

14.17 Row 17: Topological packet isomorphism

Contract classification: Exact.

Declaration targets

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.topological_packet_isomorphism`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.packetEquiv`

Exact scope. For a finite bounded projector family on a Banach space over a nontrivially normed field, all packet ranges are closed and analysis/synthesis form a continuous linear equivalence with the canonical finite dependent-product norm.

Boundary. No infinite packet family, unbounded projector, or assertion about every arbitrarily chosen equivalent product norm is included.

14.18 Row 18: Completion preserves a finite packet split

Contract classification: Exact.

Declaration targets

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.idempotentRange_eq_closure_map`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.packetRange_eq_closure_map`

Exact scope. If `M` is a dense submodule of a normed space and `P_i` is any bounded idempotent, the closure of `P_i(M)` equals the full range `P_i(X)`. The packet-family theorem is the direct specialization. No invariance of `M`, surrounding finite packet family, or completeness of `X` is required by the manuscript or the compiled declaration.

Boundary. Boundedness is required; no unbounded-projector or infinite conditional-sum claim is made.

14.19 Row 19: Exact operator reconstruction

Contract classification: Stronger.

Declaration targets

`Komorebi.Foundation.transferBlock_reconstruction_linearMap`

`Komorebi.Foundation.transferBlock_reconstruction_end`

Exact scope. The sum of all transfer blocks reconstructs an arbitrary linear map between modules carrying possibly different finite projector families; the endomorphism formula is the manuscript instance.

Boundary. This is algebraic finite reconstruction, not convergence of an infinite block expansion.

14.20 Row 20: Packet matrix multiplication

Contract classification: Stronger.

Declaration targets

`Komorebi.Foundation.transferBlock_comp_linearMap`

`Komorebi.Foundation.transferBlock_comp_end`

`Komorebi.Foundation.end_comp_eq_sum_transferBlock_comps`

Exact scope. The block of a composite is the finite sum of composite blocks, even for three different source/intermediate/target modules and projector families; the single-space operator identity is the manuscript instance.

Boundary. No infinite matrix multiplication or operator-norm convergence claim is made.

14.21 Row 21: Packet powers

Contract classification: Stronger.

Declaration targets

`Komorebi.PacketNaturalityCompletion.Packets.transferBlock_pow_eq_packetPathSum`

Exact scope. For every natural power `m`, including `m=0`, the transfer block of `T^m` equals the recursively defined finite sum over length-`m` packet paths.

Boundary. Only finite powers and finite packet sets are covered.

14.22 Row 22: Adjoint reversal

Contract classification: Stronger.

Declaration targets

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.adjoint_transferBlock`

Exact scope. On a complete real or complex inner-product space, bounded self-adjoint maps satisfy `(PβT Pα)†=PαT†Pβ`. This is stronger than the packet-projector formulation because no idempotence, mutual annihilation, or completeness of a projector family is used.

Boundary. Self-adjointness of both outer maps and boundedness/completeness needed by the adjoint API are explicit.

14.23 Row 23: Algebraic full block representation

Contract classification: Exact.

Declaration targets

`Komorebi.PacketNaturalityCompletion.FullBlocks.fullBlockAlgEquiv`

`Komorebi.PacketNaturalityCompletion.FullBlocks.restrictBlocks_synthesizeBlocks`

`Komorebi.PacketNaturalityCompletion.FullBlocks.synthesizeBlocks_restrictBlocks`

`Komorebi.PacketNaturalityCompletion.FullBlocks.packetBlockAlgebra_mul_eq_blockMul`

Exact scope. A finite projector family over a commutative semiring identifies ambient endomorphisms with the genuine dependent family of all packet-to-packet linear maps; transported multiplication is exactly the output-first block product.

Boundary. This is the algebraic endomorphism algebra. Arbitrary algebraic blocks are not asserted to be bounded in a Banach realization.

14.24 Row 24: Dimension count

Contract classification: Exact.

Declaration targets

`Komorebi.PacketNaturalityCompletion.FullBlocks.end_finrank_eq_packet_sum_eq_square`

`Komorebi.PacketNaturalityCompletion.FullBlocks.finrank_eq_sum_packet_finrank`

Exact scope. For a finite-dimensional vector space over a field, endomorphism dimension equals the double sum of packet-dimension products, which equals the square of the packet-dimension sum.

Boundary. No dimension statement for infinite-dimensional or topological dimensions is made.

14.25 Row 25: Algebraic packet support pattern

Contract classification: Exact.

Declaration targets

`Komorebi.PacketNaturalityCompletion.FullBlocks.identity_blocks_supported_iff_reflexive`

`Komorebi.PacketNaturalityCompletion.FullBlocks.blockMulClosed_iff_transitive`

Exact scope. Over a field, with every packet range nontrivial and arbitrary packet-Hom blocks allowed, the identity is supported exactly for reflexive relations and universal multiplication closure holds exactly for transitive relations.

Boundary. The converse is not promoted to arbitrary bounded/continuous categories without enough nonzero composable maps.

14.26 Row 26: Reachability obstruction

Contract classification: Exact.

Declaration targets

`Komorebi.PacketNaturalityCompletion.Reachability.algebraicOrbitHull_le_reachable_support`
`Komorebi.PacketNaturalityCompletion.Reachability.unreachable_nonzero_packet_obstruction`
`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.closure_le_ker_of_le_ker`
`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.topological_reachability_obstruction`

Exact scope. Word orbits from packet-supported seeds stay in the reflexive-transitive reachable support, and a nontrivial unreachable packet makes the algebraic hull proper. Separately, if the algebraic hull lies in the kernel of a nonzero bounded projector, its closure also lies there and is not dense.

Boundary. The analytic theorem consumes the algebraically proved kernel inclusion; it does not infer graph reachability on its own. No general source-count lower bound is claimed for mixed-packet seeds.

14.27 Row 27: Coordinate transport

Contract classification: Exact.

Declaration targets

`Komorebi.Foundation.LinearProjectorFamily.conjugate`
`Komorebi.Foundation.conjugate_transferBlock`
`Komorebi.PacketNaturalityCompletion.Reachability.conjugate_transferEdge_iff`
`Komorebi.PacketNaturalityCompletion.Reachability.conjugate_reachableFrom_iff`

Exact scope. A linear equivalence transports a finite projector family and conjugates every transfer block. For the conjugated operator family, every zero/nonzero edge and every reflexive-transitive reachability statement is preserved.

Boundary. The full invariance assertion requires invertible coordinate transport, not an arbitrary non-injective map.

14.28 Row 28: Naturality of generation and packets

Contract classification: Stronger.

Declaration targets

`Komorebi.PacketNaturalityCompletion.StrictNaturality.generatedHull_natural`
`Komorebi.PacketNaturalityCompletion.StrictNaturality.strict_naturality_package`
`Komorebi.PacketNaturalityCompletion.StrictNaturality.strict_seedRank_le`
`Komorebi.PacketNaturalityCompletion.StrictNaturality.strict_seedRank_eq_of_bijective`
`Komorebi.PacketNaturalityCompletion.StrictNaturality.full_transfer_edge_zero_pattern_correspondence`

Exact scope. For a strict morphism over a field, generated hulls are natural over the exact image algebra, packet analysis and blocks intertwine, a surjective realization gives the cardinal rank inequality, bijective realization/algebra maps give equality, and bijective packet transport gives complete edge/zero-pattern correspondence. These conclusions do not require the manuscript's finite-dimensional hypothesis.

Boundary. Packet merging is excluded by the injective label map. Full target-algebra rank equality and full target edge coverage require the stated surjectivity/bijectivity hypotheses.

14.29 Row 29: Dense realization theorem

Contract classification: Exact.

Declaration targets

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.dense_operatorHull_image`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.map_packetRange_eq`

Exact scope. For normed spaces and bounded operator families, a continuous surjection that sends each source operator into the target family and intertwines it sends a dense source operator hull to a dense target hull. A surjective map intertwining bounded projectors maps the source range onto the target range.

Boundary. No algebra-homomorphism law, openness, or completeness is needed or concluded. Surjectivity is sufficient for the stated conclusions; dense range alone suffices for the density conclusion, but not for exact range equality. The algebraic hulls need not be equal as sets. The range equality itself needs only an intertwining surjective map; it does not require idempotence.

14.30 Row 30: Typed reachability certificate

Contract classification: Exact.

Declaration targets

`Komorebi.PacketNaturalityCompletion.TypedQuiver.typed_reachability_certificate`

Exact scope. For the displayed `U=k`^{2}, `V=k`^{3} quiver realization, Lean proves `BA=id`, exhibits the nonzero missing direction in `kerB` but outside `rangeA`, proves every `U`-supported family insufficient, and proves that the displayed two seeds generate.

Boundary. This is a certificate for the stated finite model, not a classification or minimum-seed theorem for arbitrary quivers.

14.31 Row 31: Bilateral-shift seed

Contract classification: Exact.

Declaration targets

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.BilateralShiftRepresentation.concretePower_apply`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.concreteBilateralShift_topologicallyCyclic`

`KomorebiVerification.TopologicalCompletion.BoundedProjectorFamily.concreteBilateralShift_seedCardinality_isLeast`

Exact scope. For the explicit reindexing representation on ℓ^2`(ℤ,𝕂), (S_mx)(n)=x(n-m)`, the orbit of δ_0 is dense and one is the least finite cardinality of a densely generating seed set.

Boundary. This does not define or equate an unrestricted cardinal-valued Laurent-algebra rank, and it does not formalize the later residue-packet discussion.

14.32 Row 32: Graph seed rank, path, and cycle

Contract classification: Exact.

Declaration targets

`Komorebi.SingleOperatorGraph.graph_seedNumber_eq_max_eigenspace_multiplicity`

`Komorebi.SingleOperatorGraph.graph_seedNumber_eq_max_eigenspace_multiplicity_of_distinct`

`Komorebi.SingleOperatorGraph.operatorAlgebra_seedFinrank_eq_of_seedNumber_isLeast`

`Komorebi.SingleOperatorGraph.operatorAlgebra_seedRank_eq_of_seedNumber_isLeast`

`Komorebi.SingleOperatorGraph.path_endpoint_seedNumber_isLeast_one`

`Komorebi.SingleOperatorGraph.complex_cycle_seedNumber_isLeast_two`

Exact scope. Certificate-explicit general formula: a finite eigenbasis grouped by multiplicity, an attained maximum `R`, and either explicit polynomial projectors or distinct eigenvalue labels prove that `R` is the least operator-seed number; the bridge declarations identify it with both canonical ranks over `k[A]`. Independently, every nonempty path (`n+1` vertices) has minimum one from an endpoint over any field, and every complex simple cycle (`n+3` vertices) has minimum two.

Boundary. Lean does not derive the eigenbasis from the bare assertion that a matrix is symmetric, nor identify an arbitrary graph's algebraic multiplicities without supplied spectral data. The unqualified spectral theorem remains cited classical input.

14.33 Row 33: Orbit-hull algorithm

Contract classification: Exact.

Declaration targets

`Komorebi.FiniteAlgorithms.orbitHull_algorithm_terminates_and_correct`

`Komorebi.FiniteAlgorithms.orbitClosureIter_eq_orbitHull_of_stop`

Exact scope. For a finite operator index on a finite-dimensional vector space over a field and any seed set, the ascending subspace iteration stops after finitely many passes, and the stopped subspace equals the least invariant subspace containing the seeds.

Boundary. The proof is a mathematical termination/correctness specification; it does not extract the paper's basis-maintenance/rank-test implementation or prove a complexity bound.

14.34 Row 34: Transfer-block algorithm

Contract classification: Exact.

Declaration targets

`Komorebi.FiniteAlgorithms.transferBlockTable`

`Komorebi.FiniteAlgorithms.assembleTransferBlockTable`

`Komorebi.FiniteAlgorithms.transferBlock_algorithm_correct`

`Komorebi.FiniteAlgorithms.transferGraph_iff_block_ne_zero`

Exact scope. For finite source and target projector families, the table is exactly all transfer blocks, summing it reconstructs the input linear map, and its support predicate is exactly block nonvanishing.

Boundary. No decidable zero-test, sparse edge-list extractor, floating-point tolerance, or runtime bound is verified.

14.35 Row 35: Exact graph seed-rank algorithm

Contract classification: Exact.

Declaration targets

`Komorebi.FiniteAlgorithms.exactGraphSeedRank`

`Komorebi.FiniteAlgorithms.exactGraphSeedRank_isLeast`

Exact scope. For a finite square matrix over a field, supplied exact eigenbasis, polynomial-projector, spectrum-coverage, eigenspace-dimension, and attained-maximum certificates prove that the finite-spectrum maximum computed by `exactGraphSeedRank` is the least operator-seed number.

Boundary. `exactGraphSeedRank` is noncomputable in Lean. No verified eigensolver, symbolic factorization routine, symmetry-to-diagonalization step, code extraction, or performance guarantee is claimed.

Projector Resolved Seed Calculus II

The formal companion to Chapter II explains the declared hypotheses, theorem correspondences and evidence boundaries.

IN THIS COMPANION

Formal companion 1722

Return to Chapter II

How to use this volume

This formal companion separates the chapter-wide correspondence from the foundational 25-row contract. The overview records exact source scope and verification evidence. The tutorial explains the foundational source architecture, representative proofs, and evidence with their original boundaries. **Formal correspondence.** The correspondence records 81 source items, including

53 proof-level items. Its status is FINAL_SOURCE_BOUND_CORRESPONDENCE_53_OF_53. The tables retain the recorded states and verification checks. The inherited 25-row map remains a separate foundational contract.

53 of 53 proof-level source records have kernel checked, semantically accepted scope. No partial or pending proof records are listed in this correspondence. These are source-record counts under their stated hypotheses, not counts of independent discoveries.

1 Formal scope and evidence

The Lean project is formal/current/. Its correspondence records exact statement and proof text, source hashes, declaration targets and execution evidence. The source records include the complete machine-readable correspondence.

Formal correspondence. The correspondence records 81 source items, including 53 proof-level items. Its status is FINAL_SOURCE_BOUND_CORRESPONDENCE_53_OF_53. The tables retain the recorded states and verification checks. The inherited 25-row map remains a separate foundational contract.

53 of 53 proof-level source records have kernel checked, semantically accepted scope. No partial or pending proof records are listed in this correspondence. These are source-record counts under their stated hypotheses, not counts of independent discoveries.

1.1 Proof inventory

Recorded status	Items
Kernel checked, scope accepted	53

Exact statement comparison, semantic acceptance, aggregate compilation, and kernel replay provide distinct kinds of evidence. The table records the results of those checks. Typesetting does not repeat them.

1.2 Verification checks

Gate	Recorded state
exact source aggregate compile	PASS
owned kernel type body replay	PASS
standard axiom and runtime helper closure	PASS
manuscript semantic acceptance	53_COMPLETE_SCOPES_ACCEPTED

1.3 The rectifiable analytic endpoints

The rectifiable analytic endpoints use a representation whose velocity length is bounded by the original geometric length. This inequality supplies the manuscript estimate. Equality of the two lengths is not required. The accepted correspondence identifies the exact canonical endpoints and their hypotheses.

1.4 Statement map

The following table lists the proof-level source records. The correspondence gives exact declaration names, statement and proof hashes, hypotheses and inherited evidence. Mathematical definitions marked `noncomputable` do not supply an executable solver.

Source label	Recorded status

1.5 Reading the formal walkthrough

The following tutorial explains the foundational 25-row Lean contract. Its counts, excerpts, and certificate boundaries refer to the archived source identified in the orientation. Use the chapter-wide map above for the broader constructions and their verification evidence. Each report retains its own source identity and evidence scope.

2 From original contours to canonical values

The analytic development follows the contours that occur in the mathematical text. A contour is a continuous complex path of bounded variation on the closed unit interval. A cycle is a finite family of closed contours. An occurrence in that family contributes once to every sum, so a repeated contour retains its multiplicity. The construction permits constant paths, retracing, and an empty family.

The proof has three distinct tasks. It identifies the classical contour integral, controls the original geometric length, and proves that admissible contours give the same functional calculus value. Each task has an explicit endpoint in the current sources. The identity of a chosen integral is kept separate from independence of that choice.

2.1 The original tagged integral

For a path γ and a continuous function F on its trace with values in a complex Banach space, the tagged sums are

$$S(\gamma, F; P, \tau) = \sum_{j=0}^{m-1} (\gamma(t_{j+1}) - \gamma(t_j)) F(\gamma(\tau_j)), \qquad t_j \le \tau_j \le t_{j+1}.$$

The factor on the left acts by complex scalar multiplication. The partition is monotone, begins at 0, and ends at 1. Repeated partition points are allowed. The definition of the integral quantifies over every such tagged partition with sufficiently small mesh. Arbitrarily fine partitions are constructed, and the value is proved unique. The definition therefore expresses an actual limit of the original path increments.

For an absolutely continuous path, the difference between a tagged increment and its velocity integral is an integral of the oscillation of F along that subinterval. Its norm is bounded by that oscillation times the integral of the speed. Summing over the partition and using uniform continuity on the compact trace proves convergence of all the tagged sums to the Bochner velocity integral.

An arbitrary continuous rectifiable path need not be absolutely continuous in its original parameter. The project constructs its normalized arclength path and a continuous monotone map from the original parameter interval. Tagged partitions are transported through this map. Their increments and tagged function values agree exactly. Uniform continuity controls the transported mesh, including flat portions of the parameter map. The zero length case is handled separately. This proves equality between the original contour integral and the represented velocity integral without assuming a comparison certificate.

The source `ReleaseRectifiableRSError.lean` contains the tagged definition, existence and uniqueness results, monotone transport, and the finite cycle comparison. In particular, the original winding expression obtained by integrating $(z-w)^{-1}$ agrees with the represented winding whenever w avoids the trace.

2.2 The geometric length used in the estimate

Write $L(\gamma)$ for the total variation of the original path. The normalized arclength path is Lipschitz with constant $L(\gamma)$. Its coordinate velocity consequently satisfies

$$\int_0^1 \|v_\gamma(t)\|\, dt \le L(\gamma).$$

For a cycle, these inequalities add over its occurrences. This is the inequality needed by the manuscript. The proof does not require an additional theorem asserting equality between integrated speed and variation.

Combining this inequality with the actual cycle integral estimate gives

$$\left\| \int_\Gamma F(z)\,dz \right\| \le \operatorname{length}(\Gamma) \sup_{z\in\Gamma} \|F(z)\|,$$

where the length on the right is the original geometric length with multiplicities. Each supremum of norms is defined to be zero when its trace is empty. The separate supremum factors in Theorem 11.6 are retained by `ReleaseRectifiableDefect.lean`. They are not replaced by an unspecified product bound.

2.3 General Cauchy comparison

The represented cycle has integrable velocities. Its curves are absolutely continuous, and composition with a holomorphic scalar function on a neighborhood of the compact trace is absolutely continuous. The chain rule and the fundamental theorem of calculus therefore give

$$\int_\Gamma G'(z)\,dz = 0$$

for a supplied holomorphic primitive G. This scalar primitive result also proves local constancy of the actual normalized winding integral away from the trace. Applying it to an inverse kernel on an enclosing ball proves that winding vanishes sufficiently far from the trace.

For a holomorphic function F with values in a complex Banach space on an arbitrary open set U, define

$$H_{1,\Gamma}(w) = \int_\Gamma [w,z]F\,dz, \qquad H_{2,\Gamma}(w) = \int_\Gamma (z-w)^{-1}F(z)\,dz.$$

The divided difference $[w,z]F$ takes the value $F'(w)$ on the diagonal. The first function is holomorphic on U. The second is holomorphic away from the trace. Compact trace bounds justify differentiation under the actual Banach integral in both cases.

Suppose that two cycles Γ and Λ lie in U and have equal winding outside U. Use $H_{1,\Gamma} - H_{1,\Lambda}$ on U and $H_{2,\Gamma} - H_{2,\Lambda}$ outside U. At an exterior point, both traces are absent from a neighborhood. Local constancy of winding and the divided difference identity make the two expressions agree there. The resulting function is entire, even when U is disconnected or unbounded. Far from the traces it tends to zero. Banach valued Liouville then makes it identically zero.

To recover the integral of F, replace it by $(z-a)F(z)$ for any $a \in U$. Its divided difference at a equals $F(z)$, including at $z = a$. Thus no point outside the traces has to be chosen. The empty domain case is handled directly by the zero bound on an empty trace. The resulting theorem is

$$\int_\Gamma F(z)\,dz = \int_\Lambda F(z)\,dz.$$

Its only geometric inputs are the actual finite cycles and equality of winding outside the open domain. It assumes neither a general Cauchy conclusion nor contour independence.

2.4 The canonical defect and compatibility

For a bounded operator T, admissibility records an open holomorphy domain, a genuine cycle in that domain and the resolvent set, winding one on the spectrum, and winding zero outside the domain. These are input data. No functional calculus value or independence equation is a field of that record.

Two admissible choices are compared on the union of their holomorphy domains intersected with the resolvent set. Outside this comparison domain, their windings are both zero or both one. General Cauchy comparison proves equality of their normalized Dunford integrals. A canonical value can therefore be selected from any nonempty family of admissible data and then represented by every admissible original contour.

The original contour supplied in Theorem 11.6 provides this witness for both operators. After rewriting the two canonical values through that contour, the actual resolvent defect identity proves the manuscript's original tagged integral formula and its geometric length bound. No extra existence assumption is needed for this theorem.

For compatibility, the two endpoint operators may use different admissible contours. When the operator defect is zero, their two intertwined resolvents agree on the overlap of their resolvent sets. They glue to one holomorphic map on the union. General Cauchy comparison again identifies the integrals. Applying this naturality result to the total map of a finite tower proves Corollary 11.10 whenever its endpoint expressions are defined. The formal witnesses express this definedness. They do not assert compatibility as a premise.

The current coverage statement concerns the manuscript's enumerated proof scopes. It does not assert a separate theorem constructing an admissible contour for every possible operator and holomorphic germ, or an identification with a different software library's calculus API.

The relevant final endpoints are in `ReleaseCanonicalHFC.lean`, `ReleaseCanonicalNaturality.lean`, and `ReleaseCanonicalDefect.lean`. Their exact source identity and execution receipts are recorded separately from this exposition.

3 Reading the inherited formal walkthrough

The mathematical text develops the mathematical theory and its written proofs. The visual guide provides finite models for its identities, precision statements, and boundaries. This guide explains how to read and use the preserved Lean component: the types accepted by each theorem, the objects actually constructed, the obligations supplied by a caller, and the evidence attached to the source. These three companions have complementary roles.

This walkthrough describes the foundational 25-row formal contract. Section 1 records the chapter-wide correspondence and its boundaries.

The source register identifies the foundational formalization. The mathematical text includes broader written proofs of lattice gluing, necessary precision delay, inverse-limit convergence, general DVR arithmetic, holomorphic and exponential defects, and multilevel identities. Their appearance beside mapped results does not give them Lean proofs.

The fixed formal contract contains 25 rows: 21 numbered canonical statements, one Smith phase identity, and three mathematical algorithm specifications. The appendix crosswalk identifies their locations in the mathematical text. Throughout this guide, "row" means a row of the canonical formal map, never a count of every theorem in the mathematical text.

Quantity	What is counted
15 Lean source files	Four shared foundation modules, eight substantive Chapter II modules, two aggregate imports, and one audit module.
5,603 source lines	Physical lines in those files, including comments and blank lines.
25 map rows	Statement families, constructions, and specifications in the foundational contract.
160 unique targets	Distinct mapped declarations. Not all are theorem declarations.
171 target occurrences	Targets counted again when reused by another contract row.
1,034 namespace entries	Entries reported by the recorded compiled namespace scan, includ- ing generated auxiliaries.

A name count is not a measure of mathematical depth. A short wrapper can collect several substantial conclusions. A large structure can expose a difficult hypothesis without constructing its witness. The useful unit is a complete type together with its proof, its dependencies, and an accurate comparison with the prose statement.

3.1 Three useful reading routes

For a first reading, follow Sections 4–12: exact coordinates lead to weighted transfer, then arithmetic and typed defects. For a coverage review, use the crosswalk to the mathematical text in Appendix A, read the corresponding row in Section 15, and inspect its source type. For a reproduction attempt, read Section 13 before running any build command. The source checksum check and the compiler audit establish different things.

The main walkthroughs use exact source excerpts, with explanatory equations outside the listings. Names are case sensitive. `PowerSeries`, `Polynomial`, `LinearMap`, and `ContinuousLinearMap` are different types. Similar notation is not a license to replace one with another in a theorem application.

4 Lean types as mathematical bookkeeping

The basic theorem syntax places assumptions before a colon and a conclusion after it. A term after `:=` supplies the definition or proof. A `by` block is tactic syntax that elaborates a proof term. A successful elaboration still leaves a semantic question for the reader: does this exact type express the intended mathematical assertion?

Expression	Reading in this component
`[Semiring R]`	A typeclass instance supplying semiring operations and laws. Subtraction need not exist.
`[Ring R]`	A ring, possibly noncommutative. Multiplicative order remains significant.
`[CommSemiring R]`	Commutative multiplication is available, as in the general Fourier certificate.
`[Module R M]`	A scalar action with its laws. The scalar type is explicitly named.
`M →ₗ[R] N`	An R-linear map from M to N, including additive and scalar compatibility.
`Module.End R M`	The endomorphism ring or semiring of a single module.
`X →L[k] Y`	A continuous linear map with operator norm in the relevant normed setting.
`M ≃ₗ[R] N`	A linear equivalence, including both inverse laws.
`R →+* S`	A ring or semiring homomorphism. It preserves the operations used to transport an inverse.
`[Fintype E]`	A finite enumeration of all elements of E.
`Fin n`	Natural numbers strictly below n, bundled with their bound.
`ZMod n`	Integers modulo n. The nonzero modulus hypotheses matter for finite cardinality.
`AddSubgroup M`	An additive subgroup, without automatically being a valuation-ring lattice.
`Nonempty A`	Existence of a term of type A. It does not by itself supply a computational search procedure.
`Prop`	The sort of propositions, used for certificates whose fields are proof obligations.

Parenthesized arguments are normally supplied explicitly. Braced arguments can be inferred. Arguments in square brackets request typeclass synthesis. Section variables become parameters of later declarations when used. Therefore a source theorem must be read with its section context. In this project, `autoImplicit = false` and `relaxedAutoImplicit = false` prevent undeclared identifiers from silently becoming new implicit parameters.

The common `constructor` tactic splits a structure or conjunction into its fields. `rcases` opens a supplied witness into its data and proofs. `rw` rewrites using proved equalities. `simp` applies simplification rules and produces a proof term. `ext` reduces equality of structured maps to pointwise equality. `exact` supplies a term of the required type. `rfl` uses definitional equality. None of these words is a substitute for a missing mathematical hypothesis.

4.1 Definitions, certificates, and algorithms

A structure such as `TwoSidedInverse x y` records equations about already supplied x and y. A theorem that accepts this structure does not discover y. By contrast, the rationality branch for finite graphs

defines a denominator and numerator from the graph and proves their properties without accepting rationality as an input.

`noncomputable` does not mean unproved. It marks a definition that is not offered as executable code through Lean's ordinary computational evaluation. This component uses noncomputable choices from finite sets, instances for finite types, determinants, adjugates, and constructions of least exponents. Their mathematical properties can be proved even though a standalone executable implementation is not supplied.

The three algorithm rows certify mathematical contracts relating inputs to outputs. They do not certify the companion Python package, its storage layout, its numerical residuals, or its performance. Even where a finite enumeration is executable in principle, the contract contains no general complexity estimate or extraction theorem.

5 Source architecture and entry points

In the foundational project, the main entry point is import KomorebiVerification.PaperII. It imports the eight substantive modules but not the audit command. The root module KomorebiVerification.lean imports the aggregate for Lake's default library target. The standalone audit imports the substantive modules explicitly and inspects the resulting environment.

Module or layer	Responsibility
Shared foundation	`ProjectorCore`, `ExactCoordinates`, `FibreRefinement`, and `ResidueProjectors`: complete finite projector families, range coordinates, masks, and refinement.
`NestedRefinement`	Parent maps, absorption, child uniqueness, exact coordinate equivalences, cocycles, naturality, and block aggregation.
`ResidueFourierCRT`	Division-free masks, finite Fourier certificates, primitive-root specialization, polyphase refinement, and CRT labels.
`WeightedTransfer`	Ordered geometric inverses, normed Neumann inverses, multiplicative filtrations, and precise word pruning.
`TransferZeta`	Finite weighted walks, exact enumeration, first-edge recurrence, determinant rationality, and coefficient recurrence.
`ResultantSeparation`	Evaluated Bézout identities, numerator and kernel actions, denominator clearing, and certificate-based precision delay.
`SmithDyadic`	Concrete modular fibers, abstract certified products, rational sign matrices, local denominator weights, and the Smith-phase formula.
`TypedLinearDefects`	Fine-to-coarse maps between distinct spaces, power and resolvent defects, polynomial compatibility, and operator-norm estimates.
`LinearDefects`	Ring-valued counterparts and auxiliary inverse identities.
`KernelAudit`	Representative axiom reports and the fail-closed namespace gate.

The main mathematical dependencies are modular. Coordinate refinement does not require a valuation. Weighted pruning needs a filtration but not a graph incidence law. Transfer zeta counts graph walks but uses integer formal power series, not operator norms. Smith fibers work in finite modular arithmetic. The typed defect module is independent of a particular packet construction: a caller may use a coarsening map, but the theorem accepts any map of the stated type.

6 Exact packets and refinement

Rows 1–5 start from finite complete projector families. A family $P = (P_i)$ satisfies $P_i^2 = P_i$, $P_i P_j = 0$ for $i \neq j$, and $\sum_i P_i = I$. Orthogonality here is algebraic annihilation. An inner product, self-adjointness, and topology are absent from these assumptions. The canonical formal family also permits zero projectors, whereas the expanded traditional packet terminology requires nonzero members.

The packet space is the product of actual ranges,

$$\mathcal{P}(P) = \prod_i \text{range}(P_i).$$

Its elements carry their proofs of membership in a range. Analysis sends x to $(P_i x)_i$. Synthesis sums the underlying vectors. Completeness proves synthesis after analysis. Pairwise annihilation and idempotence prove analysis after synthesis. Both maps are independently defined, so the second inverse law has mathematical content: every tuple in the product of ranges is accepted.

6.1 What a refinement witness supplies

A parent map $\pi : J \to I$ assigns fine labels to coarse labels. The finite set `children parent a` is the fiber $\pi^{-1}(a)$. The refinement witness records surjectivity and exact equality of coarse maps with sums of their fine children.

Source: `KomorebiVerification/PaperII/NestedRefinement.lean`.

```
structure Refines
    (coarse : LinearProjectorFamily R M ι)
    (fine : LinearProjectorFamily R M κ)
    (parent : κ → ι) : Prop where
  surjective : Function.Surjective parent
  coarse_eq_sum_children :
    ∀ a, coarse.proj a = ∑ b ∈ children parent a, fine.proj b
```

The structure does not construct a parent map between arbitrary families. To apply its theorems, a caller supplies a map and proves these two fields. The resulting absorption identities are genuine consequences. If $\pi(j) = i$, then

$$P_i Q_j = Q_j = Q_j P_i;$$

if $\pi(j) \neq i$, both products vanish. Expand P_i as the sum of its children, distribute composition, and use orthogonality of the fine family. Transitivity follows by applying this reasoning through two successive parent maps.

6.2 A proof walkthrough: recovering a selected finite decomposition

The most general uniqueness theorem in row 2 does not use the refinement witness. Suppose a selected finite set S of packet vectors sums to x, with $v_j \in \text{range}(P_j)$ for $j \in S$. Applying P_i kills all terms except v_i, so $v_i = P_i x$. The exact proof shows which hypotheses enter.

Source: KomorebiVerification/PaperII/NestedRefinement.lean.

```
theorem finitePacket_decomposition_unique
    (P : LinearProjectorFamily R M κ) (s : Finset κ) (x : M)
    (packets : κ → M)
    (hrange : ∀ b ∈ s, packets b ∈ LinearMap.range (P.proj b))
    (hsum : ∑ b ∈ s, packets b = x) :
    ∀ b ∈ s, packets b = P.proj b x := by
  classical
  intro b hb
  have hself : P.proj b (packets b) = packets b := by
    rcases hrange b hb with ⟨y, hy⟩
    rw [← hy]
    exact P.idempotent b y
  have hproject : P.proj b (∑ j ∈ s, packets j) = packets b := by
    rw [map_sum]
    calc
      (∑ j ∈ s, P.proj b (packets j)) = P.proj b (packets b) := by
        apply Finset.sum_eq_single_of_mem b hb
        intro j hj hjb
        rcases hrange j hj with ⟨y, hy⟩
        rw [← hy]
        exact P.orthogonal hjb.symm y
      _ = packets b := hself
  calc
    packets b = P.proj b (∑ j ∈ s, packets j) := hproject.symm
    _ = P.proj b x := congrArg (P.proj b) hsum
```

First `rcases hrange b hb with` extracts a preimage y for the selected packet. Rewriting the packet as $P_b y$ makes idempotence applicable. Next `map_sum` distributes P_b across the finite sum. `Finset.sum_eq_single_of_mem` leaves the diagonal term. Each other term vanishes after its own range witness is opened. Finally `congrArg` applies P_b to the supplied sum equality.

The conclusion is restricted to $b \in S$. No conclusion is drawn about values of the packet function outside that finite set. The source family is complete as a bundled object, but the proof of this result never uses its completeness field. This explains the map's "Stronger" classification without suggesting a theorem about arbitrary infinite sums.

6.3 Coordinate changes need no parent map

Let A_P and S_P denote analysis and synthesis. For any two complete finite families on the same module, define

$$R_{P\to Q} = \mathsf{A}_Q \mathsf{S}_P, \qquad R_{Q\to P} = \mathsf{A}_P \mathsf{S}_Q.$$

The source calls these maps refinement and coarsening.

Source: KomorebiVerification/PaperII/NestedRefinement.lean.

```
variable (coarse : LinearProjectorFamily R M ι)
variable (fine : LinearProjectorFamily R M κ)

/-- Resolve coarse range coordinates by synthesis followed by fine analysis. -/
```

```
def refineCoordinates : PacketSpace coarse →ₗ[R] PacketSpace fine :=
  fine.rangeAnalysis.comp coarse.rangeSynthesis

/-- Regroup fine range coordinates by synthesis followed by coarse analysis. -/
def coarsenCoordinates : PacketSpace fine →ₗ[R] PacketSpace coarse :=
  coarse.rangeAnalysis.comp fine.rangeSynthesis
```

These maps are inverses because $\mathsf{S}_Q\mathsf{A}_Q = I$ and $\mathsf{A}_P\mathsf{S}_P = I$. The proof uses the earlier simplification rules for exact coordinates.

Source: `KomorebiVerification/PaperII/NestedRefinement.lean`.

```
@[simp] theorem coarsenCoordinates_refineCoordinates
    (packets : PacketSpace coarse) :
    coarsenCoordinates coarse fine (refineCoordinates coarse fine packets) =
      packets := by
  simp [coarsenCoordinates, refineCoordinates]

/-- Refinement after coarsening is the identity on fine range coordinates. -/
@[simp] theorem refineCoordinates_coarsenCoordinates
    (packets : PacketSpace fine) :
    refineCoordinates coarse fine (coarsenCoordinates coarse fine packets) =
      packets := by
  simp [coarsenCoordinates, refineCoordinates]

/-- The exact linear equivalence between the two independent range products. -/
def coordinateRefinementEquiv : PacketSpace coarse ≃ₗ[R] PacketSpace fine where
  toFun := refineCoordinates coarse fine
  invFun := coarsenCoordinates coarse fine
  left_inv := coarsenCoordinates_refineCoordinates coarse fine
  right_inv := refineCoordinates_coarsenCoordinates coarse fine
  map_add' := (refineCoordinates coarse fine).map_add
  map_smul' := (refineCoordinates coarse fine).map_smul
```

The short `simp` proofs rest on established inverse laws. They are not assumptions that refinement loses no data. The two packet products are full exact presentations of the same module. Counting the number of labels alone does not measure their dimension: every label contains an entire projector range.

A parent witness adds component formulas. The fine component is obtained by applying the fine projector to its coarse parent packet. The coarse component is the sum of its fine children. These are additional identities about the already defined coordinate equivalence. They do not turn it into averaging, sampling, or truncation.

With a third complete family H, the same inverse laws give the cocycle

$$R_{Q\to H}R_{P\to Q} = R_{P\to H}.$$

The theorem `refineCoordinates_comp` first proves the equality on each packet and then uses extensionality of linear maps. A reader can thus separate the simple conceptual proof from the bookkeeping needed to state it as equality of bundled maps.

6.4 Naturality and independently refined blocks

For $T : M \to N$ with source family P and target family Q, the exact coordinate operator is $\mathsf{A}_Q T \mathsf{S}_P$. Its composition law cancels the middle pair of synthesis and analysis maps. Changing the source and target coordinate systems independently gives the corresponding commuting naturality identity.

The block convention places the output index first:

$$T_{ji} = Q_j T P_i.$$

If source and target families refine separately, a coarse block is the double sum over fine descendants of its source and target labels. The mapped theorem permits different source and target modules, which is stronger than the endomorphism special case. Its composite traceability wrapper also records reconstruction of T from all coarse blocks and from all fine blocks.

The finite algebraic result does not establish sparsity of a computed representation, a block extraction routine with a finite complexity bound, or convergence of an infinite block matrix. These need separate hypotheses and, where intended, separate formal developments.

7 Residue selectors, Fourier certificates, and CRT

Rows 6–9 act on coefficient functions $x : \mathbb{N} \to A$. At a positive modulus N, the residue projector keeps $x(n)$ when n mod $N = j$ and returns zero otherwise. Since exactly one residue label matches each n, idempotence, pairwise annihilation, and completeness follow pointwise. No division or roots of unity are required.

This representation is a sequence module, not a formal power series object with a multiplication law. It is sufficient for coefficient masks. A user wishing to apply the result to a particular function space must supply the connection to that space and any closure or convergence facts.

7.1 The finite Fourier table is an input over general semirings

A Fourier realization uses scalars ω, $\omega^\vee$, and η. The weighted residue kernel is

$$\eta \sum_{k=0}^{N-1} (\omega^\vee)^{jk} \omega^{rk}.$$

Over a general commutative semiring the source does not assume that $\omega^\vee$ is an inverse or that $\eta = 1/N$. Instead it accepts a finite orthogonality table with exactly the required conclusion at residue addresses.

Source: `KomorebiVerification/PaperII/ResidueFourierCRT.lean`.

```
structure FiniteRingFourierOrthogonalityCertificate
    (R : Type u) [CommSemiring R] (N : Nat)
    (omega omegaDual eta : R) : Prop where
  omega_pow_order : omega ^ N = 1
  weighted_residue_sum_eq (j r : Fin N) :
    eta * ringFourierResidueKernel N omega omegaDual j r =
      if r = j then 1 else 0
```

The substantive bridge is from that finite table to every coefficient address. The equation $\omega^N = 1$ reduces the exponent n to n mod N. The last line below uses `Fin.ext_iff` to equate residue labels through their underlying natural numbers.

Source: `KomorebiVerification/PaperII/ResidueFourierCRT.lean`.

```
theorem FiniteRingFourierOrthogonalityCertificate.toRingCertificate
    {R : Type u} [CommSemiring R]
    (N : Nat) (hN : 0 < N) (omega omegaDual eta : R)
    (certificate :
      FiniteRingFourierOrthogonalityCertificate R N omega omegaDual eta) :
    RingFourierOrthogonalityCertificate R N omega omegaDual eta := by
  refine (?_)
  intro j n
  rw [ringFourierKernel_eq_residueKernel N hN omega omegaDual
    certificate.omega_pow_order j n]
  rw [certificate.weighted_residue_sum_eq]
  congr 1
  simp only [Fin.ext_iff]
```

After this bridge, the average and the mask are equal coefficient by coefficient: the normalized scalar is one at the selected address and zero elsewhere. The proof works with a finite table rather than an infinite family of independent premises.

There is also a stronger field branch. A primitive root of positive order supplies the normalized orthogonality certificate for the inverse root internally. Its field hypothesis is essential to that branch's scope. Root order by itself is not a replacement for the table over arbitrary rings with zero divisors.

7.2 Refining residues and factoring their labels

For positive N and k, the modulus-N selector is the sum of all modulus-Nk selectors whose labels reduce to it. This is exact regrouping of masks. No packet is discarded and there is no approximation error to estimate.

For positive coprime m, n, CRT gives an equivalence between labels modulo mn and pairs of labels modulo m and n. The corresponding selector is the composite of the two independent selectors in either order. For $m = 2^a$ and positive odd n, the factorization into dyadic and odd moduli is a specialization.

These are coordinate facts. They do not prove that rational spectral projectors have integral denominators, that a completed lattice splits, or that solving a lifting problem is possible. The later arithmetic modules use different data for those questions. This separation is useful when reading the same terminology about dyadic and odd moduli in the mathematical text: residue factorization and spectral denominator clearing are distinct statements.

8 Weighted inversion: three separate branches

Rows 10–11 concern $D + H$ in a possibly noncommutative ring. A supplied inverse D^{-1} that works on both sides permits the factorization

$$D + H = D(1 + A), \qquad A = D^{-1}H.$$

Thus an inverse of $1 + A$ is multiplied by D^{-1} on the right. Reversing this order changes the formula in a noncommutative ring. The source parameter named `K` in these declarations means the perturbation H. It is not a fraction field.

Three hypotheses lead to three different results. Nilpotence gives a finite ring identity. A homomorphism that kills a filtration level gives a finite identity after passing to precision. A strict norm bound in a complete normed ring gives an infinite Neumann sum. The formal component does not merge these into an unrestricted adic convergence theorem.

8.1 The finite geometric identity

For $A^N = 0$, define $B = \sum_{n=0}^{N-1} (-A)^n$. The product formulas for finite geometric sums prove both $(1 + A)B = 1$ and $B(1 + A) = 1$.

Source: `KomorebiVerification/PaperII/WeightedTransfer.lean`.

```
def finiteGeometricInverse {R : Type u} [Ring R] (a : R) (N : ℕ) : R :=
  ∑ n ∈ Finset.range N, (-a) ^ n

/-- If `a ^ N = 0`, the finite geometric candidate is a genuine two-sided inverse of `1 + a`. -/
theorem finiteGeometricInverse_spec_of_pow_eq_zero {R : Type u} [Ring R]
    (a : R) (N : ℕ) (hN : a ^ N = 0) :
    TwoSidedInverse (1 + a) (finiteGeometricInverse a N) := by
  have hneg : (-a) ^ N = 0 := by
    rw [neg_pow, hN, mul_zero]
  constructor
  · simpa [finiteGeometricInverse, hneg] using geom_sum_mul_neg (-a) N
  · simpa [finiteGeometricInverse, hneg] using mul_neg_geom_sum (-a) N
```

The source separately invokes the two ordered geometric sum lemmas. This is why `TwoSidedInverse` has two fields. An inverse from one side does not automatically supply the other in a general noncommutative ring. Once this result is available, the theorem for a diagonal part with transfers transports the candidate through the factorization of $D + H$.

The cutoff N and its nilpotence proof are inputs. The theorem is not a procedure for deciding whether an arbitrary ring element is nilpotent. Its finite sum is explicit, but a concrete matrix application must still identify the matrix ring, supply D^{-1}, and prove the required equations.

8.2 The filtration is deliberately minimal

A multiplicative filtration records additive closure, decreasing levels, and multiplicative addition of indices.

Source: `KomorebiVerification/PaperII/WeightedTransfer.lean`.

```
structure MultiplicativeFiltration (R : Type u) [Ring R] where
  Mem : ℕ → R → Prop
  zero_mem : ∀ n, Mem n 0
  add_mem : ∀ {n x y}, Mem n x → Mem n y → Mem n (x + y)
  neg_mem : ∀ {n x}, Mem n x → Mem n (-x)
  one_mem : Mem 0 1
  antitone : ∀ {m n x}, m ≤ n → Mem n x → Mem m x
  mul_mem : ∀ {m n x y}, Mem m x → Mem n y → Mem (m + n) (x * y)
```

Write F^n for the predicate `Mem n`. Multiplicativity is $F^m F^n \subseteq F^{m+n}$. Antitonicity sends membership at a larger index to membership at a smaller one. Completeness, separation, and a topology for an inverse limit are not fields of this structure. Thus the word "filtration" in its name does not imply any convergence statement.

A precision certificate for a ring homomorphism $q : R \to S$ says $q(F^L) = 0$. It does not claim that S is a particular quotient or that $\ker q = F^L$. Killing the level is sufficient for the theorem. The proof below first puts a word into its cumulative filtration level and then uses antitonicity to reach F^L.

Source: `KomorebiVerification/PaperII/WeightedTransfer.lean`.

```
structure PrecisionCertificate {R : Type u} {S : Type v} [Ring R] [Ring S]
    (filtration : MultiplicativeFiltration R) (q : R →+* S) (L : ℕ) : Prop where
  map_eq_zero : ∀ {x : R}, filtration.Mem L x → q x = 0

/-- A transfer word whose cumulative weight reaches `L` vanishes in every realization carrying a
precision-`L` certificate. -/
theorem wordProduct_vanishes_at_precision {R : Type u} {S : Type v}
    [Ring R] [Ring S] (filtration : MultiplicativeFiltration R)
    (q : R →+* S) (L : ℕ) (certificate : PrecisionCertificate filtration q L)
    {E : Type w} (weight : E → ℕ) (edge : E → R)
    (hedge : ∀ e, filtration.Mem (weight e) (edge e))
    (word : List E) (hweight : L ≤ wordWeight weight word) :
    q (wordProduct edge word) = 0 := by
  apply certificate.map_eq_zero
  apply filtration.antitone hweight
  exact filtration.wordProduct_mem weight edge hedge word
```

The caller supplies the facts about edge membership $A_e \in F^{w(e)}$. Induction on a list gives $A_{e_1} \cdots A_{e_r} \in F^{w(e_1)+\cdots+w(e_r)}$. All words of weight at least L therefore disappear after applying q.

8.3 Written products and chronological paths

The definition `wordProduct edge word` is `(word.map edge).prod`. For the list $[e_1, \dots, e_r]$, it gives the written product $A_{e_1} \cdots A_{e_r}$. When these are operators, the rightmost factor acts first. This is the convention in the canonical formal branch for weighted words.

The expanded traditional discussion of block paths writes a chronologically traversed path $e_1, \dots, e_r$ as $A_{e_r} \cdots A_{e_1}$. To translate an indexed term, reverse the list. The full sums over all words of a fixed length agree under this bijection. The sums truncated by weight also agree because reversal preserves cumulative weight. Individual indexed products need not agree. An equation for one labeled path must therefore retain its order convention.

The generic formal sum over weighted words ranges over edge lists without imposing graph adjacency. In a concrete block realization, incompatible products may vanish for structural reasons, but those incidence facts are not fields of `MultiplicativeFiltration`. They must be supplied when interpreting the sum as a sum over directed block paths.

8.4 What is actually retained

The pruned expression contains only words with total weight strictly below L. Its length cutoff N is a separate parameter.

Source: KomorebiVerification/PaperII/WeightedTransfer.lean.

```
def retainedFixedWordSum {E : Type u} {R : Type v} [Fintype E] [Ring R]
    (weight : E → ℕ) (edge : E → R) (L n : ℕ) : R :=
  ∑ word : Fin n → E with wordWeight weight (List.ofFn word) < L,
    wordProduct edge (List.ofFn word)

/-- The explicit signed, weight-pruned word candidate through word length `N - 1`.

Unlike `finiteGeometricInverse`, this expression visibly contains only retained transfer words:
every summand has cumulative weight strictly below `L`.  The independent length cutoff `N` permits
the sharper cutoff obtained from a lower bound on all edge weights. -/
def prunedWordInverse {E : Type u} {R : Type v} [Fintype E] [Ring R]
    (weight : E → ℕ) (edge : E → R) (L N : ℕ) : R :=
  ∑ n ∈ Finset.range N, (-1 : R) ^ n * retainedFixedWordSum weight edge L n
```

If each edge weight is at least m, a word of length N has weight at least mN. Hence $L \le mN$ makes the Nth mapped power vanish. For $m > 0$, the proved ceiling inequality allows $N = \lceil L/m \rceil$. With merely positive integral weights, $N = L$ is a valid coarse cutoff.

The equality between the mapped full geometric sum and the mapped sum of retained words is proved by splitting the finite word sums into retained and killed terms. The inverse conclusion then follows from mapped nilpotence. This order of reasoning matters: pruning is justified by exact zero in the precision realization, not by a small numerical residual.

The full theorem for a diagonal part with transfers exposes all remaining data. It accepts the inverse of D, the normalized edge expansion, the precision certificate, the lower bound on the weights, the cutoff inequality, and the proofs about edge membership.

Source: KomorebiVerification/PaperII/WeightedTransfer.lean.

```
theorem finitePrecisionPrunedDiagonalTransferInverse_of_minWeight
    {R : Type u} {S : Type v} [Ring R] [Ring S]
    (filtration : MultiplicativeFiltration R)
    (q : R →+* S) (L m N : ℕ) (certificate : PrecisionCertificate filtration q L)
    (D Dinv K : R) (hD : TwoSidedInverse D Dinv)
    {E : Type w} [Fintype E] (weight : E → ℕ) (edge : E → R)
    (htransfer : Dinv * K = ∑ e : E, edge e)
    (hmin : ∀ e, m ≤ weight e) (hcutoff : L ≤ m * N)
    (hedge : ∀ e, filtration.Mem (weight e) (edge e)) :
    TwoSidedInverse
      (q (D + K))
      (q (prunedDiagonalTransferInverse weight edge Dinv L N)) := by
  have hpruned := prunedWordInverse_spec_of_minWeight
    filtration q L m N certificate weight edge hmin hcutoff hedge
  have htransferMapped : q Dinv * q K = ∑ e : E, q (edge e) := by
    simpa only [map_mul, map_sum] using congrArg q htransfer
  have hnormalized :
      TwoSidedInverse (1 + q Dinv * q K) (q (prunedWordInverse weight edge L N)) := by
    simpa only [map_add, map_one, map_sum, htransferMapped] using hpruned
  have hdiagonal := diagonal_inverse_of_perturbation_inverse
    (q D) (q Dinv) (q K) (q (prunedWordInverse weight edge L N)) (hD.map q) hnormalized
  simpa only [prunedDiagonalTransferInverse, map_add, map_mul] using hdiagonal
```

The proof first obtains the pruned inverse of $1+\sum_e A_e$. It maps the supplied equality for normalized transfers, rewrites the inverse target, and applies the diagonal factorization lemma. The final `simpa` only unfolds the candidate and the homomorphism's preservation of addition and multiplication. No inverse of D or quotient construction is hidden in that final simplification.

8.5 The analytic branch and the algorithm contract

In a complete normed ring, $\|D^{-1}H\| < 1$ supplies a separate inverse given by a Neumann series. The source defines the analytic candidate noncomputably and proves both inverse laws using the normed summability theory. This is neither the finite nilpotence premise nor completeness of an arbitrary filtered ring. An application using a valuation needs a bridge to one of the formal settings.

Row 24 packages the bounded geometric/pruned expression as a mathematical algorithm specification. It proves that the chosen ceiling cutoff meets the required inequality and that the mapped result is an inverse on both sides. It does not construct a modular inverse routine in a chosen basis, decide symbolic zero, certify the Python implementation, or establish a runtime bound.

9 Transfer zeta: from independent walks to rationality

Rows 12–13 and 25 describe the finite graph construction. The input is a finite directed multigraph with positive natural edge weights. Parallel edges are distinct edge values and therefore contribute their multiplicities automatically. Repeated vertices and edges are allowed: the objects counted are walks.

Source: `KomorebiVerification/PaperII/TransferZeta.lean`.

```
structure PositiveWeightedMultigraph (V : Type u) (E : Type v) where
  source : E → V
  target : E → V
  weight : E → ℕ
  weight_pos : ∀ e, 0 < weight e

namespace PositiveWeightedMultigraph

variable {V : Type u} {E : Type v}

/-- The recursive endpoint condition for an ordered list of edges. -/
def IsWalk (G : PositiveWeightedMultigraph V E) (s t : V) : List E → Prop
  | [] => s = t
  | e :: es => G.source e = s ∧ G.IsWalk (G.target e) t es
```

The recursion `IsWalk` says an empty edge list starts and ends at the same vertex. A nonempty list starts with an edge whose source is the current vertex, then continues from that edge's target. The total weight is the sum of edge weights.

9.1 Why a coefficient has a finite enumeration

Positivity implies that a walk of total weight n has length at most n. The enumerator can therefore range over lengths $0, \dots, n$ and all edge tuples of each length, then filter by endpoint validity and exact total weight.

Source: KomorebiVerification/PaperII/TransferZeta.lean.

```
/--
The exact finite enumeration used for the coefficient of weight `n`.
-/
def walkTuplesAtWeight [Fintype E] [DecidableEq E] [DecidableEq V]
    (G : PositiveWeightedMultigraph V E) (s t : V) (n : ℕ) :
    Finset (BoundedEdgeTuple E n) :=
  Finset.univ.filter fun x ↦
    G.IsWalk s t (tupleEdges x) ∧ G.pathWeight (tupleEdges x) = n

/-- Membership in the finite enumerator has exactly the advertised meaning. -/
theorem mem_walkTuplesAtWeight_iff [Fintype E] [DecidableEq E] [DecidableEq V]
    (G : PositiveWeightedMultigraph V E) (s t : V) (n : ℕ)
    (x : BoundedEdgeTuple E n) :
    x ∈ G.walkTuplesAtWeight s t n ↔
      G.IsWalk s t (tupleEdges x) ∧ G.pathWeight (tupleEdges x) = n := by
  simp [walkTuplesAtWeight]
```

The module also defines an independent semantic type of finite edge lists having the requested endpoints and weight, without building the enumeration bound into that definition. The capture theorem uses positivity to connect the unrestricted semantic representation to the bounded tuple enumeration. The counting theorem and the trace wrapper identify the returned natural number with the cardinality of this semantic walk type.

This avoids defining correctness merely as equality with the same algorithm under another name. The finite enumeration and the semantic list predicate are separate constructions connected by equivalences. The implementation remains a potentially large exhaustive enumeration. No efficiency theorem is claimed.

9.2 The recurrence from the first edge

Fix a target t and let $a_{st}(n)$ count walks from s to t of weight n. The empty walk contributes 1 exactly when $s = t$ and $n = 0$. Every other walk has a unique first edge. Removing it gives

$$a_{st}(n) = \mathbf{1}_{s=t,\, n=0} + \sum_{\substack{e:\, s\to u \\ w(e)\le n}} a_{ut}(n - w(e)).$$

The source constructs the corresponding equivalence from the first edge and obtains the recurrence by cardinality. Positivity ensures the recursive weight decreases. The bound $w(e) \le n$ is explicit, avoiding an incorrect use of truncated natural subtraction when the first edge is too heavy.

Define $Z_{st}(X) = \sum_{n\ge 0} a_{st}(n) X^n$. This is a formal power series over $\mathbb{Z}$. The weighted adjacency entry $A_{su}(X)$ sums $X^{w(e)}$ over all edges $s \to u$. The recurrence from the first edge becomes

$$(I - A(X))Z(X) = I.$$

The row/column orientation here follows traversal from the first edge. When comparing it with operator blocks with the output index first, read the definitions rather than transferring an index convention by analogy.

9.3 A second construction: determinant and adjugate

Finite vertex data define the polynomial matrix $B(X) = I - A(X)$ and

$$Q(X) = \det B(X), \qquad P_{st}(X) = \operatorname{adj}(B(X))_{st}.$$

Positive edge weights give $A(0) = 0$, hence $B(0) = I$ and $Q(0) = 1$. Thus Q is a unit in $\mathbb{Z}[\![X]\!]$. The adjugate identity constructs a matrix Z^{mat} that is an inverse on both sides.

The proof identifies the independently enumerated series matrix with this rational matrix. It uses associativity and the two inverse equations.

Source: KomorebiVerification/PaperII/TransferZeta.lean.

```
theorem enumeratedPathZetaMatrix_eq_matrixPathZetaMatrix :
    G.enumeratedPathZetaMatrix = G.matrixPathZetaMatrix := by
  calc
    G.enumeratedPathZetaMatrix = 1 * G.enumeratedPathZetaMatrix :=
      (Matrix.one_mul _).symm
    _ = (G.matrixPathZetaMatrix * G.transferSeriesMatrix) *
        G.enumeratedPathZetaMatrix := by
      rw [G.matrixPathZetaMatrix_mul_transferSeriesMatrix]
    _ = G.matrixPathZetaMatrix *
        (G.transferSeriesMatrix * G.enumeratedPathZetaMatrix) :=
      Matrix.mul_assoc _ _ _
    _ = G.matrixPathZetaMatrix * 1 := by
      rw [G.transferSeriesMatrix_mul_enumeratedPathZetaMatrix]
    _ = G.matrixPathZetaMatrix := Matrix.mul_one _
```

This is the uniqueness calculation $Z = IZ = (Z^{\mathrm{mat}}B)Z = Z^{\mathrm{mat}}(BZ) = Z^{\mathrm{mat}}$. Rationality was not assumed for the enumerated coefficients. The final existential theorem packages the already constructed numerator and denominator.

Source: KomorebiVerification/PaperII/TransferZeta.lean.

  refine ⟨G.transferNumerator s t, G.transferDenominator,
    G.transferDenominator_coeff_zero, G.transferDenominator_ne_zero, ?_⟩
  exact G.transferDenominator_mul_pathZeta s t
```

The older `RationalCertificate` interface remains available for an externally supplied pair P, Q. Its theorem is explicit about its certificate. The canonical branch for finite graphs does not take that certificate. It derives its own data from the graph. The map preserves both interfaces so users can choose one without confusing their hypothesis burdens.

9.4 The recurrence is extracted from the proved identity

Write $Q(X) = \sum q_j X^j$. Taking coefficient n in $QZ = P$ gives an antidiagonal convolution. Once $n >$ deg P, the coefficient on the right is zero.

Source: KomorebiVerification/PaperII/TransferZeta.lean.

```
theorem finite_graph_constant_coefficient_recurrence (s t : V)
    {n : ℕ} (hn : (G.transferNumerator s t).natDegree < n) :
    ∑ p ∈ Finset.HasAntidiagonal.antidiagonal n,
        G.transferDenominator.coeff p.1 *
          (G.coefficientAlgorithm s t p.2 : ℤ) = 0 := by
  have hcoeff := congrArg (PowerSeries.coeff n)
    (G.transferDenominator_mul_pathZeta s t)
  rw [PowerSeries.coeff_mul] at hcoeff
  simpa [Polynomial.coeff_eq_zero_of_natDegree_lt hn] using hcoeff
```

Because $q_0 = 1$, this can be read as an eventual recurrence with constant coefficients for $a_{st}(n)$. The source's antidiagonal form states the identity without needing to rearrange its leading term. It does not guess a recurrence from sampled coefficients.

The determinant denominator may have canceling factors for a particular matrix entry, so this construction does not prove minimality of Q or of the recurrence order. The determinant and adjugate definitions are noncomputable here. The result concerns formal power series and supplies no disk of analytic convergence, extracted symbolic determinant program, or rationality theorem for infinite graphs.

10 Evaluated separation and lattice precision

Rows 14–16 start with endomorphisms F, G, U, V of a vector space over a field K. The central premise is an evaluated Bézout equality

$$UF + VG = rI.$$

The source does not construct polynomials whose evaluation gives these maps, compute a general resultant, factor a characteristic polynomial, or instantiate Cayley–Hamilton. These operations may justify the premise in a mathematical application, but they remain upstream of this formal interface.

Let $N = VG$. The identity without denominators is $N^2 = rN$. After adding $r \neq 0$, the normalized map $E = r^{-1}N$ is idempotent. The bundled `EvaluatedBezoutCertificate` contains six pairwise commutations as well as nonvanishing, Bézout, and annihilation. The mapped minimal theorems need fewer fields and state this directly.

10.1 A proof walkthrough: the square identity without division

Only $FG = GF$, $GU = UG$, and $FG = 0$ are needed to kill the cross term $VGUF$. Using $VG = rI - UF$ on one occurrence of the numerator then proves the square identity.

Source: KomorebiVerification/PaperII/ResultantSeparation.lean.

```
theorem separatorNumerator_mul_self_of_bezout
    (bezout : U * F + V * G = r • (1 : End (K := K) (M := M)))
    (commute_FG : Commute F G) (commute_GU : Commute G U) (annihilate : F * G = 0) :
    separatorNumerator V G * separatorNumerator V G = r • separatorNumerator V G := by
  calc
    separatorNumerator V G * separatorNumerator V G =
        separatorNumerator V G *
```

```
        (r • (1 : End (K := K) (M := M)) - U * F) := by
          exact congrArg (separatorNumerator V G * ·)
            (separatorNumerator_eq_scalar_sub_of_bezout bezout)
_ = separatorNumerator V G * (r • (1 : End (K := K) (M := M))) -
      separatorNumerator V G * (U * F) := by rw [mul_sub]
_ = r • separatorNumerator V G := by
  rw [separatorNumerator_mul_complement_eq_zero_of_commute
    commute_FG commute_GU annihilate]
  simp only [sub_zero, mul_smul_comm, mul_one]
```

The proof rewrites just the second factor, distributes multiplication over subtraction, and invokes vanishing of the cross term. It needs neither $r \neq 0$ nor four unused commutations from the stronger bundle. Consequently the theorem without denominators remains meaningful even when normalization is unavailable. The later normalized theorem uses scalar associativity and field simplification with the explicit nonzero hypothesis.

On $\ker F$, the evaluated Bézout equation gives $Nx = rx$ directly. On $\ker G$, $Nx = V(Gx) = 0$. After normalization, E acts as identity and zero respectively. A statement that F is nilpotent on some larger subspace would not imply $Fx = 0$ there. The formal theorem uses exact kernel membership. This prevents an intuition about primary summands from silently strengthening the proved conclusion.

10.2 What the formal lattice means

The lattice parameter is an `AddSubgroup M`. Preservation by a map means that each member is sent back into this additive subgroup. A general valuation ring, finite generation, full rank, completeness, and a chosen basis are not built into its type.

A clearing certificate at exponent s states that $\pi^s E$ preserves the lattice. The source names this `IsSeparationWeight`. If multiplication by π also preserves the lattice, the set of clearing exponents is upward closed. Given existence of some clearing exponent, `Nat.find` defines a least one and proves its minimality property. This is a noncomputable construction of a least witness, not a search algorithm over matrix entries.

If $r = u\pi^s$, then

$$\pi^s E = u^{-1} V G.$$

To turn this algebraic identity into lattice preservation, one must know that u^{-1} preserves the chosen lattice, together with V and G. An abstract field unit need not preserve an arbitrary additive subgroup. The formal certificate for the unit action on the lattice makes this assumption visible. The resulting exponent bounds the least separation weight from above. It need not be the minimal exponent.

The expanded traditional theory identifies exact weights through a lattice gluing module and gives necessary as well as sufficient delay statements. Those ordinary written proofs are beyond these mapped consequences of clearing certificates. They should not be attributed to `separationWeight` merely because the names describe related mathematics.

10.3 Precision delay as transport of a witness

Formal congruence at depth n means an explicit equation $x - y = \pi^n z$ with z in the lattice. If $\pi^s E$ preserves the lattice, input congruence at $m + s$ becomes output congruence at m.

Source: KomorebiVerification/PaperII/ResultantSeparation.lean.

```
/-- Congruence modulo the scalar lattice `pi^n lattice`, expressed with an explicit witness. -/
def CongruentModLattice (pi : K) (lattice : AddSubgroup M) (n : ℕ) (x y : M) : Prop :=
  ∃ z : M, z ∈ lattice ∧ x - y = (pi ^ n) • z

/-- An `s`-digit denominator certificate turns `m+s` input digits into `m` output digits. -/
theorem projector_precision_delay {pi : K} {E : End (K := K) (M := M)}
    {lattice : AddSubgroup M} {s m : ℕ}
    (hweight : IsSeparationWeight pi E lattice s) {x y : M}
    (hxy : CongruentModLattice pi lattice (m + s) x y) :
    CongruentModLattice pi lattice m (E x) (E y) := by
  rcases hxy with ⟨z, hz, hxy⟩
  refine ⟨((pi ^ s) • E) z, hweight z hz, ?_⟩
  rw [← map_sub, hxy, map_smul]
  simp only [LinearMap.smul_apply, pow_add, smul_smul]
```

The proof opens the original witness z. It chooses the new witness $z' = (\pi^s E)z$, whose lattice membership is exactly the clearing hypothesis. Linearity and $\pi^{m+s} = \pi^m \pi^s$ establish the new difference equation. No digit expansion, topology, or valuation API enters this proof. It is sufficient delay from a supplied certificate, without a claim that fewer input digits must fail.

11 Concrete Smith fibers and the dyadic sign model

Row 18 proves a concrete arithmetic statement over `ZMod (p^depth)` for $p > 1$. The hypothesis is not that p is prime. Since the modulus and coefficient are powers of the same integer, the needed gcd and divisibility identities hold at this stated scope.

11.1 The solution fiber is an actual type of solutions

For a weight s and depth L, multiplication by p^s is an additive endomorphism of $\mathbb{Z}/p^L\mathbb{Z}$. Its fiber over b is the subtype of elements that map to b.

Source: KomorebiVerification/PaperII/SmithDyadic.lean.

```
def smithZModMulHom (p weight depth : ℕ) :
    ZMod (p ^ depth) →+ ZMod (p ^ depth) :=
  nsmulAddMonoidHom (p ^ weight)

/-- The actual solution fibre of the one-coordinate Smith congruence
`p ^ weight * x = target` modulo `p ^ depth`. -/
abbrev SmithZModFiber (p weight depth : ℕ) (target : ZMod (p ^ depth)) :=
  ↥(smithZModMulHom p weight depth ⁻¹' {target})

/-- The concrete fibre is finite, inherited from the finite quotient `ZMod (p ^ depth)`. -/
noncomputable instance smithZModFiberFintype (p weight depth : ℕ) [NeZero (p ^ depth)]
    (target : ZMod (p ^ depth)) : Fintype (SmithZModFiber p weight depth target) :=
  Fintype.ofFinite _

/-- Concrete divisibility admissibility for a one-coordinate Smith congruence. -/
```

```
def SmithZModAdmissible (p weight depth : ℕ) (target : ZMod (p ^ depth)) : Prop :=
  p ^ min weight depth | target.val
```

The criterion is

$$p^{\min(s,L)} \mid \mathrm{val}(b),$$

where `target.val` is the canonical natural representative. The source proves that this is equivalent to nonemptiness of the actual fiber. If $s \leq L$, an admissibility witness supplies a quotient of the target representative and hence a solution. If $L \leq s$, admissibility forces the target to be zero. The zero residue supplies a solution.

The forward direction uses the modular representative of a supplied solution and divisibility by both the coefficient and modulus. Thus solvability is proved from concrete modular arithmetic, rather than inserted as a certificate field.

11.2 A proof walkthrough: counting an admissible fiber

Once a solution x_0 exists, translation by x_0 identifies the fiber with the kernel of multiplication by p^s. The kernel cardinality in this finite cyclic additive group is the gcd of its order with p^s.

Source: `KomorebiVerification/PaperII/SmithDyadic.lean`.

```
theorem smithZModFiber_card_of_admissible {p weight depth : ℕ} [NeZero (p ^ depth)] (hp : 1 < p)
    (target : ZMod (p ^ depth))
    (hadmissible : SmithZModAdmissible p weight depth target) :
    Fintype.card (SmithZModFiber p weight depth target) = p ^ min weight depth := by
  obtain ⟨x, hx⟩ := (smithZModFiber_nonempty_iff hp target).mpr hadmissible
  let f : ZMod (p ^ depth) →+ ZMod (p ^ depth) := smithZModMulHom p weight depth
  have hxEq : f x = target := Set.mem_singleton_iff.mp hx
  have e : SmithZModFiber p weight depth target ≃ f.ker := by
    simpa only [SmithZModFiber, f, hxEq] using f.fiberEquivKer x
  calc
    Fintype.card (SmithZModFiber p weight depth target) =
        Nat.card (SmithZModFiber p weight depth target) := Nat.card_eq_fintype_card.symm
    _ = Nat.card f.ker := Nat.card_congr e
    _ = (Nat.card (ZMod (p ^ depth))).gcd (p ^ weight) := by
      simpa [f, smithZModMulHom] using
        IsAddCyclic.card_nsmulAddMonoidHom_ker (ZMod (p ^ depth)) (p ^ weight)
    _ = (p ^ depth).gcd (p ^ weight) := by rw [Nat.card_zmod]
    _ = p ^ min weight depth := by
      rcases Nat.le_total weight depth with hwd | hdw
      · rw [Nat.min_eq_left hwd, Nat.gcd_eq_right_iff_dvd.mpr (Nat.pow_dvd_pow p hwd)]
      · rw [Nat.min_eq_right hdw, Nat.gcd_eq_left_iff_dvd.mpr (Nat.pow_dvd_pow p hdw)]
```

The final two cases use the divisibility of one power of p by the other to obtain

$$\#\{x : p^s x = b \pmod{p^L}\} = p^{\min(s,L)}.$$

This is an exact cardinality of a finite type. It does not enumerate the solutions or provide a particular coordinate normal form for every one of them.

For a finite diagonal system, the global fiber is a dependent function type: one solution in each coordinate. Products of finite cardinalities give the count, while one inadmissible coordinate makes the product type empty.

Source: KomorebiVerification/PaperII/SmithDyadic.lean.

```
theorem smithZMod_global_conditional_count {p depth : ℕ} [NeZero (p ^ depth)] (hp : 1 < p)
    (weight : κ → ℕ) (target : κ → ZMod (p ^ depth)) :
    Fintype.card (GlobalFiber (fun i => SmithZModFiber p (weight i) depth (target i))) =
      if ∀ i, SmithZModAdmissible p (weight i) depth (target i)
      then p ^ ∑ i, min (weight i) depth else 0 := by
  classical
  exact smith_conditional_product_count
    (fiber := fun i => SmithZModFiber p (weight i) depth (target i))
    (admissible := fun i => SmithZModAdmissible p (weight i) depth (target i))
    p depth weight (fun i => smithZModCoordinateCertificate hp (target i))
```

If all coordinates are admissible, the cardinality is $p^{\sum_i \min(s_i, L)}$. Otherwise it is zero. At depth zero, the quotient has one element and the exponent is zero, consistent with the stated formula. A literal zero diagonal coefficient can be represented at precision L by any weight at least L, since p^s then vanishes in the quotient.

11.3 The abstract extension keeps its certificate boundary

The same module has separate `SmithSolvabilityCertificate` and `SmithCardinalityCertificate` structures. For arbitrary finite coordinate fibers, these supply the equivalence and count for each coordinate, with an externally chosen base q. The global product theorems then assemble them.

In a general discrete valuation ring with residue field of cardinality q, the familiar coordinate count has the analogous form. The formal component does not construct that DVR arithmetic or derive its cardinality theorem. Likewise it does not calculate Smith normal form of an input matrix, find matrices for a change of basis, or extract diagonal weights. The automatic result for row 18 begins with a diagonal system over the concrete modular quotient. The abstract extension begins with certificates.

11.4 Rational sign projectors and local denominator weight

Row 17 fixes the rational matrices

$$J = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}, \qquad P_+ = \begin{pmatrix} 1 & 1/2 \\ 0 & 0 \end{pmatrix}, \qquad P_- = \begin{pmatrix} 0 & -1/2 \\ 0 & 1 \end{pmatrix}.$$

Entrywise proofs establish $J^2 = I$, projector idempotence, mutual annihilation, and $P_+ + P_- = I$. The local integrality predicate says that a rational entry's reduced denominator is not divisible by p. Each projector has exact local denominator weight zero at every prime other than two and exact weight one at two.

The local word matters. Global integrality demands integer entries. Integrality at p permits denominators prime to p. A global denominator weight and a local denominator weight are defined separately in the source. The resultant of the sign factors is explicitly computed as $\mathrm{Res}(X-1, X+1) = 2$, and its dyadic valuation is matched to the exact local weights of these matrices.

This is a model with rational entries using valuations with natural number values. It does not construct $\mathbb{Q}_p$ or its valuation ring, identify arbitrary completed lattices, or prove a general equivalence between all rational integrality criteria and lattice preservation. Reduction modulo two applies to the characteristic factors. The rational matrices containing $1/2$ do not have an entrywise reduction modulo two.

11.5 The Smith phase identity has only algebraic scope

Row 22 checks the fractional expression `smithPhase`, obtained by pulling back the action, at phase -1. Over a field with $2 \neq 0$ and $z \neq 0$, its value is z^{-1}. The extra manuscript condition $z \neq -1$ is unnecessary for this algebraic identity and is removed by the formal theorem.

The result does not formalize the complex Smith disk, an interpretation on a Möbius domain, radius preservation, or physical impedance. In the traditional companion, see the subsection on Smith chart coordinates and its unnumbered phase identity. The subsection counter is not an equation number.

12 Typed defects: domain and codomain stay visible

Rows 19–21 keep the domain and codomain explicit. Let X_f and X_c be fine and coarse modules, $C : X_f \to X_c$, and let T_f and T_c act on their respective spaces. The defect for one step is

$$\Delta = CT_f - T_cC : X_f \longrightarrow X_c.$$

The source does not assume that the two spaces coincide.

Source: `KomorebiVerification/PaperII/TypedLinearDefects.lean`.

```
variable {R : Type u} [Semiring R]
variable {Xf : Type v} {Xc : Type w}
variable [AddCommGroup Xf] [AddCommGroup Xc]
variable [Module R Xf] [Module R Xc]

/-! ## Typed power defects -/

/-- The typed one-step defect `C ∘ Tf - Tc ∘ C`. -/
def defect (C : Xf →ₗ[R] Xc)
    (Tf : Module.End R Xf) (Tc : Module.End R Xc) : Xf →ₗ[R] Xc :=
  C.comp Tf - Tc.comp C
```

Notice that the scalar type is a semiring while the spaces have additive group structures, allowing subtraction of maps. Scalar subtraction is not needed for the basic power identity. This is one example of why the complete type is more informative than a loose description such as “linear algebra over a ring.”

12.1 The telescoping mechanism

Define $E_n = CT_f^n - T_c^nC$. The induction uses

$$E_{n+1} = T_cE_n + \Delta T_f^n.$$

Expanding E_n gives

$$CT_f^n - T_c^nC = \sum_{k=0}^{n-1} T_c^{n-1-k}\Delta T_f^k.$$

Every summand is a map $X_f \to X_c$: the right power acts in X_f, the defect crosses to X_c, and the left power acts there. Treating C as an endomorphism would hide this type constraint.

The theorem for all powers includes $n = 0$. The left side is $C - C = 0$ and the finite sum is empty. The theorem for positive powers is a wrapper around this stronger statement. In the successor proof, `Finset.sum_range_succ` separates the new last term. Arithmetic of natural numbers verifies the shifted exponents. The exponent $n - 1 - k$ occurs only at $k < n$, where it has the intended value.

If the defect for one step is zero, every term in the sum vanishes.

Source: `KomorebiVerification/PaperII/TypedLinearDefects.lean`.

```
theorem powers_compatible_of_defect_eq_zero
    (C : Xf →ₗ[R] Xc) (Tf : Module.End R Xf) (Tc : Module.End R Xc)
    (hdefect : defect C Tf Tc = 0) (n : ℕ) :
    C.comp (Tf ^ n) = (Tc ^ n).comp C := by
  apply sub_eq_zero.mp
  rw [power_defect_identity_all]
  simp [hdefect]
```

This extends to finite polynomial functional calculus by summing the corresponding power identities with scalar coefficients. The definition of polynomial action explicitly carries the commutative scalar assumptions needed for those coefficients to act centrally. The result does not establish holomorphic, exponential, or other infinite functional calculus without further analytic work.

12.2 The operator norm estimate

In the branch for continuous linear maps, the same finite identity yields

$$\|CT_f^n - T_c^n C\| \le \|\Delta\| \sum_{k=0}^{n-1} \|T_c\|^{n-1-k} \|T_f\|^k.$$

The triangle inequality bounds the norm of the sum. Submultiplicativity bounds each composition, and the endomorphism power estimate bounds each power. Completeness of the spaces is unnecessary because this is a finite sum.

If both operator norms are at most ρ, the component derives the following majorant

$$\|CT_f^n - T_c^n C\| \le n\rho^{n-1}\|\Delta\|.$$

The source states the endpoint for natural exponents carefully, so the theorem for all n also includes zero. The hypotheses supply ρ and the two norm bounds. A bound on the spectral radius is not interchangeable with an operator norm bound here, and the majorant is not asserted to be sharp.

For example, exact intertwining $\Delta = 0$ forces every defect for finite powers to vanish. A small nonzero defect may still be amplified by large powers. The theorem gives an upper bound with the stated norm data. It does not identify the actual error for a particular trajectory or nonlinear dynamics.

12.3 Resolvents from the inverse equations actually used

Let R_f and R_c be supplied inverse candidates for the scalar shifts. The continuous theorem needs only

$$(zI - T_f)R_f = I, \qquad R_c(zI - T_c) = I.$$

The fine witness is a right inverse. The coarse witness is a left inverse. They are sufficient for the ordered sandwich calculation

$$CR_f - R_cC = R_c\Delta R_f.$$

Source: KomorebiVerification/PaperII/TypedLinearDefects.lean.

```
theorem continuous_scalarShift_resolvent_identity
    (z : 𝕜) (C : Ef →L[𝕜] Ec)
    (Tf Rf : Ef →L[𝕜] Ef) (Tc Rc : Ec →L[𝕜] Ec)
    (hf : (continuousScalarShift z Tf).comp Rf = 1)
    (hc : Rc.comp (continuousScalarShift z Tc) = 1) :
    C.comp Rf - Rc.comp C =
      (Rc.comp (continuousDefect C Tf Tc)).comp Rf := by
  calc
    C.comp Rf - Rc.comp C =
        (Rc.comp
          ((continuousScalarShift z Tc).comp C -
            C.comp (continuousScalarShift z Tf))).comp Rf :=
      continuous_inverse_sandwich_identity
        (continuousScalarShift z Tc) Rc
        (continuousScalarShift z Tf) Rf C hc hf
    _ = (Rc.comp (continuousDefect C Tf Tc)).comp Rf := by
      rw [continuousScalarShift_comp_sub_comp_continuousScalarShift]
```

The source first applies a general sandwich identity for inverse candidates. The difference of shifted compositions simplifies to $CT_f - T_cC$ because the two scalar terms cancel. The sign is therefore positive on the right for this convention of Δ. Reversing the defect definition would change that sign.

Applying the operator norm gives

$$\|CR_f - R_cC\| \le \|R_c\|\,\|\Delta\|\,\|R_f\|.$$

No theorem here constructs the inverse candidates or proves that z lies in a resolvent set. The algebraic typed branch uses explicit structures certifying inverse equations on both sides. The continuous branch needs only the two inverse equations displayed above. A user should choose the theorem matching the available data rather than infer inverse existence from the word “resolvent.”

12.4 What remains in the written companion

The mathematical text also proves holomorphic functional calculus, exponential, and multilevel defect identities with their own analytic or compositional hypotheses. The preserved Lean map records finite polynomial compatibility, the power estimates, and the resolvent identities with inverse witnesses. Those additional results are outside this inherited map. The chapter-wide correspondence and the analytic constructions are recorded in Section 1.

13 Replaying the formal project

Reproduction has two separate layers. The lightweight guide checks confirm that the supplied source matches its checksum manifest, that all mapped names can be found lexically, and that the printed

excerpts are exact slices of those files. The Lean replay builds the project, resolves names in the compiled environment, and traverses axiom dependencies. Only the latter executes Lean.

13.1 Start with the preserved pins

`Use a writable copy of the formal source directory.`
Keep lean-toolchain, lakefile.toml and lake-manifest.json together. The source records specify the compiler and dependency pins.

A working Lean/Elan installation, network access for dependencies or a suitable local cache, and sufficient disk space are prerequisites. The source records provide the replay procedure.

The cache command obtains compiled dependency artifacts. The build checks the aggregate library against the pinned environment. The Python map checker parses exactly one specified theorem map, expands its namespace prefixes, requires rows 1 through 25, and writes a temporary Lean command that checks every mapped name in the compiled environment. The script removes that temporary file afterward. Its environment check is stronger than this guide's lexical source lookup.

The final command separately executes the audit that rejects violations. Warning escalation is part of the documented invocation. Preserve the exit status and full output of each command. A report written after the fact should not substitute for those transcripts in a new replay.

13.2 The audit gate and its trust boundary

The audit has two parts. `#print axioms` displays dependencies for a representative public sample. A subsequent command traverses every compiled declaration in the imported `Komorebi` namespace and rejects unsafe entries or dependencies outside the allowed basis.

Source: `KomorebiVerification/PaperII/KernelAudit.lean`.

```
run_cmd do
  let env ← getEnv
  let mut audited : Nat := 0
  for (name, info) in env.checked.get.constants.toList do
    if Name.isPrefixOf `Komorebi name then
      audited := audited + 1
      if info.isUnsafe then
        throwError "unsafe project declaration: {name}"
      let axioms ← Lean.collectAxioms name
      for axiomName in axioms do
        unless axiomName == ``propext || axiomName == ``Classical.choice ||
            axiomName == ``Quot.sound do
          throwError "unexpected axiom {axiomName} in project declaration {name}"
  if audited == 0 then
```

```
    throwError "kernel audit found no Komorebi declarations"
  logInfo m!"FAIL-CLOSED KERNEL AUDIT PASS: {audited} Komorebi declarations; allowed axioms only:
   ↪ propext, Classical.choice, Quot.sound"
```

The approved foundations are `propext`, `Classical.choice`, and `Quot.sound`. The gate rejects any other axiom dependency, including `sorryAx`, and explicitly fails if no project declaration was inspected. A successful audit is a property of the imported compiled environment at that run. It is not inferred solely from the absence of the word `sorry` in source text.

The sample of printed axioms is not the complete traversal. Conversely, the namespace count includes generated declarations and helper entries, so it is not a count of independent mathematical theorems. The map checker and namespace gate also do not decide whether a theorem's type faithfully represents a prose theorem. That requires scope comparison such as the canonical map and this guide.

13.3 A minimal session for source inspection

After a successful build, create a scratch Lean file beside the project's aggregate import. The following inspection commands ask Lean to display two representative declarations and the axiom dependencies of the automatic rationality result.

```
import KomorebiVerification.PaperII
#check Komorebi.PaperII.NestedRefinement.coordinateRefinementEquiv
#check Komorebi.PaperII.SmithDyadic.smithZMod_global_conditional_count
#print axioms
 ↪ Komorebi.PaperII.TransferZeta.PositiveWeightedMultigraph.finite_graph_pathZeta_rationality
```

Run it with `lake env lean YourInspection.lean`. These are suggested inspection commands, not a new executed transcript. Use `#print` or editor hover to inspect elaborated types, including inferred section parameters and typeclass assumptions. The printed source excerpt alone may omit surrounding binders. The full declaration type is decisive.

When applying a theorem, first fix the intended scalar type and domain/codomain. Then assemble the structural object and prove its fields. For a weighted inverse, this means the filtration, map q, precision certificate, diagonal inverse, and edge expansion. For a finite graph, it means finite vertex/edge types, endpoint maps, and positive weights. For a Smith system, it means a diagonal weight function and modular target. This preparation makes failures informative: a missing instance differs from a missing mathematical witness.

13.4 Common failure modes

Symptom	What to check
Toolchain mismatch	Read lean-toolchain. Use the compiler specified by lean-toolchain.
Missing imported module	Confirm dependencies and cache availability, then build from the Lean project root.
Unknown mapped name	Run the map checker only after a successful aggregate build. Verify source and manifest identity.
Unsolved typeclass	Inspect the theorem's complete type and the scalar/module, finite-type, or normed-space assumptions.

Symptom	What to check
Missing inverse proof	Supply the actual equation required by the chosen theorem. Naming a candidate does not prove it invertible.
Unexpected axiom	Preserve the failing declaration and transcript. Do not weaken the allowed-axiom gate to make the run pass.
Different namespace count	Compare toolchain, dependencies, source hashes, and imports before treating the run as a replay of the recorded source.
Successful Python tests	Interpret them as tests of the Python component. They are not Lean kernel evidence.

A new successful run should record the source hashes, dependency pins, commands, exit codes, output hashes, and environment. If any formal source changes, the old report no longer supplies execution evidence for that changed source, even if the filenames remain the same.

14 Evidence retained and evidence newly checked

The foundational `VERIFICATION_REPORT.md` reports successful aggregate build, theorem-map resolution of 160 unique declarations, and a successful scan of 1,034 compiled namespace entries with a gate that rejects violations. It records the approved axiom basis and states that no audited declaration reports `sorryAx`. These are the claims of that report.

The inspected canonical component contains no raw transcript of those Lean commands and no log hash attestation for each command. Consequently the foundational component alone does not establish a fresh compiler replay, a fresh environment scan, or an identity chain to missing transcripts. Execution evidence for the chapter-wide correspondence is reported separately in Section 1. The report itself is checksummed, so its preservation is verifiable. Checksumming a report does not independently establish its execution claims.

The new lightweight check establishes the following facts directly from the delivered files:

1. All 22 files under the preserved formal component match their entries in the archived `SHA256SUMS.txt` manifest.
2. The same 22 files match the separately preserved baseline copy in this editing workspace.
3. The normative map has exactly rows 1–25 and 160 distinct expanded declaration names, with 171 occurrences across rows.
4. Every mapped name has a lexical declaration location in the preserved source. This is navigation evidence, not compiled name resolution.
5. The 15 Lean source files contain 5,603 physical lines. A scan that accounts for comments and strings finds no active token from the documented placeholder/unsafe source policy list.
6. Every exact excerpt matches its recorded inclusive source slice. Each source and excerpt has a SHA-256 digest.

The scan policy checks active occurrences of `sorry`, `admit`, `sorryAx`, `axiom`, `unsafe`, `native_decide`, and named shortcuts for dynamic declaration. It strips nested block comments, line comments, and strings while retaining line positions. This is a useful static check, not a replacement for Lean elaboration or the environment's transitive axiom inspection.

The guide audit records PDF and static source checks, including lean_compiler_run: false. PDF checks and Lean replay are separate evidence records. A document build verifies rendering and navigation. Formal coverage depends on the exact source types and their own compiler evidence.

14.1 A practical rule for reporting success

Report the strongest evidence actually obtained. After running only the data generator, say that static source identity and map reconciliation passed. After a new successful Lean replay, cite that replay's own logs and environment. When quoting the preserved count of 1,034 entries, attribute it to the historical report. When using an expanded traditional theorem, identify its ordinary written proof unless a precise Lean target with matching hypotheses has been supplied.

This discipline makes the component usable: readers can trust an automatic construction where it exists, supply a certificate where it is required, and locate the written mathematics that remains beyond the formal contract.

15 The inherited contract of 25 rows

The following map preserves the foundational contract's classifications, checked scopes, and explicit boundaries. The targets use the namespace abbreviations below. These abbreviations are only typography: the companion JSON expands every name and records its source file and line. A declaration may occur in several rows. There are 171 occurrences and 160 distinct names. Definitions, structures, equivalences, and theorems all count as declaration targets.

Prefix	Full namespace
PC	Komorebi.Foundation.LinearProjectorFamily
NR	Komorebi.PaperII.NestedRefinement
R	Komorebi.Residue
WT	Komorebi.PaperII.WeightedTransfer
TZ	Komorebi.PaperII.TransferZeta.PositiveWeightedMultigraph
TZC	Komorebi.PaperII.TransferZeta.PositiveWeightedMultigraph.RationalCertificate
RS	Komorebi.PaperII.ResultantSeparation
SD	Komorebi.PaperII.SmithDyadic
LD	Komorebi.PaperII.LinearDefects
TLD	Komorebi.PaperII.TypedLinearDefects

15.1 Row 1: Refinement map

Classification: Exact.

Declaration targets

`NR.children`

`NR.mem_children`

`NR.Refines`

Checked scope. For finite complete projector families over a semiring module, `Refines` records a surjective parent map and equality of every coarse projector with the finite sum over its fine children.

Boundary. No refinement is constructed from arbitrary projector families; no infinite or topological sum is asserted.

15.2 Row 2: Nested refinement theorem

Classification: Stronger.

Declaration targets

`NR.finitePacket_decomposition_unique`

`NR.finitePacket_decomposition_ext`

`NR.Refines.coarse_comp_fine_eq_self`

`NR.Refines.coarse_comp_fine_eq_zero`

`NR.Refines.fine_comp_coarse_eq_self`

`NR.Refines.fine_comp_coarse_eq_zero`

`NR.Refines.coarse_packet_reconstruction`

`NR.Refines.child_decomposition_unique`

`NR.Refines.trans`

Checked scope. Parent/child absorption holds in both composition orders and refinements compose. More generally, any finite sum of vectors lying in mutually orthogonal packet ranges has uniquely determined components, without a refinement or completeness hypothesis.

Boundary. Uniqueness is only asserted on the selected finite set and requires each component to lie in its stated projector range. All index types and sums are finite.

15.3 Row 3: Exact coordinate refinement

Classification: Stronger.

Declaration targets

`NR.refineCoordinates`

`NR.coarsenCoordinates`

`NR.refineCoordinates_self`

`NR.refineCoordinates_comp`

`NR.coordinateRefinementEquiv_trans`

`NR.Refines.refineCoordinates_component`

`NR.Refines.coarsenCoordinates_component`

Checked scope. Analysis after synthesis defines cross-level linear maps for any two finite complete projector families; these maps obey identity and cocycle laws through every intermediate family. A `Refines` witness gives the parent/child component formulas.

Boundary. These are coherent changes of exact coordinates, not truncation or dimensional reduction operators; the cocycle uses exact completeness at each finite level.

15.4 Row 4: Perfect reconstruction across levels

Classification: Stronger.

Declaration targets

`NR.coarsenCoordinates_refineCoordinates`

`NR.refineCoordinates_coarsenCoordinates`

`NR.coordinateRefinementEquiv`

`NR.coordinateOperator`

`NR.coordinateOperator_comp`

`NR.coordinateOperator_naturality`

Checked scope. Cross-level refinement and coarsening are mutual inverses over a semiring module. The typed coordinate representation of every linear map preserves identities and composition and commutes with independent exact coordinate changes on source and target.

Boundary. The inverse laws need completeness of the projector families but no parent map. This is finite algebraic naturality, not convergence for an infinite packet tower.

15.5 Row 5: Transfer-block refinement

Classification: Stronger.

Declaration targets

`NR.transferBlock_refinement_between`

`NR.transferBlock_refinement`

`NR.transferBlock_refinement_and_reconstruction`

Checked scope. Source and target projector families may live on different modules and refine independently; every coarse linear-map block is the double finite sum of its fine descendant blocks. The direct traceability wrapper also records reconstruction of the same map from all coarse blocks and from all fine blocks. The endomorphism formula is a specialization.

Boundary. No sparse extraction algorithm, infinite block matrix, or norm convergence is proved here.

15.6 Row 6: Residue projector algebra

Classification: Exact.

Declaration targets

`R.residueProj_idempotent`

`R.residueProj_orthogonal`

`R.residueProj_complete`

Checked scope. For every positive modulus, coefficient residue selectors on `Nat -> A` are idempotent, mutually annihilating, and complete over an arbitrary semiring and module.

Boundary. This is the division-free coefficient selector, not a character-average formula.

15.7 Row 7: Root-of-unity realization

Classification: Stronger / certificate-explicit.

Declaration targets

`R.ringFourierResidueKernel`

`R.ringFourierKernel_eq_residueKernel`

`R.FiniteRingFourierOrthogonalityCertificate`

`R.FiniteRingFourierOrthogonalityCertificate.toRingCertificate`

`R.ringFourierAverage`

`R.ringFourierAverage_eq_residueProj_of_finite_certificate`

`R.primitiveRoot_fourierOrthogonalityCertificate`

`R.fourierAverage_eq_residueProj_of_primitiveRoot`

Checked scope. Over any commutative semiring, `omega^N = 1` reduces the arbitrary coefficient address to a finite residue address. Consequently an explicit finite `N x N` orthogonality table identifies the division-free Fourier average with the residue selector. Over a field, a positive-order primitive root automatically supplies the normalized inverse-root certificate.

Boundary. The general semiring branch still requires the finite orthogonality table; root-of-unity order alone is not enough in rings with zero divisors. The primitive-root construction is field-only.

15.8 Row 8: Polyphase refinement

Classification: Exact.

Declaration targets

`R.polyphase_refinement`

Checked scope. For positive `N` and `k`, the modulus-`N` selector is the finite sum of exactly those modulus-`N*k` selectors that merge to it, over any semiring module.

Boundary. The theorem concerns exact coefficient masks; it gives no approximation or discarded-packet estimate.

15.9 Row 9: Dyadic-odd packet factorization

Classification: Exact.

Declaration targets

`R.crtEquiv`

`R.crtComponents_bijective`

`R.residueProj_crt`

`R.residueProj_crt_comm`

`R.dyadicOddEquiv`

`R.dyadicOddComponents_bijective`

`R.residueProj_dyadicOdd`

Checked scope. Positive coprime moduli give a bijection of residue labels and the composite selector in both composition orders. For positive odd `M`, this specializes to `2^a * M`.

Boundary. This is coordinate CRT factorization. It does not identify the denominator or lifting behavior of spectral projectors.

15.10 Row 10: Certified weighted inverse

Classification: Stronger / certificate-explicit.

Declaration targets

`WT.TwoSidedInverse`

`WT.finiteGeometricInverse_spec_of_pow_eq_zero`

`WT.diagonalTransferInverse_spec`

`WT.analyticGeometricInverse_spec`

`WT.analyticDiagonalTransferInverse_spec`

Checked scope. In a possibly noncommutative ring, an explicit two-sided inverse for `D` and nilpotence of the normalized perturbation `Dinv*H` give a finite two-sided inverse of `D+H`. In a complete normed ring, `norm (Dinv*H) < 1` gives the separate infinite Neumann inverse.

Boundary. The manuscript perturbation is `H`; the Lean declaration's parameter name `K` has no fraction-field meaning. There is no unrestricted convergence theorem for an abstract complete filtered ring. The analytic candidate is noncomputable.

15.11 Row 11: Finite precision and weighted pruning

Classification: Stronger / certificate-explicit.

Declaration targets

`WT.MultiplicativeFiltration`

`WT.PrecisionCertificate`

`WT.retainedFixedWordSum`

`WT.prunedWordInverse`

`WT.map_finiteGeometricInverse_eq_prunedWordInverse`

`WT.minWeight_mul_length_le_wordWeight`

`WT.map_sum_pow_eq_zero_at_scaled_cutoff`

`WT.prunedWordInverse_spec_of_minWeight`

`WT.finitePrecisionPrunedInverse_of_weightedEdges`

`WT.finitePrecisionPrunedDiagonalTransferInverse_of_minWeight`

`WT.finitePrecisionPrunedDiagonalTransferInverse_of_weightedEdges`

Checked scope. The mapped finite geometric inverse equals an explicit noncommutative word sum retaining exactly the words of cumulative weight below `L`. If every edge weight is at least `m` and `L <= m*N`, the `N`th mapped power vanishes and the pruned word sum is a two-sided inverse; the corresponding diagonal-plus-transfer formula follows from supplied `Dinv` and `Dinv*H = sum edge`.

Boundary. The filtration, precision quotient map, edge-membership data, diagonal inverse, and edge expansion remain inputs. No DVR quotient, quotient map, basis-level modular matrix routine, or extracted pruning implementation is constructed.

15.12 Row 12: Finite-graph transfer-zeta rationality

Classification: Automatic.

Declaration targets

`TZ.coefficientAlgorithm_correct`

`TZ.coefficientAlgorithm_firstEdge`

`TZ.weightedAdjacency`

`TZ.transferMatrix`

`TZ.transferDenominator`

`TZ.transferNumerator`

`TZ.transferDenominator_coeff_zero`

`TZ.pathZeta_eq_matrixPathZeta`

`TZ.transferDenominator_mul_pathZeta`

`TZ.finite_graph_pathZeta_rationality`

`TZ.finite_graph_transferZeta_trace`

`TZC.certificate_explicit_rationality`

Checked scope. For every finite positive-weight directed multigraph and source/target pair, finite walk enumeration satisfies the first-edge recurrence. Lean constructs `Q = det(I-A(X))` and `P` as the corresponding adjugate entry, proves `Q(0)=1`, identifies the independently enumerated `pathZeta` with the matrix inverse entry, and proves `Q*Z=P` without a rationality certificate. A direct wrapper packages

the manuscript's enumeration, recurrence, normalization, nonvanishing, and rational identity in one declaration. The older coefficient-certificate route remains available.

Boundary. Walks may repeat vertices and edges; no simple-path restriction is imposed. Parallel edges are distinct edge values. Determinant and adjugate are noncomputable Lean definitions here; no denominator cancellation, minimality, extracted symbolic implementation, or analytic convergence claim is made.

15.13 Row 13: Linear recurrence

Classification: Automatic.

Declaration targets

`TZ.finite_graph_constant_coefficient_recurrence`

`TZC.constant_coefficient_recurrence`

Checked scope. The automatically constructed determinant denominator gives an antidiagonal constant-coefficient recurrence for every `n` beyond the degree of the canonical adjugate numerator. A separately supplied `P,Q` certificate yields the same form through the legacy route.

Boundary. The canonical recurrence is not claimed minimal, and no recurrence is guessed or certified from finitely many sampled coefficients alone.

15.14 Row 14: Evaluated Bezout spectral projector

Classification: Stronger / certificate-explicit.

Declaration targets

`RS.EvaluatedBezoutCertificate`

`RS.separatorNumerator_eq_scalar_sub_of_bezout`

`RS.separatorNumerator_mul_self_of_bezout`

`RS.separator_idempotent_of_bezout`

`RS.separatorNumerator_apply_of_mem_ker_F_of_bezout`

`RS.separator_apply_of_mem_ker_F_of_bezout`

`RS.separator_apply_of_mem_ker_G`

`RS.scalar_mul_separator_of_ne_zero`

`RS.scalar_mul_separator_preservesLattice_of_ne_zero`

Checked scope. Over a field, the evaluated equality `U*F + V*G = r*1`, `F*G=0`, and only the two commutations actually used prove the denominator-free identity `(VG)^2=r(VG)`; adding `r!=0` gives idempotence of `r^-1*VG`. The kernel actions need only the displayed evaluated Bezout or kernel hypotheses, and lattice preservation of the numerator follows when `V,G` preserve the lattice.

Boundary. The evaluated Bezout equality and annihilation are supplied. No polynomial Bezout identity, resultant, characteristic factorization, or Cayley-Hamilton instance is constructed; nilpotence alone is not used to infer exact kernel action.

15.15 Row 15: Separation weight

Classification: Stronger / certificate-explicit.

Declaration targets

`RS.ScalarPreservesLattice`
`RS.IsLatticeUnit`
`RS.IsSeparationWeight`
`RS.IsSeparationWeight.mono`
`RS.separationWeight`
`RS.separationWeight_clears`
`RS.separationWeight_le_of_clears`
`RS.pow_smul_separator_eq_unit_inv_smul_separatorNumerator`
`RS.separator_isSeparationWeight_of_unit_mul_pow_eq_of_inv_preserves`
`RS.separator_hasFiniteSeparationWeight_of_eq_unit_mul_pow`
`RS.separator_separationWeight_le_of_eq_unit_mul_pow`

Checked scope. `IsSeparationWeight pi E lattice s` means that `(pi^s)E` preserves the chosen lattice; weights are upward closed when scalar multiplication by `pi` preserves it. If `r=u*pi^s`, then `pi ^s E=u^-1 VG`; preservation by the inverse unit and numerator proves clearing, while a bundled lattice-unit certificate gives existence and the least-weight upper bound `separationWeight<=s`.

Boundary. The unit action on the chosen lattice is explicit data. The least weight is noncomputable via `Nat.find`; no valuation, polynomial resultant construction, search procedure, or claim that the displayed exponent is minimal is supplied.

15.16 Row 16: Projector precision delay

Classification: Exact from certificate.

Declaration targets

`RS.CongruentModLattice`
`RS.projector_precision_delay`

Checked scope. For an arbitrary field scalar `pi`, additive lattice, and clearing-weight certificate, an explicit congruence witness at depth `m+s` maps to one at depth `m`.

Boundary. Congruence is witness-based scalar-lattice membership; no topology, completion, digit representation, or valuation API is required or concluded.

15.17 Row 17: Odd-adic versus dyadic sign behavior

Classification: Stronger / scoped realization.

Declaration targets

`SD.signInvolution_mul_self`
`SD.positiveSignProjector_idempotent`
`SD.negativeSignProjector_idempotent`
`SD.signProjectors_complete`
`SD.HasExactPLocalDenominatorWeight`

SD.positiveSignProjector_exact_pLocal_weight_zero_of_prime_ne_two

SD.negativeSignProjector_exact_pLocal_weight_zero_of_prime_ne_two

SD.signFactors_resultant

SD.signProjectors_resultant_dyadic_weight_endpoint

SD.padicValNat_two_at_odd_prime

SD.oddAdicVersusDyadicSignBehavior_trace

Checked scope. The displayed rational `2 x 2` involution and sign projectors are checked entrywise. Each projector has exact local denominator weight zero at every prime other than `2` and exact `2`-local weight one. Lean also computes `resultant(X-1,X+1)=2` and identifies its `2`-adic valuation with the exact local weight of both projectors. The direct trace wrapper combines both local regimes and the resultant statements.

Boundary. This is an explicit rational-entry, natural-valuation model. Reduction modulo `2` applies to the characteristic factors, not to the rational projector matrices containing `1/2`. Lean does not construct `Q_p`, its valuation ring, or a general equivalence between rational `p`-integrality and preservation of an arbitrary completed lattice.

15.18 Row 18: Concrete ZMod Smith-weighted congruence solve

Classification: Automatic at concrete scope / certificate-explicit extension.

Declaration targets

SD.smithZModMulHom

SD.SmithZModAdmissible

SD.smithZModFiber_nonempty_iff

SD.smithZModFiber_card_of_admissible

SD.smithZModCoordinateCertificate

SD.smithZMod_global_solvable_iff

SD.smithZMod_global_conditional_count

SD.SmithSolvabilityCertificate

SD.SmithCardinalityCertificate

SD.smith_conditional_product_count

Checked scope. For `p>1`, Lean proves directly over `ZMod(p^depth)` that `p^weight*x=target` is solvable exactly when `p^min(weight,depth)` divides `target.val`, and every admissible fibre has cardinality `p^min(weight,depth)`. It then proves the coordinatewise criterion and the exact conditional count `p^(sum min(weight,depth))` for finite diagonal systems, including cardinality zero when a coordinate is inadmissible. The split certificate API gives the analogous product statement for abstract finite fibres, with the residue cardinality supplied as `q`.

Boundary. The counted manuscript theorem is the concrete `ZMod(p^L)` result with `q=p`. The arbitrary-DVR, residue-size-`q` extension is classical/certificate-explicit, not derived by Lean. Diagonal weights and targets are inputs; Lean does not construct Smith normal form. A literal zero diagonal factor is represented at precision `L` by a weight at least `L`, or handled by an explicit abstract coordinate certificate.

15.19 Row 19: Power-defect identity

Classification: Stronger.

Declaration targets

`TLD.defect`

`TLD.power_defect_identity_all`

`TLD.power_defect_identity`

`TLD.powers_compatible_of_defect_eq_zero`

`TLD.polynomialAction`

`TLD.polynomialAction_compatible_of_defect_eq_zero`

`TLD.continuousPolynomialAction_compatible_of_defect_eq_zero`

`LD.power_defect_identity_all`

Checked scope. The primary theorem is typed for distinct fine and coarse semiring modules and proves the ordered telescoping identity for every natural `n`, including zero. Zero one-step defect gives exact compatibility with every power and every finite polynomial functional calculus; the continuous version is also proved.

Boundary. This is linear algebra and finite polynomial calculus; no nonlinear higher-jet, operator-tree defect expansion, or analytic functional calculus is asserted.

15.20 Row 20: Power-defect norm bound

Classification: Stronger.

Declaration targets

`TLD.continuousDefect`

`TLD.continuous_power_defect_identity_all`

`TLD.continuous_end_pow_norm_le`

`TLD.continuous_norm_power_defect_le`

`TLD.continuous_norm_power_defect_le_geometric_majorant`

`LD.norm_power_defect_le_raw`

`LD.norm_power_defect_le`

Checked scope. Over a nontrivially normed field, continuous maps between distinct normed fine and coarse spaces satisfy the exact finite-sum operator-norm bound for every natural `n`, including zero. If both dynamics have norm at most `rho`, Lean derives the closed majorant `n*rho^(n-1)*norm(defect)`. No completeness assumption on the spaces is needed.

Boundary. These are operator-norm estimates, not spectral-radius estimates, equality statements, or nonlinear defect bounds. The majorant takes `rho` and both norm inequalities as hypotheses.

15.21 Row 21: Resolvent-defect identity

Classification: Stronger / certificate-explicit.

Declaration targets

`TLD.TwoSidedInverse`

`TLD.scalarShift_resolvent_identity`

`TLD.resolvents_compatible_of_defect_eq_zero`

`TLD.continuousScalarShift`

`TLD.continuous_scalarShift_resolvent_identity`

`TLD.continuous_norm_resolvent_defect_le`

`TLD.continuous_resolvents_compatible_of_defect_eq_zero`

`LD.resolvent_defect_identity`

Checked scope. Algebraically, supplied two-sided inverse witnesses give the typed resolvent identity on distinct modules. For continuous maps, the proof needs only `(zI-Tf)Rf=I` and `Rc(zI-Tc)=I` and yields `norm(C Rf-Rc C) <= norm(Rc)*norm(defect)*norm(Rf)`; zero defect gives exact intertwining.

Boundary. All inverse equations are supplied witnesses. Lean does not construct resolvents, prove spectral membership, or infer inverse existence from analytic hypotheses.

15.22 Row 22: Smith phase inversion identity

Classification: Stronger / scoped realization.

Declaration targets

`SD.smithPhase`

`SD.smithPhase_neg_one_eq_inv`

Checked scope. Over any field in which `2` is nonzero, the pulled-back phase formula at `omega = -1` equals `z^-1` for `z != 0`; this includes `Q`, `R`, and `C` and does not need the manuscript's additional `z != -1` condition.

Boundary. Only the algebraic formula is checked. No Smith disk, Mobius-domain, radius-preservation, or physical impedance theorem is formalized.

15.23 Row 23: Residue analysis and synthesis algorithm

Classification: Specification.

Declaration targets

`PC.rangeSynthesis_rangeAnalysis`

`PC.rangeAnalysis_rangeSynthesis`

`PC.exactPacketCoordinates`

`NR.coordinateRefinementEquiv`

Checked scope. For finite complete projector families, range-restricted analysis and finite-sum synthesis are inverse linear maps; cross-level analysis/synthesis gives an exact coordinate equivalence.

Boundary. This is the mathematical contract behind the array routine, not extracted interleaving code or a proof about Python storage shapes.

15.24 Row 24: Weighted finite-precision inverse algorithm

Classification: Specification / certificate-explicit.

Declaration targets

`WT.finiteGeometricInverse`

`WT.prunedWordInverse`

`WT.map_finiteGeometricInverse_eq_prunedWordInverse`

`WT.le_mul_ceilDiv`

`WT.prunedWordInverse_spec_of_minWeight`

`WT.prunedDiagonalTransferInverse`

`WT.finitePrecisionPrunedDiagonalTransferInverse_of_minWeight`

`WT.finitePrecisionPrunedDiagonalTransferInverse_of_weightedEdges`

Checked scope. The bounded geometric loop maps exactly to an explicit signed sum of retained noncommutative words. For `m>0`, Lean proves `L <= m * ceil(L/m)`, so the pseudocode choice `N=ceil(L/m)` meets the cutoff premise. Filtration data and `L<=m*N` prove that the pruned expression is a two-sided inverse; supplied `Dinv` and a normalized-transfer edge expansion lift it to the explicit pruned diagonal-plus-transfer inverse after applying `q`.

Boundary. This is a mathematical specification. The manuscript calls the perturbation `H`; the Lean parameter name `K` has no fraction-field meaning. The result does not provide an extracted modular matrix inverse, basis representation, zero test, complexity bound, or proof of equivalence to the companion Python implementation.

15.25 Row 25: Transfer-zeta walk construction algorithm

Classification: Specification / automatic.

Declaration targets

`TZ.walkTuplesAtWeight`

`TZ.mem_walkTuplesAtWeight_iff`

`TZ.tuple_captured_iff`

`TZ.coefficientAlgorithm`

`TZ.coefficientAlgorithm_correct`

`TZ.exactWalkFirstEdgeEquiv`

`TZ.coefficientAlgorithm_firstEdge`

`TZ.pathZetaAlgorithm_trace`

`TZ.weightedAdjacency`

`TZ.weightedAdjacency_coeff`

`TZ.enumeratedPathZetaMatrix_eq_matrixPathZetaMatrix`

`TZ.pathZeta_eq_inverse_mul_transferNumerator`

`TZ.finite_graph_pathZeta_rationality`

`TZ.finite_graph_constant_coefficient_recurrence`

Checked scope. The coefficient loop is a finite `Finset` enumeration with exact capture and cardinality theorems. A direct trace wrapper pairs its semantic walk count with the first-edge recurrence. Finite matrix determinant/adjugate data are then constructed and proved equal to the enumerated se-

ries, yielding the normalized rational identity and eventual recurrence without a supplied rationality certificate.

Boundary. The objects counted are directed walks, with repetitions allowed. The Lean polynomial matrix definitions are noncomputable, and no extracted determinant/adjugate program, cancellation or minimal-denominator routine, performance bound, or analytic convergence theorem is claimed.

A Navigation in the mathematical text

The locators below use statement and section numbers in the Chapter II mathematical text. A shared label is a navigation aid. It does not extend the formal scope to additional claims in the surrounding section. In particular, the Smith phase display has no equation number.

Projector Resolved Seed Calculus III

The formal companion to Chapter III explains the declared hypotheses, theorem correspondences and evidence boundaries.

IN THIS COMPANION

Formal companion 1769

Return to Chapter III

How to use this volume

A guide to the finite algebraic core, its analytic continuation, and the complete 41-row finite contract. Read exact excerpts from the proofs, follow the direction of each map, distinguish exact coordinate transport from independent connection data, and locate every formal target.

Formal evidence. The verification record includes a pinned compilation, a compiled ownership and axiom audit, upstream-only kernel replay, and adverse controls. The opening chapter gives their exact scope. The preserved finite map still has 143 targets and its recorded namespace audit has 468 entries. Those counts describe the finite baseline, not the enlarged ownership closure.

The formal core and analytic continuation

The formal development combines finite algebraic constructions, exact nonlinear packet coordinates, and an analytic packet interface. Its verification record includes compilation in the pinned environment, an audit of the compiled ownership boundary and transitive axioms, replay of the owned logical declarations into an environment initially containing only upstream dependencies, and rejection controls.

The mathematical objects are the actual ranges

The input space for a jet is the dependent finite product of the submodules ran P_{α_i}. The output is ran Q_γ. These submodules carry their inherited norms. The continuous jet uses the actual inclusions and output restriction. Its underlying multilinear map is the previously defined algebraic range jet.

$$\|J_{\gamma|\alpha}B\| \le \|Q_\gamma\|\,\|B\|.$$

The product of norms of the input projectors belongs to the estimate for the ambient extension. It is unnecessary in the sharper bound for the literal restricted jet. Closed ranges and the continuous coordinate equivalence are proved for continuous projectors.

Source module	Formal content
`PacketCoordinates.lean`	Analysis and synthesis for a finite complete pairwise annihilating
`PacketDirectSum.lean`	idempotent family, with range-valued coordinates and the direct-sum comparison.
`NonlinearPacketCoordinates.lean`	Exact coordinate representation of arbitrary functions, composition and coordinate changes.
`MultilinearPacketJets.lean`	Complete finite multilinear expansion, literal range jets, and reconstruction. Mixed input labels are retained.
`BoundedPacketJetNorm.lean`	The ambient continuous multilinear extension and its product norm bound.
`ContinuousPacketJets.lean`	Closed ranges, continuous packet coordinates, literal continuous range jets, the sharper norm bound, and specialization to `iteratedFDeriv`.
`PacketJetComposition.lean`	Composition over all finite ordered partitions and intermediate labels, structural vanishing, and one-way support inclusion.

All paths in this table are relative to `formal/KomorebiPaperIII/`. The formal sources state their own field, norm, finiteness and regularity assumptions. The composition theorem assumes `ContDiffAt K n f x` and `ContDiffAt K n g (f x)`. The intermediate and output projectors are continuous. Input range inclusions are continuous without an additional continuity hypothesis on the input family.

What the derivative notation commits to

Mathlib defines `iteratedFDeriv` as a total function. Reconstructing its chosen value is unconditional. That identity alone does not assert differentiability of an arbitrary map. The composition theorem supplies local differentiability hypotheses explicitly. Its `OrderedFinpartition n` uses the canonical order of the blocks by their greatest elements. Each original slot is selected by the partition embedding, and every intermediate label assignment is summed. In the real or complex smooth setting, symmetry identifies this formula with the manuscript's unordered-partition notation.

The support theorem says that a nonzero composite jet has at least one decorated partition with a nonzero outer jet and all inner jets nonzero. It gives no converse. Constituent maps can compose to zero, and distinct terms can cancel. The formal composition identity also covers order zero through the unique empty partition. The positive-order manuscript formula requires no new nullary convention.

Compilation and kernel evidence

The verification run compiled **16 production modules** from an initially empty owned object directory. The compiled ownership audit recorded **608 owned declarations**. The clean kernel replay accepted **594 logical declarations**, with **14 generated runtime helpers** separately inventoried. The full build, ownership audit, kernel replay, and control suite all passed.

The exact compiler is Lean `4.34.0-rc2`, commit `6a10ac8c22beadecabdbb0919c2b50214762f91d`. Mathlib is pinned at `aeb72f1e9981b6d35b426b16dca7759be3e7ba06`. The machine-readable summary is `formal/verification/FINAL_VERIFICATION_SUMMARY.json`. The full command transcripts and exact source snapshots accompany every phase. The owned audit examines compiled declarations by module ownership, including names outside the main namespace. It rejects project axioms, unreviewed opaque or partial declarations, unsafe declarations, and transitive axioms outside the standard basis `propext`, `Classical.choice`, and `Quot.sound`.

Generated runtime helpers are inventoried separately from the logical declarations replayed by the kernel. A helper count is not a theorem count. The rejection controls include foreign owned axioms, opaque, unsafe and partial declarations, false arithmetic, a proof placeholder, and a deliberately corrupted replay declaration. A harmless foreign namespace is a positive control. The negative controls pass when the designated defect is rejected for the recorded reason.

The original 41-row map below remains the finite baseline map. Its 143 targets comprise 88 theorem declarations and 55 constructions. The recorded count of 468 namespace entries includes 229 theorem entries. These denominators are different from the enlarged ownership closure and from the manuscript's 98 result environments plus two classical standard facts.

Mathematical and finite evidence

The main text contains 98 result environments and two classical standard facts. Its finite and nonlinear coordinate arguments, the Section 17 analytic arguments, and the 59 later results plus two classical inputs have ordinary mathematical reviews under their stated hypotheses. The statement register identifies their status individually. These review counts do not assert complete Lean coverage.

The accompanying finite evidence records 18,630 exact assertions across three coordinate and calculus suites, 124 visual-model checks, and four rejected false controls. The computation audit specifies the tested ranges and repeated cases. These finite calculations support the examples and implementations. They do not replace the ordinary proofs or extend the formal contract.

The mathematical reading route is the main text, the analytic packet supplement, the 24 worked visual plates with 22 exact model figures, and this declaration-level guide. The supplement supplies the range-space, norm, Taylor, composition, and support arguments, including degenerate cases and the relation to the formal interface. The formal source distribution includes its exact sources, dependency pins, verification transcripts, mathematical reviews, computation scripts, statement register, and SHA-256 manifest.

Reproduce the formal verification

The archive supplies owned source, pins, receipts and scripts. Restore the pinned Lean distribution and the dependency identities using formal/README.md. Build in a separate working copy so the recorded manifest and transcripts stay intact. From formal/, run the four phases with a fresh object directory and unique labels:

```
python3 scripts/run_release_verification.py --lean /absolute/path/to/lean --phase full --label
 ↪  local_full --objects build/local_objects
python3 scripts/run_release_verification.py --lean /absolute/path/to/lean --phase audit --label
 ↪  local_audit --objects build/local_objects
python3 scripts/run_release_verification.py --lean /absolute/path/to/lean --phase replay --label
 ↪  local_replay --objects build/local_objects
python3 scripts/run_release_verification.py --lean /absolute/path/to/lean --phase controls --label
 ↪  local_controls --objects build/local_objects
```

The runner refuses a preexisting owned object directory for the full build. It records source hashes before and after compilation, the exact executable and command, output hashes, exit codes, and the expected diagnostics for adverse controls. Changing a dependency or toolchain creates a new verification event.

The remaining formal boundary

The manuscript's integral Taylor remainder, its factorial estimate, and the Stirling count of decorated terms are supplied as ordinary proofs. The 59 later results and two classical standard facts in Sections 18–27 were reviewed mathematically. Matching Lean formalizations for that expanded portion were not recovered.

The statement register distinguishes fully mapped statements, partial formal correspondence, inherited references, and ordinary proofs.

1 Reading the formal development

Chapter III turns three kinds of data into precise finite statements: directed packet operators, coordinate and connection transport, and local obstruction certificates. The preserved finite predecessor is small enough to read as a connected development. Its seven mathematical modules contain the author's constructions and proofs. An aggregate import exposes them together. A separate audit module checks the compiled namespace. The opening chapter describes the finite core and its analytic continuation.

This guide follows the definitions before using their theorem names. A declaration name is a precise destination, but its type determines what has actually been proved. The preserved finite map has 41 rows and 143 distinct targets. Of these, 88 are theorem declarations and 55 are constructions. A construction can be a structure, inductive type, definition, or abbreviation. The count does not mean 143 independent mathematical theorems.

1.1 Three levels of evidence

The finite algebraic verification report records a successful aggregate build of 3,076 jobs, the gate that checks parity with the theorem map, and a namespace audit of 468 declarations including 229 entries of kind `theoremInfo`. Chapter III also preserves the kernel audit transcript. That transcript contains one axiom report for each of the 143 mapped targets and the final namespace PASS line.

A static reconciliation matches all 41 map rows with their lexical source locations, all 143 explicit `#print axioms` directives, and all 143 transcript records. It checked the 16 files in the preserved formal component against the original checksum manifest. The theorem map and transcript hashes also match the values printed in the inherited verification report. These are static checks of the preserved evidence. They do not replace a Lean execution. The opening chapter separately records the compiler and replay runs.

The expanded mathematical text includes additional ordinary mathematical proofs. The finite algebraic formal contract stays fixed. A section of the main text may combine a formally covered finite result with a stronger ordinary theorem. The presence of a related Lean name does not make every statement in that section part of the contract.

1.2 A route through the source

Module	Reading objective
`EdgeOperators`	Orientation, broken-word vanishing, and finite walk expansion.
`EdgeExtensions`	Endpoint blocks, reachability, and heterogeneous factor types.
`Transport`	Exact frames, the minimal connection, and a nontrivial loop.
`CoordinateNaturality`	Exact coordinate representation of arbitrary functions.
`ReversibleConnections`	Dependent fibers, defect, holonomy, gauges, paths, and blocks.
`HolonomyBlocks`	The commutation hypothesis for packetwise gauge covariance.
`NonlinearObstructions`	Tree locality and candidate-specific obstruction certificates.

The name of a file and the namespace of its declarations need not coincide. For example, the basic packet resolution declarations occur at the end of `ReversibleConnections.lean` under `Komorebi.Pap`

`erIII.HolonomyBlocks`. The complete map gives both the fully qualified name and the file and line. Follow that location when searching a source checkout.

1.3 Notation that carries mathematical content

Lean writes a linear map as `M →ₗ[R] N` and a linear equivalence as `M ≃ₗ[R] N`. The latter includes an inverse and its inverse laws. An arbitrary equivalence is `X ≃ Y`. A function `X → Y` carries no linear structure. Replacing one of these types with another changes the claim.

Bracketed arguments such as `[Semiring R]` are typeclass hypotheses. They supply operations and laws, not merely notation. Braced arguments such as `\{R : Type u\}` are implicit parameters inferred from use. `Type u` allows the object to live in a universe. Different universe names allow different input, fiber, and coefficient types. `autoImplicit false` requires undeclared identifiers to be rejected rather than silently generalized.

`Fintype V` supplies finite enumeration. `DecidableEq V` supplies a decision procedure for equality. Some definitions use `classical` so that a finite sum can be filtered by a proposition without demanding a decision procedure supplied by the user. This logical choice does not turn an abstract graph theorem into an efficient graph algorithm.

Three composition conventions must remain distinct:

Written expression	Execution order
`B * A`	Matrix A acts first, then B.
`g.comp f`	Linear map f acts first, then g.
`e.trans f`	Equivalence e acts first, then f.

A calculation translated from matrices to `LinearEquiv.trans` therefore reverses the written composition pattern. The underlying maps still execute in the same order.

1.4 What a short proof is doing

`rfl` closes a definitional equality: the two sides reduce to the same expression. `ext x` or `LinearEquiv.ext` reduces equality of maps to equality at an arbitrary input. `simp` uses definitions and registered simplification rules, including inverse laws and zero laws. `rw` rewrites by an explicit equality. `induction` exposes a finite recursive object, such as a list or tree, and proves the conclusion from the smaller objects.

The printed excerpts are exact source selections, not standalone files. Implicit variables, local instances, namespaces, and earlier lemmas may be outside a selection. Every exact UTF-8 excerpt has a source path, inclusive line range, and hashes in `generated/excerpts.json`. Copy the adjacent `.lean.txt` file when exact tokens matter. The PDF display uses font fallbacks for otherwise unsupported characters.

2 Edges, words, and reachable packets

2.1 Graph orientation and finite enumeration

`PacketGraph V E` has two fields, `source : E → V` and `target : E → V`. Distinct values of `E` may share endpoints, so parallel edges are allowed. The structure itself does not carry a finite enumeration. The theorems that sum over vertices or edges request the appropriate `Fintype` instances separately. This makes the boundary visible in each declaration.

The elementary scalar block is the matrix whose only potentially nonzero entry is in target row and source column.

Source: `KomorebiPaperIII/EdgeOperators.lean`.

```
def packetMatrix [Zero R] [DecidableEq V]
    (source target : V) (coefficient : R) : Matrix V V R :=
  fun row column ↦ if row = target ∧ column = source then coefficient else 0

@[simp] theorem packetMatrix_apply [Zero R] [DecidableEq V]
    (source target row column : V) (coefficient : R) :
    packetMatrix source target coefficient row column =
      if row = target ∧ column = source then coefficient else 0 :=
  rfl
```

For a column vector x, this block sends the source coordinate to the target coordinate and multiplies it by the stored coefficient. `EdgeSystem G R` is a coefficient function `E → R`. It adds weights to graph edges without changing their endpoints.

If $e : a \to b$ has coefficient r and $f : b \to c$ has coefficient s, the product for the traversal e followed by f is $E_f E_e$, and its coefficient is sr. A semiring need not be commutative. That coefficient cannot in general be replaced by rs.

Source: `KomorebiPaperIII/EdgeOperators.lean`.

```
theorem edgeOp_mul_edgeOp_of_composable
    [Fintype V] [DecidableEq V] [Semiring R]
    (e f : E) (h : G.target e = G.source f) :
    edgeOp G S f * edgeOp G S e =
      packetMatrix (G.source e) (G.target f)
        (S.coefficient f * S.coefficient e) := by
  ext row column
  by_cases hrow : row = G.target f
  · by_cases hcolumn : column = G.source e
    · simp [edgeOp, packetMatrix, Matrix.mul_apply, h, hrow, hcolumn]
    · simp [edgeOp, packetMatrix, Matrix.mul_apply, h, hcolumn]
  · simp [edgeOp, packetMatrix, Matrix.mul_apply, hrow]
```

The proof examines one matrix entry. The sum over intermediate vertices has at most one surviving term after support conditions are imposed. If the interface does not match, the companion theorem `edgeOp_mul_edgeOp_eq_zero` shows every intermediate term is zero. The zero conclusion depends on support, not on an assumed numerical cancellation.

2.2 Lists record chronological traversal

`Composable G` accepts the empty list and every singleton. A longer list must satisfy equality between the target of one edge and the source of the next at each step. The evaluator then places the first listed edge on the right:

Source: `KomorebiPaperIII/EdgeOperators.lean`.

```
def wordOp [Fintype V] [DecidableEq V] [Semiring R]
    (G : PacketGraph V E) (S : EdgeSystem G R) : List E → Matrix V V R
  | [] => 1
  | e :: rest => wordOp G S rest * edgeOp G S e

@[simp] theorem wordOp_nil [Fintype V] [DecidableEq V] [Semiring R] :
    wordOp G S [] = 1 :=
  rfl

@[simp] theorem wordOp_singleton [Fintype V] [DecidableEq V] [Semiring R]
    (e : E) : wordOp G S [e] = edgeOp G S e := by
  simp [wordOp]
```

Thus `[e,f,g]` evaluates to $E_g E_f E_e$. The empty list evaluates to the identity matrix, including when the finite vertex type is empty. The formal definitions cover the empty case directly.

The concatenation law gives a quick way to check the orientation:

Source: `KomorebiPaperIII/EdgeOperators.lean`.

```
theorem wordOp_append [Fintype V] [DecidableEq V] [Semiring R]
    (first second : List E) :
    wordOp G S (first ++ second) = wordOp G S second * wordOp G S first := by
  induction first with
  | nil => simp
  | cons e rest ih =>
      simp [wordOp, ih, Matrix.mul_assoc]
```

The operator for `first ++ second` is the operator for `second` multiplied by the operator for `first`. The proof is list induction plus associativity. Its order is essential in a noncommutative coefficient system.

The next theorem removes every word with a broken interface, not just a break at the start.

Source: `KomorebiPaperIII/EdgeOperators.lean`.

```
theorem wordOp_eq_zero_of_not_composable
    [Fintype V] [DecidableEq V] [Semiring R]
    (word : List E) (h : ¬ Composable G word) :
    wordOp G S word = 0 := by
  induction word with
  | nil => simp [Composable] at h
  | cons e rest ih =>
      cases rest with
      | nil => simp [Composable] at h
      | cons f tail =>
```

```
          simp only [Composable, not_and_or] at h
          rcases h with hbreak | htail
          · exact wordOp_eq_zero_of_first_break G S e f tail hbreak
          · change wordOp G S (f :: tail) * edgeOp G S e = 0
            rw [ih htail]
            simp
```

The induction distinguishes a mismatch in the first pair from a mismatch in the tail. The former invokes the support result for two edges. The latter uses the induction hypothesis to make the tail operator zero. Empty and singleton words cannot satisfy the noncomposability hypothesis, so those branches eliminate a contradiction.

2.3 From a transfer power to a finite walk sum

The transfer operator is $T = \sum_{e \in E} E_e$. Four related objects are kept separate:

1. `wordExpansion` recursively multiplies on the left by T.
2. `tupleWordOp` converts a tuple `Fin n → E` to an execution list.
3. `explicitWordExpansion` sums over every tuple of length n.
4. `walkExpansion` keeps precisely the composable tuples.

At length zero there is one empty tuple, not zero tuples. Its contribution is the identity. This is why the explicit sum agrees with T^0.

To pass from length n to length $n + 1$, the proof separates a tuple into its first n entries and its final entry. `Fin.snocEquiv` supplies the finite indexing equivalence. Appending the final edge places its operator to the left of the prefix operator.

Source: `KomorebiPaperIII/EdgeOperators.lean`.

```
theorem explicitWordExpansion_succ
    [Fintype E] [Fintype V] [DecidableEq V] [Semiring R]
    (n : ℕ) :
    explicitWordExpansion G S (n + 1) =
      transferOp G S * explicitWordExpansion G S n := by
  unfold explicitWordExpansion
  rw [← (Fin.snocEquiv (fun _ : Fin (n + 1) ↦ E)).sum_comp]
  rw [Fintype.sum_prod_type]
  change (∑ final : E, ∑ prior : Fin n → E,
    tupleWordOp G S (n + 1) (Fin.snoc prior final)) = _
  simp only [tupleWordOp_snoc]
  unfold transferOp
  rw [Finset.sum_mul]
  simp_rw [Finset.mul_sum]
```

This is a finite distributivity argument. It uses neither an infinite geometric series nor a convergence limit. The proof then identifies the recursive expansion with the explicit tuple sum by induction on n.

Pruning the tuple sum uses the theorem for words with a broken interface, term by term:

Source: KomorebiPaperIII/EdgeOperators.lean.

```
theorem explicitWordExpansion_eq_walkExpansion
    [Fintype E] [Fintype V] [DecidableEq V] [Semiring R]
    (n : ℕ) :
    explicitWordExpansion G S n = walkExpansion G S n := by
  classical
  unfold explicitWordExpansion walkExpansion
  apply Finset.sum_congr rfl
  intro word _
  by_cases hwalk : Composable G (List.ofFn word)
  · simp [hwalk]
  · have hzero : tupleWordOp G S n word = 0 :=
      wordOp_eq_zero_of_not_composable G S (List.ofFn word) hwalk
    simp [hwalk, hzero]
```

When a tuple is composable, the filtered term is unchanged. When it is not, its unfiltered operator was already zero. Combining this equality with the recursive power identity gives `transferOp_pow_eq_walkExpansion`.

2.4 Endpoint coefficients retain the empty path

`reverseCoefficient` recursively multiplies coefficients in operator order. `terminalTarget` records the last endpoint of a nonempty word. `Connects G source target word` combines the endpoint conditions with composability. For an empty word it means `source = target`.

Source: KomorebiPaperIII/EdgeExtensions.lean.

```
theorem wordOp_apply_eq_if_connects
    [Fintype V] [DecidableEq V] [Semiring R]
    (word : List E) (source target : V) :
    wordOp G S word target source =
      if Connects G source target word then reverseCoefficient G S word else 0 := by
  cases word with
  | nil =>
      by_cases h : source = target
      · subst target
        simp [wordOp, Connects, reverseCoefficient]
      · have hreverse : target ≠ source := fun h' => h h'.symm
        simp [wordOp, Connects, h, hreverse]
  | cons first rest =>
      by_cases hwalk : Composable G (first :: rest)
      · rw [wordOp_eq_packetMatrix_of_composable G S first rest hwalk]
        simp [packetMatrix, Connects, hwalk, and_comm]
      · rw [wordOp_eq_zero_of_not_composable G S (first :: rest) hwalk]
        simp [Connects, hwalk]
```

This theorem includes both a nonempty composable word and the diagonal entry of the empty identity word. The endpoint sum is consequently valid for every natural length, including zero. The entry of T^n at the chosen endpoints is the sum of the reverse coefficients of exactly those words of length n connecting them.

2.5 What the support theorem implies

`Reachable G source target` means that some finite list connects the vertices. The empty list makes reachability reflexive. Absence of a walk of length n forces the corresponding entry of T^n to vanish. Absence of any walk gives this conclusion at every length.

The source also handles a seed supported on a specified set:

Source: `KomorebiPaperIII/EdgeExtensions.lean`.

```
theorem transferOp_pow_mulVec_apply_eq_zero_of_unreachable_support
    [Fintype E] [Fintype V] [DecidableEq V] [Semiring R]
    (n : ℕ) (x : V → R) (support : Set V) (target : V)
    (hx : ∀ source, source ∉ support → x source = 0)
    (hunreachable : ∀ source, source ∈ support → ¬ Reachable G source target) :
    ((transferOp G S ^ n) *ᵥ x) target = 0 := by
  rw [Matrix.mulVec_apply_eq_sum]
  apply Finset.sum_eq_zero
  intro source _
  by_cases hsource : source ∈ support
  · rw [transferOp_pow_apply_eq_zero_of_not_reachable G S n source target
      (hunreachable source hsource)]
    simp
  · rw [hx source hsource]
    simp
```

For each source vertex, the proof splits on membership in the support. Inside the support, the relevant transfer entry vanishes by unreachability. Outside it, the seed coordinate vanishes. Every term in the sum defining the matrix action is therefore zero.

The direction cannot be reversed without extra assumptions. A graph may contain a path whose coefficient is zero. Distinct paths may cancel over a ring. Thus a zero orbit coordinate does not by itself prove that the target is unreachable. The Lean theorem uses unreachability as a hypothesis and returns zero as a conclusion.

3 Heterogeneous products and exact coordinates

3.1 What varies in a heterogeneous path

There are two different kinds of heterogeneity. The matrix factor may change at every step while the packet index type stays fixed. Alternatively, the source, intermediate, and target packet types themselves may differ. The formal component includes a theorem for arbitrary finite length of the first kind and separate theorems for two and three steps of the second kind.

The statement for two steps displays all three packet types:

Source: `KomorebiPaperIII/EdgeExtensions.lean`.

```
theorem heterogeneousPacketPathExpansion_two
    {I0 : Type u0} {I1 : Type u1} {I2 : Type u2}
    [Fintype I1] [NonUnitalNonAssocSemiring R]
    (first : Matrix I1 I0 R) (second : Matrix I2 I1 R)
    (source : I0) (target : I2) :
    (second * first) target source =
      ∑ middle : I1, second target middle * first middle source := by
  rw [Matrix.mul_apply]
```

Only the intermediate type `I1` needs a finite enumeration. The source and target types are not enumerated in this entrywise identity. The coefficient hypothesis is `NonUnitalNonAssocSemiring R`. No multiplicative unit or associativity is needed for a single entry sum with two factors.

The statement for three steps introduces two finite intermediate types and a semiring:

Source: `KomorebiPaperIII/EdgeExtensions.lean`.

```
theorem heterogeneousPacketPathExpansion_three
    {I0 : Type u0} {I1 : Type u1} {I2 : Type u2} {I3 : Type u3}
    [Fintype I1] [Fintype I2] [Semiring R]
    (first : Matrix I1 I0 R) (second : Matrix I2 I1 R)
    (third : Matrix I3 I2 R) (source : I0) (target : I3) :
    ((third * second) * first) target source =
      ∑ middle2 : I2, ∑ middle1 : I1,
        (third target middle2 * second middle2 middle1) * first middle1 source := by
  rw [Matrix.mul_apply]
  simp_rw [Matrix.mul_apply, Finset.sum_mul]
  rw [Finset.sum_comm]
```

The parentheses on the coefficient product match `(third * second) * first`. The proof expands matrix multiplication twice, distributes multiplication across a finite sum, and exchanges the two finite sums. The packet index types remain separate throughout the calculation.

3.2 Arbitrary finite length on one packet type

`heterogeneousProduct` evaluates a list of square matrices in execution order. The head acts first and appears on the right. `heterogeneousPathSum` independently sums the intermediate packet at each recursive step. Its empty case is the identity coefficient, equal to one when source and target agree and zero otherwise.

Source: `KomorebiPaperIII/EdgeExtensions.lean`.

```
theorem heterogeneousPacketPathExpansion
    [Fintype V] [DecidableEq V] [Semiring R]
    (steps : List (Matrix V V R)) (source target : V) :
    heterogeneousProduct steps target source =
      heterogeneousPathSum steps source target := by
  induction steps generalizing source target with
  | nil =>
      by_cases h : source = target
      · subst target
        simp [heterogeneousProduct, heterogeneousPathSum]
      · have hreverse : target ≠ source := fun h' => h h'.symm
        simp [heterogeneousProduct, heterogeneousPathSum, hreverse]
  | cons step rest ih =>
      simp [heterogeneousProduct, heterogeneousPathSum, Matrix.mul_apply, ih]
```

The induction is on the list of factors. The base case is the matrix identity. The successor case is exactly the entry formula for matrix multiplication, with the induction hypothesis substituted into the remaining product. The theorem quantifies over every finite list, but all factors are `Matrix V V R`.

The mathematical text may treat a fully dependent chain with a new packet index type at every stage. That theorem lies outside the fixed Lean contract of 41 rows. Rows 13 and 14 make the distinction explicit: differing types at lengths two and three, varying factors on one common type at arbitrary finite length.

3.3 Declared support is a certificate

A `SupportedStep` stores an operator, a relation on source and target packets, and a proof that an entry is zero whenever the relation does not hold. The relation need not be the exact nonzero support. It can be a conservative relation of allowed packet transitions. `SupportedPath` says each successive step respects the corresponding relation.

Source: `KomorebiPaperIII/EdgeExtensions.lean`.

```
theorem heterogeneousPathSum_eq_zero_of_no_supportedPath
    [Fintype V] [DecidableEq V] [Semiring R]
    (steps : List (SupportedStep (V := V) (R := R))) (source target : V)
    (h : ¬ SupportedPath steps source target) :
    heterogeneousPathSum (steps.map SupportedStep.operator) source target = 0 := by
  induction steps generalizing source target with
  | nil =>
      have hreverse : target ≠ source := fun h' => h h'.symm
      simp [heterogeneousPathSum, hreverse]
  | cons step rest ih =>
```

```
      simp only [List.map_cons, heterogeneousPathSum]
      apply Finset.sum_eq_zero
      intro middle _
      by_cases hedge : step.relation source middle
      · have hrest : ¬ SupportedPath rest middle target := by
          intro hpath
          exact h ⟨middle, hedge, hpath⟩
        rw [ih middle target hrest]
        simp
      · rw [step.supported source middle hedge]
        simp
```

The proof splits at every candidate intermediate packet. If the first relation fails, the first matrix entry is zero by the stored certificate. If it holds, absence of an entire supported path forces absence of a supported tail, and the induction hypothesis makes the tail sum zero. This is useful even when exact nonzero support would be expensive to decide.

3.4 Exact frames point from coordinates to ambient space

In `Transport.lean`, a frame synthesizes an ambient vector from its coordinate representation. The homogeneous model uses an automorphism of one module, so source and target types look alike, but the direction still matters:

Source: `KomorebiPaperIII/Transport.lean`.

```
def exactTransport (frame : X → M ≃ₗ[R] M) (a b : X) : M ≃ₗ[R] M :=
  (frame a).trans (frame b).symm

@[simp] theorem exactTransport_apply (frame : X → M ≃ₗ[R] M)
    (a b : X) (x : M) :
    exactTransport frame a b x = (frame b).symm (frame a x) :=
  rfl
```

If Ψ_a is the frame, this is $\Psi_b^{-1}\Psi_a$. It first synthesizes through frame a, then analyzes through frame b. Cancellation of the intervening frame proves the cocycle law:

Source: `KomorebiPaperIII/Transport.lean`.

```
theorem exactTransport_cocycle (frame : X → M ≃ₗ[R] M) (a b c : X) :
    (exactTransport frame a b).trans (exactTransport frame b c) =
      exactTransport frame a c := by
  apply LinearEquiv.ext
  intro x
  simp [exactTransport]
```

The proof applies extensionality and simplifies an equivalence followed by its inverse. The results for self transport, return trips, triangles, and finite paths follow from the same cancellation. Exact transport obtained from one frame family cannot acquire a nontrivial loop merely by changing the path.

3.5 Exact coordinate systems point the other way

`CoordinateNaturality.lean` uses an equivalence `X ≃ Source` from an ambient type to a coordinate type. This is an analysis map, inverse in direction to the frame convention above.

Source: `KomorebiPaperIII/CoordinateNaturality.lean`.

```
def exactCoordinateTransport
    {X : Type u} {Source : Type v} {Target : Type w}
    (source : X ≃ Source) (target : X ≃ Target) : Source ≃ Target :=
  source.symm.trans target

@[simp] theorem exactCoordinateTransport_apply
    {X : Type u} {Source : Type v} {Target : Type w}
    (source : X ≃ Source) (target : X ≃ Target) (value : Source) :
    exactCoordinateTransport source target value = target (source.symm value) :=
  rfl
```

For analysis equivalences $\Phi_a : X \to A$ and $\Phi_b : X \to B$, the transport is $\Phi_b \Phi_a^{-1}$. Both conventions express the same operation of synthesizing and then analyzing. Check the direction of the supplied equivalence before comparing the formulas. This avoids an apparent inverse error.

> **Two directions for exact coordinates**
>
> A frame takes coordinates to ambient space. An analysis equivalence takes ambient data to coordinates. In both conventions, transport first returns to the ambient object and then enters the destination coordinates. The different written formulas reflect the different directions of the supplied equivalences.

An arbitrary function $f : X \to Y$ has coordinate representative

$$f_{a,r} = \Phi_r f \Phi_a^{-1}.$$

The type is an ordinary function `Source → Target`. It need not be linear, invertible, continuous, or differentiable. Composition is preserved exactly:

Source: `KomorebiPaperIII/CoordinateNaturality.lean`.

```
theorem exactCoordinateMap_comp
    {X : Type u} {Y : Type v} {Z : Type w}
    {CX : Type x} {CY : Type y} {CZ : Type z}
    (xCoordinate : X ≃ CX) (yCoordinate : Y ≃ CY)
    (zCoordinate : Z ≃ CZ) (first : X → Y) (second : Y → Z) :
    exactCoordinateMap xCoordinate zCoordinate (second ∘ first) =
      exactCoordinateMap yCoordinate zCoordinate second ∘
        exactCoordinateMap xCoordinate yCoordinate first := by
  funext value
  simp [exactCoordinateMap]
```

The middle coordinate analysis and synthesis cancel. The source proves equality of functions with `funext`, then simplifies at one value. No approximation is involved.

3.6 The naturality square is a typed equality

Source: `KomorebiPaperIII/CoordinateNaturality.lean`.

```
theorem exactCoordinateMap_naturality
    {X : Type u} {Y : Type v}
    {XA : Type w} {XB : Type x} {YR : Type y} {YS : Type z}
    (sourceA : X ≃ XA) (sourceB : X ≃ XB)
    (targetR : Y ≃ YR) (targetS : Y ≃ YS) (map : X → Y) :
    exactCoordinateTransport targetR targetS ∘
        exactCoordinateMap sourceA targetR map =
      exactCoordinateMap sourceB targetS map ∘
        exactCoordinateTransport sourceA sourceB := by
  funext value
  simp [exactCoordinateTransport, exactCoordinateMap, Function.comp_def]
```

On the left, represent the map in the first coordinate systems and then change target coordinates. On the right, change source coordinates first and then use the second representative. Both sides map `XA` to `YS`. Expanding them gives the same function.

This exact statement about sets already applies to a nonlinear function. It does not imply differentiability, a chain rule for jets, or convergence of a formal series. Those stronger properties require further structure and separate theorems. The formal contribution here is exact representation and naturality for arbitrary functions under exact equivalences.

4 Connections, defects, and holonomy

4.1 The minimal interface separates a choice from a theorem

The minimal `Connection R M X` stores an equivalence for each ordered pair of vertices, together with the identity law at equal endpoints.

Source: `KomorebiPaperIII/Transport.lean`.

```
structure Connection (R : Type u) (M : Type v) (X : Type w)
    [Semiring R] [AddCommMonoid M] [Module R M] where
  transport : X → X → M ≃ₗ[R] M
  transport_self : ∀ x, transport x x = LinearEquiv.refl R M
```

Neither reversal by inversion nor the cocycle equation is a field. Both could fail for an instance. This makes the distinction from exact frame transport substantive: exact transport has a prescribed construction that forces the cocycle law, while a connection carries separately chosen pair maps.

The minimal connection's defect is an equivalence. It compares the direct map with the route through an intermediate vertex by composing with an inverse:

Source: `KomorebiPaperIII/Transport.lean`.

```
def cocycleDefect (a b c : X) : M ≃ₗ[R] M :=
  (C.transport a c).symm.trans
    ((C.transport a b).trans (C.transport b c))
```

With ordinary function composition, this is

$$D_{a,b,c} = (\Gamma_{b,c}\Gamma_{a,b})\Gamma_{a,c}^{-1}.$$

It is based at the target coordinate space. In this multiplicative model, absence of a defect means that the comparison is the *identity*, rather than an additive zero map. Since the fibers here are homogeneous, the Lean type does not itself display which endpoint is the base. The definition fixes that interpretation.

4.2 A counterexample to automatic flatness in the source

`doubleEquiv` multiplies rational coordinates by two and divides by two for its inverse. The connection on three points chooses it for the directed edge $0 \to 1$ and chooses the identity for every other unequal pair.

Source: `KomorebiPaperIII/Transport.lean`.

```
def twistedThreePointConnection : Connection ℚ ℚ (Fin 3) where
  transport a b :=
    if a = b then LinearEquiv.refl ℚ ℚ
    else if a = (0 : Fin 3) ∧ b = (1 : Fin 3) then doubleEquiv
    else LinearEquiv.refl ℚ ℚ
  transport_self a := by simp
```

The loop $0 \to 1 \to 2 \to 0$ doubles the input one. Equality with the identity would therefore force $2 = 1$. The source proves nonidentity by applying the proposed equality of equivalences to that input:

Source: KomorebiPaperIII/Transport.lean.

```
theorem twisted_triangleHolonomy_ne_refl :
    twistedThreePointConnection.triangleHolonomy
        (0 : Fin 3) (1 : Fin 3) (2 : Fin 3) ≠ LinearEquiv.refl ℚ ℚ := by
  intro h
  have happly := congrArg (fun e : ℚ ≃ₗ[ℚ] ℚ ↦ e (1 : ℚ)) h
  norm_num [Connection.triangleHolonomy, twistedThreePointConnection,
    doubleEquiv] at happly
```

This is an example for the minimal connection interface. The reverse edge $1 \to 0$ is the identity, so it is not the inverse of doubling. The example must not be advertised as an instance of the stronger reversible interface.

4.3 Reversible connections use dependent fibers

The second interface assigns a module $F(a)$ to each vertex. Pair transport is a linear equivalence between the actual endpoint modules, and reverse transport is required to be its inverse.

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
structure ReversibleConnection
    (R : Type u) (X : Type v) (F : X → Type w)
    [CommRing R] [∀ a, AddCommGroup (F a)] [∀ a, Module R (F a)] where
  transport : ∀ a b, F a ≃ₗ[R] F b
  transport_self : ∀ a, transport a a = LinearEquiv.refl R (F a)
  transport_reverse : ∀ a b, transport b a = (transport a b).symm
```

The hypotheses include a commutative ring, additive commutative groups on all fibers, and module structures. These permit subtraction of parallel linear maps. The cocycle law is still not a structural field. Thus reversible connections may have nontrivial triangle holonomy.

The additive defect has a source and target visible in its type:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
def cocycleDefect (a b c : X) : F a →ₗ[R] F c :=
  (C.transport b c).toLinearMap.comp (C.transport a b).toLinearMap -
    (C.transport a c).toLinearMap
```

Write

$$\Delta_{a,b,c} = \Gamma_{b,c}\Gamma_{a,b} - \Gamma_{a,c} \quad : F(a) \longrightarrow F(c).$$

The triangle holonomy is

$$H_{a,b,c} = \Gamma_{c,a}\Gamma_{b,c}\Gamma_{a,b} \quad : F(a) \longrightarrow F(a),$$

and the triangle obstruction is $O_{a,b,c} = H_{a,b,c} - I$. Unlike the minimal multiplicative defect, this Δ is a linear map that need not be invertible. Both APIs use the short name `cocycleDefect`, but they live in different namespaces and have different types.

4.4 The identity between defect and holonomy

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem triangleHolonomy_sub_id (a b c : X) :
    C.triangleObstruction a b c =
      (C.transport c a).toLinearMap.comp (C.cocycleDefect a b c) := by
  ext x
  simp only [triangleObstruction, triangleHolonomy, cocycleDefect,
    LinearMap.sub_apply, LinearMap.id_apply, LinearMap.comp_apply,
    LinearEquiv.coe_toLinearMap, LinearEquiv.trans_apply, map_sub]
  rw [C.transport_reverse a c]
  simp
```

Pointwise, the identity reads

$$(H - I)x = \Gamma_{c,a}(\Gamma_{b,c}\Gamma_{a,b}x - \Gamma_{a,c}x).$$

Linearity moves the subtraction through $\Gamma_{c,a}$. The reverse law makes $\Gamma_{c,a}\Gamma_{a,c}$ the identity. The source proof uses exactly these two steps after unfolding the definitions.

Because $\Gamma_{c,a}$ is injective, the obstruction is zero exactly when the defect is zero. Vanishing of the additive defect is the cocycle equation. Vanishing of holonomy minus identity means the holonomy is the identity. The theorem chain establishes these equivalences at a fixed ordered triple before quantifying over every triple.

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem flat_iff_triangleHolonomy_eq_refl :
    C.Flat ↔ ∀ a b c,
      C.triangleHolonomy a b c = LinearEquiv.refl R (F a) := by
  constructor
  · intro hflat a b c
    rw [← C.cocycleDefect_eq_zero_iff_triangleHolonomy_eq_refl a b c,
      C.cocycleDefect_eq_zero_iff_cocycleAt]
    exact hflat a b c
  · intro hhol a b c
    rw [← C.cocycleDefect_eq_zero_iff_cocycleAt,
      C.cocycleDefect_eq_zero_iff_triangleHolonomy_eq_refl]
    exact hhol a b c
```

Here `Flat` means the pair-cocycle law at every triple of vertices. It is a global algebraic condition on all pair transports. It is not a differential curvature condition obtained from a limiting process or a local chart cover.

4.5 Finite paths and their endpoint types

The path function on lists returns `F start ≃[R] F (pathEndpoint start vertices)`. The return type depends on the endpoint computed from the list. Flatness lets induction replace every remaining segment by direct transport, then collapse the next triangle by the cocycle law.

The indexed alternative packages the endpoints in the path's type. `VertexPath X a b` is a finite path from a to b. An empty path has equal endpoints. A constructor prefixes a step to a path from the intermediate vertex. Its transport theorem is:

Source: `KomorebiPaperIII/ReversibleConnections.lean`.

```
theorem indexedPathTransport_eq_direct_of_flat (hflat : C.Flat) :
    ∀ {a b : X} (path : VertexPath X a b),
      indexedPathTransport C path = C.transport a b := by
  intro a b path
  induction path with
  | nil a => exact (C.transport_self a).symm
  | cons a b c rest ih =>
      simp only [indexedPathTransport]
      rw [ih]
      exact hflat a b c
```

The loop corollary takes `path : VertexPath X a a`. Its output is then already an automorphism of `F a`, and the self law identifies it with the identity. This avoids an extra coercion between a computed endpoint and the initial vertex.

The paths are finite syntax. Nothing here states that an infinite composition exists or that approximating finite paths converge. The finite endpoint theorem is exact on its stated domain.

5 Gauge reconstruction and packet obstruction blocks

5.1 The gauge action fixes its own convention

A gauge is a family of fiber automorphisms $G_a : F(a) \to F(a)$. The source convention is

$$\Gamma^G_{a,b} = G_b \Gamma_{a,b} G_a^{-1}.$$

The definition has to prove that the new pair maps satisfy the self and reverse laws, because its return value is again a reversible connection.

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
def gauge (G : Gauge (R := R) (F := F)) : ReversibleConnection R X F where
  transport a b := ((G a).symm.trans (C.transport a b)).trans (G b)
  transport_self a := by
    apply LinearEquiv.ext
    intro x
    rw [C.transport_self]
    simp
  transport_reverse a b := by
    rw [C.transport_reverse a b]
    apply LinearEquiv.ext
    intro x
    simp
```

The proof of each structural law is pointwise cancellation. Flatness is not needed to define the gauge action.

The defect has different source and target fibers, so it transforms with a gauge at each end:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem gauge_cocycleDefect
    (G : Gauge (R := R) (F := F)) (a b c : X) :
    (C.gauge G).cocycleDefect a b c =
      (G c).toLinearMap.comp
        ((C.cocycleDefect a b c).comp (G a).symm.toLinearMap) := by
  ext x
  simp [gauge, cocycleDefect]
```

Thus $\Delta^G_{a,b,c} = G_c \Delta_{a,b,c} G_a^{-1}$. Holonomy is based at a, so both endpoint gauges are at that vertex:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem gauge_triangleHolonomy
    (G : Gauge (R := R) (F := F)) (a b c : X) :
    (C.gauge G).triangleHolonomy a b c =
      ((G a).symm.trans (C.triangleHolonomy a b c)).trans (G a) := by
  apply LinearEquiv.ext
  intro x
  simp [gauge, triangleHolonomy]
```

The transformed matrix is conjugate to the original. Whether the holonomy is the identity is invariant, and the source also proves that the cocycle condition and flatness are invariant. A coordinate change may alter entries while preserving these exact statements.

5.2 Reconstructing a flat connection from canonical transport

Suppose a family of frames $\Psi_a : F(a) \simeq M$ and a base vertex o are supplied. The canonical connection is $K_{a,b} = \Psi_b^{-1}\Psi_a$. The source defines

$$G_a = \Gamma_{o,a} K_{a,o}.$$

Its type is a gauge on each fiber:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
def flatGauge (frame : ∀ a, F a ≃ₗ[R] M) (o : X) :
    Gauge (R := R) (F := F) :=
  fun a ↦ (canonicalTransport frame a o).trans (C.transport o a)
```

The reconstruction theorem proves $\Gamma_{a,b} = G_b K_{a,b} G_a^{-1}$ under flatness.

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem flat_isGaugeOfCanonical
    (hflat : C.Flat) (frame : ∀ a, F a ≃ₗ[R] M) (o a b : X) :
    C.transport a b =
      ((C.flatGauge frame o a).symm.trans
        ((canonicalConnection frame).transport a b)).trans
          (C.flatGauge frame o b) := by
  apply LinearEquiv.ext
  intro x
  have hg : (C.flatGauge frame o a).symm =
      (C.transport o a).symm.trans (canonicalTransport frame a o).symm := rfl
  rw [hg]
  have hcanonical_symm (p q : X) :
      (canonicalTransport frame p q).symm = canonicalTransport frame q p := rfl
  rw [hcanonical_symm]
  simp only [flatGauge, canonicalConnection, LinearEquiv.trans_apply]
  rw [show (C.transport o a).symm = C.transport a o by
    rw [C.transport_reverse o a]]
  simp only [canonicalTransport, LinearEquiv.trans_apply,
    LinearEquiv.symm_apply_apply, LinearEquiv.apply_symm_apply]
  have hao : (C.transport a o).trans (C.transport o b) = C.transport a b :=
    hflat a o b
  exact (congrArg (fun e : F a ≃ₗ[R] F b ↦ e x) hao).symm
```

The proof first expands the inverse of the defined gauge, then cancels the canonical frame maps. What remains is $\Gamma_{o,b}\Gamma_{a,o} = \Gamma_{a,b}$, the flatness equation at a, o, b.

The theorem is relative to supplied frames and a supplied vertex. It does not silently choose a vertex from an empty type. Nor does this declaration prove a classification theorem for topological bundles. Its result is an explicit algebraic formula for a flat normalized reversible pair connection on the supplied data.

5.3 A packet resolution need not be orthogonal

The formal interface for packet resolution asks for a finite complete family of idempotent endomorphisms.

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
structure PacketResolution (R : Type u) (M : Type v) (I : Type w)
    [CommRing R] [AddCommGroup M] [Module R M] [Fintype I] where
  projector : I → M →ₗ[R] M
  complete : ∑ i, projector i = LinearMap.id
  idempotent : ∀ i, (projector i).comp (projector i) = projector i
```

Completeness is $\sum_i P_i = I$. Idempotence is $P_i^2 = P_i$. The structure does not assert pairwise orthogonality. The block from input packet ν to output packet μ is

$$A_{\mu\nu} = P_\mu A P_\nu.$$

Reconstruction only needs completeness on both sides:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem sum_blocks (A : M →ₗ[R] M) :
    ∑ mu, ∑ nu, P.block A mu nu = A := by
  have hcomplete (x : M) : ∑ i, P.projector i x = x := by
    have hx := congrArg (fun L : M →ₗ[R] M ↦ L x) P.complete
    simpa using hx
  ext x
  simp only [block, LinearMap.sum_apply, LinearMap.comp_apply]
  calc
    (∑ mu, ∑ nu, P.projector mu (A (P.projector nu x))) =
        ∑ mu, P.projector mu (A (∑ nu, P.projector nu x)) := by
          apply Finset.sum_congr rfl
          intro mu _
          calc
            (∑ nu, P.projector mu (A (P.projector nu x))) =
                P.projector mu (∑ nu, A (P.projector nu x)) := by
                  exact (map_sum (P.projector mu)
                    (fun nu ↦ A (P.projector nu x)) Finset.univ).symm
            _ = P.projector mu (A (∑ nu, P.projector nu x)) := by
                  congr 1
                  exact (map_sum A
                    (fun nu ↦ P.projector nu x) Finset.univ).symm
    _ = ∑ mu, P.projector mu (A x) := by rw [hcomplete x]
    _ = A x := hcomplete (A x)
```

The proof applies the completeness equation to a vector. It combines the finite inner sum using linearity, applies completeness at the input, and then uses completeness at the output. No orthogonality cancellation appears.

All blocks vanish if and only if the map vanishes:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem blocks_zero_iff (A : M →ₗ[R] M) :
    (∀ mu nu, P.block A mu nu = 0) ↔ A = 0 := by
  constructor
  · intro h
    rw [← P.sum_blocks A]
    simp [h]
  · intro h mu nu
    simp [block, h]
```

The forward direction rewrites the map as its double block sum. The reverse direction substitutes the zero map into the definition of a block. This result is a detector for the whole map even when the projectors overlap.

5.4 Extracting a witness supported in a packet

Idempotence is needed for the stronger witness statement:

Source: KomorebiPaperIII/ReversibleConnections.lean.

```
theorem exists_packetWitness_of_block_ne_zero
    (A : M →ₗ[R] M) (mu nu : I) (hne : P.block A mu nu ≠ 0) :
    ∃ x, P.projector nu x = x ∧ P.projector mu (A x) ≠ 0 := by
  classical
  have hexists : ∃ y, P.block A mu nu y ≠ 0 := by
    by_contra h
    apply hne
    ext y
    by_contra hy
    exact h ⟨y, hy⟩
  rcases hexists with ⟨y, hy⟩
  refine ⟨P.projector nu y, ?_, ?_⟩
  · have hid := congrArg (fun L : M →ₗ[R] M ↦ L y) (P.idempotent nu)
    simpa using hid
  · simpa [block] using hy
```

A nonzero block supplies some vector y on which that block is nonzero. The proof then takes $x = P_\nu y$. Idempotence ensures $P_\nu x = x$, and the original nonzero block value becomes $P_\mu A x \neq 0$.

The extraction is classical. It proves existence and does not supply a numerical search routine for an arbitrary module. Its input is a proof that a block is nonzero. It does not decide that predicate for the user.

Apply these results to $O = H - I$ on the base fiber of a fixed triangle. The declarations in rows 33 and 34 show

$$\Delta = 0 \iff H = I \iff O = 0 \iff (\forall \mu, \nu)\ P_\mu O P_\nu = 0.$$

The theorem for the whole map, `obstructionDetection_equivalences`, records the three equivalences joining these four criteria. Nonzero obstruction blocks inherit the theorem giving a witness supported in a packet.

5.5 When a fixed packet pattern survives a gauge

Total obstruction always transforms by conjugation at the base vertex. For a *fixed* packet family to transform block by block, the gauge must commute with every projector.

Source: `KomorebiPaperIII/HolonomyBlocks.lean`.

```
def PacketPreserving (gauge : M ≃ₗ[R] M) : Prop :=
  ∀ packet, gauge.toLinearMap.comp (P.projector packet) =
    (P.projector packet).comp gauge.toLinearMap
```

The source first proves that the inverse gauge also commutes with the projectors. This lets the proof move both the gauge and its inverse past the output and input projectors:

Source: `KomorebiPaperIII/HolonomyBlocks.lean`.

```
theorem block_gauge_of_commutes
    (gauge : M ≃ₗ[R] M) (map : M →ₗ[R] M)
    (hpreserves : P.PacketPreserving gauge) (target source : I) :
    P.block (gaugeConjugate gauge map) target source =
      gaugeConjugate gauge (P.block map target source) := by
  ext value
  simp only [block, gaugeConjugate, LinearMap.comp_apply,
    LinearEquiv.coe_toLinearMap]
  have htarget (y : M) :
      P.projector target (gauge y) = gauge (P.projector target y) :=
    (LinearMap.congr_fun (hpreserves target) y).symm
  have hsource :
      gauge.symm (P.projector source value) =
        P.projector source (gauge.symm value) :=
    LinearMap.congr_fun
      (P.symm_commutes_of_packetPreserving gauge hpreserves source) value
  calc
    P.projector target
        (gauge (map (gauge.symm (P.projector source value)))) =
        gauge
          (P.projector target
            (map (gauge.symm (P.projector source value)))) :=
      htarget _
    _ = gauge
          (P.projector target
            (map (P.projector source (gauge.symm value)))) := by
      rw [hsource]
```

Consequently each block is conjugated separately, and each block's zero or nonzero status is invariant. Row 37 specializes this statement to a triangle obstruction and requires `P.PacketPreserving (G a)` at the base vertex.

An arbitrary gauge need not preserve the blocks of a fixed resolution. The unconditional fact is conjugation of the total obstruction. The conditional fact is conjugation of each fixed block. Keeping those hypotheses distinct is essential when interpreting a packet obstruction diagram.

6 Operation trees and certificates for individual candidates

6.1 The grammar does not assume algebraic laws

The nonlinear module starts with a finite syntax tree. Inputs, constants, unary labels, and binary labels can each have their own type.

Source: KomorebiPaperIII/NonlinearObstructions.lean.

```
inductive OperationTree
    (Input : Type u) (Constant : Type v) (Unary : Type w) (Binary : Type x)
    where
  | input : Input → OperationTree Input Constant Unary Binary
  | constant : Constant → OperationTree Input Constant Unary Binary
  | unary : Unary → OperationTree Input Constant Unary Binary →
      OperationTree Input Constant Unary Binary
  | binary : Binary → OperationTree Input Constant Unary Binary →
      OperationTree Input Constant Unary Binary →
      OperationTree Input Constant Unary Binary
```

To evaluate a tree, supply four functions: input values, constant values, unary semantics, and binary semantics. Unary and binary semantics are arbitrary functions on one common value type. They are not assumed additive, multilinear, differentiable, associative, or commutative. This generality is what makes the locality theorem applicable to any chosen semantics.

Every tree has finitely many nodes. The input type itself need not be finite. The function `inputs` computes a finite set of names appearing in the tree:

Source: KomorebiPaperIII/NonlinearObstructions.lean.

```
def inputs [DecidableEq Input] :
    OperationTree Input Constant Unary Binary → Finset Input
  | .input i => {i}
  | .constant _ => ∅
  | .unary _ child => inputs child
  | .binary _ left right => inputs left ∪ inputs right
```

A constant reads no input. A unary node reads exactly the names read by its child. A binary node reads the union of its two children's names. Because this is a set, repeated uses of one input are recorded once. The semantics may still depend nonlinearly on repeated occurrences.

6.2 The locality proof follows the syntax

Source: KomorebiPaperIII/NonlinearObstructions.lean.

```
theorem eval_congr_on_inputs [DecidableEq Input]
    (tree : OperationTree Input Constant Unary Binary)
    (first second : Input → Value)
    (constantValue : Constant → Value)
    (unaryValue : Unary → Value → Value)
    (binaryValue : Binary → Value → Value → Value)
```

```
  (hagree : ∀ i ∈ tree.inputs, first i = second i) :
  tree.eval first constantValue unaryValue binaryValue =
    tree.eval second constantValue unaryValue binaryValue := by
induction tree with
| input i =>
    exact hagree i (by simp [inputs])
| constant c =>
    rfl
| unary op child ih =>
    simp only [eval]
    congr 1
    exact ih fun i hi ↦ hagree i (by simpa [inputs] using hi)
| binary op left right ihLeft ihRight =>
    simp only [eval]
    congr 1
    · exact ihLeft fun i hi ↦ hagree i (by simp [inputs, hi])
    · exact ihRight fun i hi ↦ hagree i (by simp [inputs, hi])
```

In an input case, the agreement hypothesis applies to that input's singleton support. In a constant case, both evaluations are definitionally equal. At a unary node, the induction hypothesis identifies the child values, and applying the same unary function preserves equality. At a binary node, the two child induction hypotheses apply because each child's support lies in the union.

The result states one implication: agreement on the syntactically named inputs gives equal evaluation. It does not claim every named input is semantically influential. For example, an operation may ignore one argument. The syntactic support remains a safe dependency set.

If `tree.inputs = ∅`, agreement on the empty set is vacuous, so the value is independent of the input environment. The source proves this as `eval_eq_of_inputs_eq_empty`. Constants and semantics are held fixed between the two evaluations. Changing the semantics would require a different comparison theorem.

6.3 What the nonlinear extension adds outside this contract

The mathematical text develops stronger ordinary statements about typed or colored trees, multilinear packet expansions, composition defects, and higher-order structures. The finite Lean contract contains the common-value unary/binary grammar and its input-locality theorem. It does not contain the dependent colored-tree development or a tree-level Faà di Bruno theorem.

This boundary is mathematical, not stylistic. A colored tree needs compatibility between node input and output types. A multilinear packet expansion needs algebraic hypotheses absent from arbitrary unary and binary semantics. The existing locality proof cannot certify these statements by a change of terminology.

6.4 Residuals and a fixed proposed solution

The obstruction API asks for a function `residual : Candidate → Packet → Residual`, with only `Zero Residual` assumed. A candidate is a solution when every packet residual is zero. A certificate stores one packet at which its residual is nonzero:

Source: KomorebiPaperIII/NonlinearObstructions.lean.

```
structure ObstructionPacket
    (residual : Candidate → Packet → Residual) (candidate : Candidate) where
  packet : Packet
  nonzero : residual candidate packet ≠ 0
```

The candidate appears in the certificate's type. A certificate for one candidate cannot directly be passed as a certificate for a different one. The theorem `ObstructionPacket.not_isSolution` uses the stored packet to contradict the condition that every packet residual is zero.

Classically, failure of the condition that every packet residual is zero supplies a nonempty certificate type. The combined equivalence is:

Source: KomorebiPaperIII/NonlinearObstructions.lean.

```
theorem not_isSolution_iff_nonempty_obstructionPacket
    {residual : Candidate → Packet → Residual} {candidate : Candidate} :
    ¬ IsSolution residual candidate ↔
      Nonempty (ObstructionPacket residual candidate) := by
  constructor
  · exact obstructionPacket_of_not_isSolution
  · rintro (certificate)
    exact certificate.not_isSolution
```

The output is `Nonempty (ObstructionPacket residual candidate)`. This is a proposition asserting that the certificate type has an inhabitant. It is not a computable function that enumerates packets or finds one within a time bound.

Neither `Packet` nor `Candidate` needs a finite enumeration for this logical equivalence. The adjective "finite" in the overall contract describes the walk sums, paths, packet resolutions, and operation-tree syntax where finiteness is imposed. It should not be misread as an extra `Fintype` assumption on this candidate theorem.

6.5 The quantifiers determine the conclusion

For one proposed candidate c, the theorem says

$$\neg(\forall p,\ r(c,p) = 0) \quad \Longleftrightarrow \quad \text{a certificate of } r(c,p) \neq 0 \text{ exists.}$$

To show that a global solution does not exist, one needs the additional assertion that *every* candidate fails, or an argument producing an obstruction for each candidate. To prove existence of a global solution, one must produce a candidate with every residual zero. Neither conclusion follows merely from the certificate interface.

Once a witness is supplied, the interface makes local failure portable and checkable. The formal type records the residual, the candidate, the packet, and the exact nonzero assertion. A later theorem can build on these data without confusing rejection of one candidate with a universal impossibility result.

7 The finite baseline: evidence, trust, and replay

This chapter explains the finite algebraic core and its verification gates. For the combined core and analytic continuation, use the opening chapter and `formal/README.md`. The finite namespace counts in the excerpts apply only to that finite baseline.

7.1 The pinned environment is part of the claim

The source records specify the compiler and dependency environment.

The recorded compiler controls identify the warning policy actually checked.

The source distribution omits compiled outputs and dependency caches. A fresh environment therefore needs the pinned toolchain and the dependencies named by the manifest. Rebuilding the PDF guide does not need Lean. Replaying the mathematical formalization does.

Descriptive dependency branches such as `master` or `main` are not substitutes for exact manifest revisions. Updating a dependency and obtaining a successful build may be useful, but it is a new verification event. The original event remains tied to the recorded environment.

7.2 A map gate and a namespace gate answer different questions

The authoritative `scripts/verify_theorem_map.py` checks the map row sequence, uniqueness, compiled declaration kinds, manuscript status annotations, inherited references, and explicit audit coverage. In the pinned compiled environment, it distinguishes the 88 theorem targets from the 55 construction targets. A lexical scan can locate these declarations in source, but does not independently elaborate their types.

The kernel audit file asks Lean to print transitive axioms for all mapped targets. It then inspects the compiled `Komorebi.PaperIII` namespace, including generated declarations and implementation auxiliaries. This second step protects the boundary beyond just the manually listed names.

Source: `KomorebiPaperIII/KernelAudit.lean`.

```
run_cmd do
  let env ← getEnv
  let mut audited : Nat := 0
  let mut theorems : Nat := 0
  for (name, info) in env.checked.get.constants.toList do
    if Name.isPrefixOf `Komorebi.PaperIII name then
      audited := audited + 1
      match info with
      | .thmInfo _ => theorems := theorems + 1
      | _ => pure ()
      if info.isUnsafe then
        throwError "unsafe Paper III declaration: {name}"
      match info with
      | .axiomInfo _ =>
          throwError "Paper III axiom declaration: {name}"
      | .opaqueInfo _ =>
```

```
        throwError "opaque Paper III declaration: {name}"
    | _ => pure ()
    let axioms ← Lean.collectAxioms name
    for axiomName in axioms do
      unless axiomName == ``propext || axiomName == ``Classical.choice ||
          axiomName == ``Quot.sound do
        throwError "unexpected axiom {axiomName} in Paper III declaration {name}"
if audited != 468 then
  throwError "Paper III namespace declaration count changed: expected 468, found {audited}"
if theorems != 229 then
  throwError "Paper III namespace theorem count changed: expected 229, found {theorems}"
```

The gate rejects unsafe declarations, project axioms, opaque declarations, and any collected axiom outside propext, Classical.choice, and Quot.sound. It also checks the exact namespace and theorem-kind counts. These expected counts identify the audited declaration set. A deliberate addition requires reviewing the counts while retaining the checks.

The source policy check additionally rejects proof placeholders and specified shortcuts. Text scanning alone cannot establish a theorem's correctness. It is one gate among the build, compiled map checks, axiom traversal, and checks of source integrity.

7.3 Reading the inherited transcript

The saved transcript has 143 named records. Some say that the target depends on no axioms. Others list a subset of the allowed standard basis. The final line records 468 audited namespace declarations, including 229 `theoremInfo` entries, and 143 explicit mapped targets.

The difference between 88 and 229 is not a discrepancy. Eighty-eight counts the theorem declarations deliberately mapped to the chapter. The compiled namespace count includes generated theorems and other supporting theorem entries. Similarly, 143 and 468 refer to different denominators: the explicitly mapped targets versus every compiled entry under the audited namespace.

This guide checked that the transcript's named records agree with the map and the audit directives. It also checked the transcript hash against the inherited report. That establishes consistency and byte identity of the preserved materials. It does not authenticate an external compiler session by itself. A new execution is the direct way to regenerate compiler evidence from those sources.

7.4 The inherited Chapters I–II references

Chapter III records twelve unique declarations from the separately verified foundational Chapters I–II bundle. They appear in fourteen manuscript references because two refinement declarations are used twice. The bundle is pinned by SHA-256:

`a20cf9353f0e882834d31e665dfd819a04e43fa606d402309be63e3b94447052`

The standalone Chapter III project does not import or recompile those declarations. Its gate checks inherited annotations against the dependency manifest. These are inherited references, not additional entries in the 143-target Chapter III namespace audit. Appendix B gives the exact dependency names and roles.

7.5 Replay from a preserved source copy

The source distribution offers an offline integrity mode. From its root, run:

```
bash VERIFY.sh
```

This mode checks source membership, checksums, map and audit consistency, manuscript status references, and the saved transcript. It does not run Lean. It is suitable for checking that a copied source tree still matches its manifest.

For a formal replay, work in a separate copy of the source distribution. From formalization/lean, run the documented commands in order:

```
lake --wfail build
python3 scripts/verify_theorem_map.py
lake env lean -E warning KomorebiPaperIII/KernelAudit.lean
```

Retain the exit code and the complete standard output and error stream for every command. The first command builds the project. The second checks the human map against the compiled environment and the original manuscript. The third regenerates the axiom reports and namespace result. A missing dependency, toolchain failure, timeout, or nonzero exit is not a passing proof run.

The source distribution also supplies bash VERIFY.sh --full. That path creates a temporary copy, regenerates figures, runs Lean and its gates, rebuilds the original finite manuscript, and verifies the original artifact hashes. It requires its documented TeX, graphics, Python, and Lean dependencies. It verifies the finite source distribution. The expanded companion PDF has a separate scope.

7.6 The formal verification boundary

The finite portion of this guide supplies exact source excerpts, the complete 41-row map, the preserved transcript, and static reconciliation. The opening chapter separately reports compiler and kernel verification. The package records separate computational checks and the chapter's earlier bounded mathematical review. These records concern different objects. They do not establish fresh Lean proofs of every ordinary theorem.

The finite algebraic contract has explicit types and evidence. To expand it, add the required types and proofs, update the map, run the pinned or newly documented environment, and retain the new transcript.

8 The complete 41-row formal contract

This index preserves every row, target, status, and boundary of the authoritative finite algebraic map. Fully qualified declaration names are printed in full. File and line locations are a current lexical navigation aid, not a second compiled type audit. Each target appears in exactly one row. The 143 names comprise 88 theorem declarations and 55 constructions.

The finite limits are part of the statements: edge sums use finite packet and edge types, arbitrary-length heterogeneous products keep one common finite packet type, and packet reconstruction uses a finite complete idempotent family. Rows 38–41 have the separate grammar and candidate-specific scopes explained in Section 6.

8.1 Row 1: Packet graph and scalar packet matrix

Status and boundary. Defined; row is target and column is source

`Komorebi.PaperIII.EdgeOperators.PacketGraph`
structure, `KomorebiPaperIII/EdgeOperators.lean`, line 27.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.packetMatrix`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 36.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.packetMatrix_apply`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 40.

8.2 Row 2: Typed edge system, elementary edge operator, and finite transfer operator

Status and boundary. Defined for the finite scalar matrix model

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem`
structure, `KomorebiPaperIII/EdgeOperators.lean`, line 47.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 55.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_apply`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 58.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 162.

8.3 Row 3: Edge support outside the target-source block vanishes

Status and boundary. Proved

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_eq_zero_off_support`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 65.

8.4 Row 4: Scalar packet multiplication and the two-edge composition dichotomy

Status and boundary. Proved; right factor acts first

`Komorebi.PaperIII.EdgeOperators.PacketGraph.packetMatrix_mul_packetMatrix`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 31.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_mul_edgeOp_eq_zero`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 75.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.edgeOp_mul_edgeOp_of_composable`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 92.

8.5 Row 5: Composable edge words and their operators

Status and boundary. Defined and proved

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.Composable`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 106.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 112.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_nil`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 117.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_singleton`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 121.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_append`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 126.

8.6 Row 6: Broken and noncomposable words vanish

Status and boundary. Proved

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_eq_zero_of_first_break`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 135.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_eq_zero_of_not_composable`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 144.

8.7 Row 7: Recursive, tuple, explicit-word, and walk expansions

Status and boundary. Defined; all sums are finite

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordExpansion`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 170.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.tupleWordOp`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 177.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.explicitWordExpansion`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 182.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.walkExpansion`
def, `KomorebiPaperIII/EdgeOperators.lean`, line 190.

8.8 Row 8: Successor laws for explicit words

Status and boundary. Proved

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.tupleWordOp_snoc`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 198.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.explicitWordExpansion_succ`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 210.

8.9 Row 9: Transfer powers equal recursive, explicit-word, and composable-walk expansions

Status and boundary. Proved

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordExpansion_eq_explicitWordExpansion`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 226.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.explicitWordExpansion_eq_walkExpansion`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 237.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_eq_wordExpansion`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 252.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_eq_explicitWordExpansion`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 263.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_eq_walkExpansion`
theorem, `KomorebiPaperIII/EdgeOperators.lean`, line 274.

8.10 Row 10: Endpoint block and coefficient of a composable word

Status and boundary. Defined and proved; coefficient order follows operator composition

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.reverseCoefficient`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 49.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.terminalTarget`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 54.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.Connects`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 59.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_eq_packetMatrix_of_composable`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 75.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.wordOp_apply_eq_if_connects`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 98.

8.11 Row 11: Fixed-endpoint coefficient sum

Status and boundary. Defined and proved for fixed length

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.endpointWalkCoefficientSum`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 118.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_apply_eq_sum_walks`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 128.

8.12 Row 12: Fixed-length and global reachability obstructions

Status and boundary. Proved; reachability includes the empty path

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_apply_eq_zero_of_no_walk`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 142.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.Reachable`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 153.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_apply_eq_zero_of_not_reachable`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 157.

`Komorebi.PaperIII.EdgeOperators.PacketGraph.EdgeSystem.transferOp_pow_mulVec_apply_eq_zero_of_unreachable_support`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 169.

8.13 Row 13: Fully typed two- and three-step packet expansions

Status and boundary. Proved; intermediate packet types may differ

`Komorebi.PaperIII.EdgeOperators.heterogeneousPacketPathExpansion_two`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 195.

`Komorebi.PaperIII.EdgeOperators.heterogeneousPacketPathExpansion_three`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 205.

8.14 Row 14: Arbitrary-length heterogeneous factor expansion

Status and boundary. Defined and proved for varying factors on one common finite packet type

`Komorebi.PaperIII.EdgeOperators.heterogeneousProduct`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 221.

`Komorebi.PaperIII.EdgeOperators.heterogeneousPathSum`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 231.

`Komorebi.PaperIII.EdgeOperators.heterogeneousPacketPathExpansion`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 242.

8.15 Row 15: Supported heterogeneous paths and vanishing

Status and boundary. Defined and proved; support relations are explicit data

`Komorebi.PaperIII.EdgeOperators.SupportedStep`
structure, `KomorebiPaperIII/EdgeExtensions.lean`, line 258.

`Komorebi.PaperIII.EdgeOperators.SupportedPath`
def, `KomorebiPaperIII/EdgeExtensions.lean`, line 265.

`Komorebi.PaperIII.EdgeOperators.heterogeneousPathSum_eq_zero_of_no_supportedPath`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 273.

`Komorebi.PaperIII.EdgeOperators.supportedHeterogeneousPacketPathExpansion`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 296.

`Komorebi.PaperIII.EdgeOperators.heterogeneousProduct_apply_eq_zero_of_no_supportedPath`
theorem, `KomorebiPaperIII/EdgeExtensions.lean`, line 304.

8.16 Row 16: Canonical homogeneous linear coordinate transport

Status and boundary. Defined from one frame family

`Komorebi.PaperIII.Transport.exactTransport`
def, `KomorebiPaperIII/Transport.lean`, line 35.

`Komorebi.PaperIII.Transport.exactTransport_apply`
theorem, `KomorebiPaperIII/Transport.lean`, line 38.

8.17 Row 17: Exact self, cocycle, round-trip, and triangle laws

Status and boundary. Proved

`Komorebi.PaperIII.Transport.exactTransport_self`
theorem, `KomorebiPaperIII/Transport.lean`, line 44.

`Komorebi.PaperIII.Transport.exactTransport_cocycle`
theorem, `KomorebiPaperIII/Transport.lean`, line 51.

`Komorebi.PaperIII.Transport.exactTransport_roundTrip`
theorem, `KomorebiPaperIII/Transport.lean`, line 59.

`Komorebi.PaperIII.Transport.exactTransport_triangleLoop`
theorem, `KomorebiPaperIII/Transport.lean`, line 65.

8.18 Row 18: Exact finite path transport telescopes

Status and boundary. Defined and proved for arbitrary finite vertex lists

`Komorebi.PaperIII.Transport.pathEndpoint`
def, `KomorebiPaperIII/Transport.lean`, line 71.

`Komorebi.PaperIII.Transport.exactPathTransport`
def, `KomorebiPaperIII/Transport.lean`, line 76.

`Komorebi.PaperIII.Transport.exactPathTransport_eq_endpoint`
theorem, `KomorebiPaperIII/Transport.lean`, line 84.

`Komorebi.PaperIII.Transport.exactPathTransport_loop`
theorem, `KomorebiPaperIII/Transport.lean`, line 96.

8.19 Row 19: Set-level exact coordinate transport

Status and boundary. Defined and proved for arbitrary equivalences, without linearity assumptions

`Komorebi.PaperIII.Transport.exactCoordinateTransport`
def, `KomorebiPaperIII/CoordinateNaturality.lean`, line 24.

`Komorebi.PaperIII.Transport.exactCoordinateTransport_apply`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 29.

`Komorebi.PaperIII.Transport.exactCoordinateTransport_self`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 36.

`Komorebi.PaperIII.Transport.exactCoordinateTransport_symm`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 43.

`Komorebi.PaperIII.Transport.exactCoordinateTransport_cocycle`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 52.

`Komorebi.PaperIII.Transport.exactCoordinateTransport_triangle`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 61.

8.20 Row 20: Representation, composition, and naturality of arbitrary functions

Status and boundary. Defined and proved at set level

`Komorebi.PaperIII.Transport.exactCoordinateMap`
def, `KomorebiPaperIII/CoordinateNaturality.lean`, line 71.

`Komorebi.PaperIII.Transport.exactCoordinateMap_apply`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 77.

`Komorebi.PaperIII.Transport.exactCoordinateMap_id`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 86.

`Komorebi.PaperIII.Transport.exactCoordinateMap_comp`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 93.

`Komorebi.PaperIII.Transport.exactCoordinateMap_naturality`
theorem, `KomorebiPaperIII/CoordinateNaturality.lean`, line 109.

8.21 Row 21: Minimal homogeneous noncanonical connection and its defects

Status and boundary. Defined; only self-transport is structural

`Komorebi.PaperIII.Transport.Connection`
structure, `KomorebiPaperIII/Transport.lean`, line 113.

`Komorebi.PaperIII.Transport.Connection.CocycleAt`
def, `KomorebiPaperIII/Transport.lean`, line 123.

`Komorebi.PaperIII.Transport.Connection.Flat`
def, `KomorebiPaperIII/Transport.lean`, line 127.

`Komorebi.PaperIII.Transport.Connection.cocycleDefect`
def, `KomorebiPaperIII/Transport.lean`, line 133.

`Komorebi.PaperIII.Transport.Connection.triangleHolonomy`
def, `KomorebiPaperIII/Transport.lean`, line 138.

8.22 Row 22: Flat minimal connections have trivial defect and triangle holonomy

Status and boundary. Proved

`Komorebi.PaperIII.Transport.Connection.triangleHolonomy_eq_refl_of_flat`
theorem, `KomorebiPaperIII/Transport.lean`, line 142.

`Komorebi.PaperIII.Transport.Connection.cocycleDefect_eq_refl_of_flat`
theorem, `KomorebiPaperIII/Transport.lean`, line 147.

8.23 Row 23: Explicit three-point connection with nontrivial loop

Status and boundary. Constructed and proved over the rationals

`Komorebi.PaperIII.Transport.doubleEquiv`
def, `KomorebiPaperIII/Transport.lean`, line 160.

`Komorebi.PaperIII.Transport.doubleEquiv_apply`
theorem, `KomorebiPaperIII/Transport.lean`, line 170.

`Komorebi.PaperIII.Transport.twistedThreePointConnection`
def, `KomorebiPaperIII/Transport.lean`, line 177.

Formal companion 1816

Return to Chapter IV

How to use this volume

A guide to the actual formal development. 119 Lean source files. 151 map rows. 1,164 mapped declarations. All 68 theorem-like manuscript results have full scoped coverage in the recorded formal contract. Read the eight tutorial chapters for the mathematical route, the coverage ledger for complete manuscript results, and the declaration catalog for exact source targets.

This guide relates the source, contract, theorem map, and saved kernel transcript. The verification chapter records the replay using pinned sources and its precise scope. Static reconciliation remains a distinct form of evidence.

1 How to read this formalization

1.1 What has been completed

Chapter IV studies one scalar cyclic family through several realizations. A residue-class projector selects coefficients. Its exponential sections become entire functions. Signed sections produce a distinguished denominator, whose reciprocal coefficients form parameterized polynomial families. The denominator's zeros then control canonical products, a diagonal determinant, coefficient asymptotics, and zeta functions.

The formal development follows these transitions explicitly. It does not identify a formal series with an analytic function by notation alone. It proves summation bridges, matches ordinary and factorial-normalized coefficients, and carries zero multiplicities and logarithm choices into the analytic statements.

The completed formal contract has **68 full scoped manuscript results, zero partial, and zero unmapped**. The 151 map rows name 1,164 distinct declarations: 953 theorems and 211 constructions. The saved fail-closed namespace audit reports 2,234 declarations, including 1,999 theorem declarations. These are different counts. The namespace includes supporting material beyond the explicit map, while the map includes definitions as well as theorems. Neither is a count of independent mathematical discoveries.

1.2 Formal verification and source reconciliation

Evidence	Verified scope
Formal execution	The source contract is supported by the preserved aggregate build, 43 semantic checks, exact target-kind resolution, and kernel audit. The verification chapter records the separate replay using pinned sources for all 118 production modules.
Static reconciliation	This guide checks source checksums, exact map and contract parity, lexical source locations, target sets in the audit source and saved transcript, dependency pins, and excerpt identity.

The transcript permits only the disclosed standard transitive axioms `propext`, `Classical.choice`, and `Quot.sound`. This is a claim about the audited Lean environment and its declarations, not an assertion of assumption-free mathematics. Hypotheses appear in declaration types and remain part of each theorem.

1.3 The main route through the source

Layer	Mathematical work	Main map rows
Formal algebra	Residue filters, signed cycles, reciprocal powers, Appell and theta families	1–46
Entire realization	Finite exponential sums, summation bridges, Wronskians, matrix and ODE laws	47–56
Zero geometry	Dominance, local zeros, exhaustion, multiplicity, exact rays, counting	57–87

Layer	Mathematical work	Main map rows
Zeta continuation	Lattice comparison, finite exceptions, Hurwitz models, branches	88–95
Products and moments	Multiplicity-indexed products, growth rigidity, logarithmic derivatives	96–109
Growth and determinant	Exact indicator, order, trace-class diagonal realization	110–120
Normalized sections	Products, logarithms, analytic powers, Taylor coefficients	121–132
Pole asymptotics	Principal parts, removal, nearest-circle estimates, orbit reduction	133–142
Final closure modules	Pointwise filters and addition, branch laws, operator bridge, order one, determinants, hypergeometric and quotient exponentials	143–151

This ordering is a reading route, not the exact import order. The final nine modules supply 57 mapped declarations linking 15 manuscript records to their analytic or literal displayed forms.

1.4 Reading a Lean declaration

An expression such as `(hN : 0 < N)` is an explicit hypothesis. Braces indicate implicit arguments whose values Lean may infer. They do not erase hypotheses. A proposition such as `HasSum f x` asserts convergence of the indexed sum to the displayed value. A bare `tsum` is an operation with a total definition and does not, by itself, assert that a series converges. The same distinction applies to `Multipliable` and an infinite product.

Formal power series, polynomials, complex functions, and continuous linear maps inhabit different types. The transition between them is usually the mathematically important theorem. In this guide, a short final proof often rests on substantial earlier modules. A proof of the final Hadamard identity in two lines is not the whole product argument.

The code excerpts are literal source intervals, including their proofs. They are reading excerpts inside the original module context, not independent files that can be pasted without imports, variables, namespace declarations, or local instances. The complete source is supplied. The excerpt manifest records each original file, line interval, file hash, excerpt hash, and display hash.

1.5 Boundaries that completion preserves

Imported standard fact 11.1 remains imported and is outside the 68-result contract. The checked order proofs do not need it. The work does not claim universal simplicity of all zeros, positivity of every reduced zero, a full displacement expansion, or a zeta functional equation. Eventual simplicity and exact asymptotic statements are proved with their stated ranges. Nearest-pole results keep their integer reciprocal-order and local pole hypotheses. Complex powers use a formal series, a normalized germ, or one fixed holomorphic logarithm on the stated domain.

Chapter IV's diagonal determinant is a concrete scalar-family specialization. It is not the general bounded-operator theory allocated to Chapter VI, the arithmetic interpolation theory of Chapter IX, or the abstract completion questions of Chapter X.

2 Coefficient algebra and normalization

2.1 The projector acts on coefficients

For a formal series $f(X) = \sum_n a_n X^n$, the cyclic projector retains exactly those coefficients for which $n \equiv j \pmod N$. The implementation uses the total natural-number remainder operation. Idempotence makes sense without a positive-order assumption. The finite resolution over $0 \le j < N$ requires $N > 0$.

Source: KomorebiPaperIV/CyclicFilters.lean.

```
def cyclicProjector (N j : ℕ) (f : R⟦X⟧) : R⟦X⟧ :=
  PowerSeries.mk fun n => if n % N = j % N then PowerSeries.coeff n f else 0
```

Source: KomorebiPaperIV/CyclicFilters.lean.

```
theorem cyclicProjector_idempotent (N j : ℕ) (f : R⟦X⟧) :
    cyclicProjector N j (cyclicProjector N j f) = cyclicProjector N j f := by
  ext n
  by_cases h : n % N = j % N <;> simp [h]
```

The proof of idempotence is coefficientwise extensionality. After selecting an index, a case split determines whether the residue matches. This is a universal identity in the source's context of a commutative semiring, not a computation on a bounded list of coefficients.

Source: KomorebiPaperIV/CyclicFilters.lean.

```
theorem sum_cyclicProjector {N : ℕ} (hN : 0 < N) (f : R⟦X⟧) :
    (∑ j ∈ Finset.range N, cyclicProjector N j f) = f := by
  ext n
  rw [map_sum]
  rw [Finset.sum_eq_single (n % N)]
  · simp [Nat.mod_eq_of_lt (Nat.mod_lt n hN)]
  · intro j hj hne
    have hjN : j < N := Finset.mem_range.mp hj
    have hmod : j % N = j := Nat.mod_eq_of_lt hjN
    have hres : n % N ≠ j % N := by simpa [hmod] using hne.symm
    simp [hres]
  · exact fun hmem => (hmem (Finset.mem_range.mpr (Nat.mod_lt n hN))).elim
```

The positive-order hypothesis ensures that n mod N lies in the finite index set. The sum has exactly one surviving term. This is also why the proof cannot simply discard the $N = 0$ boundary.

2.2 Multiplication adds residue labels

A product of two pure packets has residue equal to the sum of their labels modulo N. The full product law first reconstructs each factor from its packet sum, distributes the product, and projects every pair. Nonmatching label pairs vanish. The displayed Lean proof records this route directly.

Source: KomorebiPaperIV/CyclicFilters.lean.

```
theorem cyclic_product_law {N : ℕ} (hN : 0 < N) (k : ℕ) (f g : R⟦X⟧) :
    cyclicProjector N k (f * g) =
      ∑ i ∈ Finset.range N, ∑ j ∈ Finset.range N,
        if (i + j) % N = k % N then
          cyclicProjector N i f * cyclicProjector N j g
        else 0 := by
  calc
    cyclicProjector N k (f * g) =
        cyclicProjector N k
          ((∑ i ∈ Finset.range N, cyclicProjector N i f) *
            (∑ j ∈ Finset.range N, cyclicProjector N j g)) := by
      rw [sum_cyclicProjector hN, sum_cyclicProjector hN]
    _ = ∑ i ∈ Finset.range N, ∑ j ∈ Finset.range N,
          if (i + j) % N = k % N then
            cyclicProjector N i f * cyclicProjector N j g
          else 0 := by
      rw [Finset.sum_mul]
      simp_rw [Finset.mul_sum]
      rw [cyclicProjector_sum]
      apply Finset.sum_congr rfl
      intro i hi
      rw [cyclicProjector_sum]
      apply Finset.sum_congr rfl
      intro j hj
      by_cases hlabel : (i + j) % N = k % N
      · simp only [hlabel, ↓reduceIte]
        rw [cyclicProjector_eq_of_mod_eq (i := k) (j := (i + j) % N)
          (by simpa using hlabel.symm)]
        exact cyclicProjector_product_packet N i j f g
      · simp only [hlabel, ↓reduceIte]
        exact cyclicProjector_product_other (R := R) (fun h => hlabel h.symm) f g
```

No analytic interchange occurs here. Every coefficient of a formal product is a finite convolution, and the outer packet decomposition is finite. The pointwise counterpart, including covariance on invariant domains, is supplied later by row 143.

2.3 Transfer and signed sections

The transfer and signed coefficient selectors are deliberately separated from their exponential-generating normalization.

Source: KomorebiPaperIV/SectionCycles.lean.

```
def transferSectionCoeff (N j : ℕ) (lambda : R) (n : ℕ) : R :=
  if n % N = j then lambda ^ n else 0
```

Source: KomorebiPaperIV/SectionCycles.lean.

```
def signedSectionCoeff (N j : ℕ) (n : ℕ) : R :=
  if n % N = j then (-1 : R) ^ (n / N) else 0
```

The transfer selector contributes λ^n in one residue class. The signed selector contributes $(-1)^{\lfloor n/N \rfloor}$. The surrounding `exponentialGeneratingSeries` construction divides the nth selected coefficient by $n!$. Thus the signed section is

$$D_{N,j}(z) = \sum_{q \geq 0} \frac{(-1)^q z^{Nq+j}}{(Nq+j)!}, \qquad 0 \leq j < N.$$

Differentiating shifts the residue label downward. At label zero, crossing the period contributes a minus sign.

Source: KomorebiPaperIV/SectionCycles.lean.

```
theorem derivative_signedSection_zero {N : ℕ} (hN : 0 < N) :
    PowerSeries.derivative R (signedSection (R := R) N 0) =
      -signedSection (R := R) N (N - 1) := by
  rw [signedSection, derivative_exponentialGeneratingSeries, signedSection]
  ext n
  simp only [coeff_exponentialGeneratingSeries, map_neg]
  rw [signedSectionCoeff_succ_zero hN]
  ring
```

For a full period, the signed family solves the corresponding negative cyclic differential equation. The formal derivative cycle is proved before the entire-function derivative cycle. The later analytic bridge ensures that the same normalization appears in both.

2.4 Reduced and original variables

The distinguished denominator is the signed section with residue label zero in the original variable. It is written in a reduced variable $w = z^N$ through

$$D_N(z) = \Delta_N(z^N), \qquad \Delta_N(w) = \sum_{n \geq 0} \frac{(-1)^n w^n}{(Nn)!}.$$

Source: KomorebiPaperIV/ReciprocalCore.lean.

```
def reducedDenominator (N : ℕ) : R⟦X⟧ :=
  PowerSeries.mk fun n =>
    algebraMap ℚ R ((-1 : ℚ) ^ n / ((N * n).factorial : ℚ))
```

The reciprocal family is generated formally by the negative logarithm of the unit series Δ_N. Its constant coefficient is one, which is the algebraic condition needed to define the normalized logarithm and reciprocal family.

Source: KomorebiPaperIV/ReciprocalCore.lean.

```
def reciprocalSeries (N : ℕ) (r : R) : R⟦X⟧ :=
  formalExpFamily (negativeLogDenominator (R := R) N) r
```

Two normalizations coexist. Write

$$\Delta_N(w)^{-r} = \sum_{n\ge 0} b_n(r) w^n = \sum_{n\ge 0} P_{N,n}(r) \frac{w^n}{(Nn)!}.$$

Then $P_{N,n}(r) = (Nn)! b_n(r)$. The source's `reciprocalOrdCoeff` denotes the ordinary coefficient, while `reciprocalCoeff` uses `blockCoeff` and the $(Nn)!$ normalization.

Source: KomorebiPaperIV/ReciprocalCore.lean.

```
def reciprocalCoeff (N n : ℕ) (r : R) : R :=
  blockCoeff N n (reciprocalSeries N r)
```

The parameter-addition law has binomial factors at the block indices, not ordinary $\binom{n}{q}$ factors.

Source: KomorebiPaperIV/ReciprocalCore.lean.

```
theorem reciprocalCoeff_addition (N n : ℕ) (r s : R) :
    reciprocalCoeff N n (r + s) =
      ∑ q ∈ Finset.range (n + 1),
        ((N * n).choose (N * q) : R) *
          reciprocalCoeff N q r * reciprocalCoeff N (n - q) s := by
  exact reciprocal_block_convolution
    (constantCoeff_negativeLogDenominator N) N n r s
```

Dividing this identity by $(Nn)!$ recovers the ordinary Cauchy convolution for the b_n. Multiplying by the wrong factorial changes the theorem. The source makes that conversion an explicit named construction.

2.5 Newton recurrence and its inputs

The logarithmic coefficients `kappaCoeff` encode the logarithmic derivative of the reduced denominator. The formal differential identity for the reciprocal series gives a recurrence for its ordinary coefficients.

Source: KomorebiPaperIV/ReciprocalCore.lean.

```
theorem reciprocalOrdCoeff_newton (N : ℕ) (r : R) (n : ℕ) :
    (n + 1 : R) * reciprocalOrdCoeff N (n + 1) r =
      r * ∑ p ∈ Finset.antidiagonal n,
        reciprocalOrdCoeff N p.1 r * kappaCoeff N (p.2 + 1) := by
  simpa [reciprocalOrdCoeff, kappaCoeff] using
    reciprocalSeries_coefficient_recurrence (R := R) N r n
```

The antidiagonal index contains pairs with sum n. Its second component is shifted by one to match the logarithmic derivative. This is the same recurrence later specialized to a literal Hessenberg determinant. It is not necessary to assume that any zero sum converges at this stage. Zero moments are subsequently proved equal to these algebraic coefficients.

2.6 Appell and theta families

The generic Appell polynomial is built from a formal exponential family and then differentiated as a polynomial.

Source: KomorebiPaperIV/Appell.lean.

```
def formalAppellPolynomial (L : R⟦X⟧) (r : R) (m : ℕ) : Polynomial R :=
  appellPolynomial (fun q => egfCoeff q (formalExpFamily L r)) m
```

Source: KomorebiPaperIV/Appell.lean.

```
theorem derivative_formalAppellPolynomial (L : R⟦X⟧) (r : R) (m : ℕ) :
    Polynomial.derivative (formalAppellPolynomial L r (m + 1)) =
      Polynomial.C (m + 1 : R) * formalAppellPolynomial L r m := by
  exact derivative_appellPolynomial _ m
```

The derivative law holds because polynomial differentiation is finite. The residue-specialized Appell family also has parameter addition, covariance, a sparse coefficient formula, and an inverse differential-operator action. Row 146 proves that the ordinary-derivative and factorial/Hasse encodings agree. Both interpretations have an explicit bridge.

The theta construction combines two rescalings of the reciprocal family.

Source: KomorebiPaperIV/ThetaCore.lean.

```
def thetaSeries (N : ℕ) (u : R) : R⟦X⟧ :=
  PowerSeries.rescale (-u ^ N) (reciprocalSeries N 1) *
    PowerSeries.rescale (-1) (reciprocalSeries N u)
```

The rescaling factors $-u^N$ and -1 are part of the definition. Theta reconstruction, parameter factors, polynomial degree, and Newton recurrence are covered by rows 22–23 and 43–45. A later analytic zero-data formula identifies their coefficients with the corresponding Bell expressions. The formal identities remain available without importing that analytic interpretation.

3 From formal series to entire functions

3.1 Finite exponential sums are the analytic realization

The entire transfer function is defined as a finite root-weighted exponential sum.

Source: KomorebiPaperIV/EntireBridge.lean.

```
def entireTransfer (N j : ℕ) (omega lambda : ℂ) (z : ℂ) : ℂ :=
  (N : ℂ)⁻¹ *
    ∑ l ∈ Finset.range N,
      ((omega ^ j)⁻¹) ^ l * Complex.exp ((lambda * omega ^ l) * z)
```

The primitive root, residue index, and spectral parameter appear explicitly. The finite sum is entire because each exponential summand is entire. The crucial next step is a `HasSum` theorem identifying its Taylor coefficients with the formal transfer section.

Source: KomorebiPaperIV/EntireBridge.lean.

```
theorem hasSum_entireTransfer {N j : ℕ} (hN : 0 < N) (hj : j < N)
    {omega : ℂ} (homega : IsPrimitiveRoot omega N) (lambda z : ℂ) :
    HasSum (fun n => PowerSeries.coeff n (transferSection N j lambda) * z ^ n)
      (entireTransfer N j omega lambda z) := by
  simpa only [finiteRootAverage_rescale_exp_eq_transferSection hN hj homega]
    using hasSum_finiteRootAverage N j omega lambda z
```

This theorem has positive order, a residue index in range, and a primitive root as hypotheses. It provides a convergent series at every complex argument. It also permits independence-of-root proofs: two finite sums obtained from allowed root choices have the same summing series, hence the same value by uniqueness of a sum.

The signed analytic realization additionally chooses ρ with $\rho^N = -1$. The factor ρ^{-j} compensates for the residue label. It cannot be removed without changing the normalization of the basis. The independent-root statements compare the resulting functions under exactly the root assumptions they require.

3.2 Initial data and Wronskians

The formal cycle specifies derivatives at zero, while the analytic bridge transfers them to iterated complex derivatives. For the normalized signed basis, the matrix of initial data is the identity. Constancy of the Wronskian then identifies the Wronskian with one for the stated $N > 1$ range.

Source: KomorebiPaperIV/Wronskians.lean.

```
theorem signedWronskian_eq_one {N : ℕ} (hN : 1 < N) {omega rho : ℂ}
    (homega : IsPrimitiveRoot omega N) (hrho : rho ^ N = -1) (z : ℂ) :
    analyticWronskian (fun j : Fin N => entireSigned N j.val omega rho) z = 1 := by
  rw [signedWronskian_constant hN homega]
  have hm : (fun k j : Fin N => deriv^[k.val]
      (entireSigned N j.val omega rho) 0) = (1 : Matrix (Fin N) (Fin N) ℂ) := by
    ext k j
```

```
    rw [entireSigned_initial_data (by omega) j.isLt k.isLt homega hrho]
    simp [Matrix.one_apply, Fin.ext_iff]
  rw [analyticWronskian, hm, Matrix.det_one]
```

The source does not conclude linear independence from an informal appeal to distinct exponentials alone. It factors the exponential jet matrix, handles its determinant, proves the Wronskian law, and identifies the normalized initial matrix. The ODE modules then describe the corresponding realization of the solution space.

3.3 Companion matrices and finite algebras

The signed shift matrix has a negative carry across the cyclic boundary. Its powers encode paths through the residue labels. This provides a companion realization of the signed differential cycle, explicit fundamental-matrix entries, addition and inversion identities, and a spectrum controlled by the chosen roots.

There are two compatible algebra models. In the cyclic quotient algebra the generator satisfies $x^N = 1$. In the signed quotient it satisfies $x^N = -1$. Earlier modules construct the quotient algebras and their power bases, then prove formal exponential identities. Row 151 equips the finite-dimensional quotients with coefficient norm topologies and proves convergence of the actual exponential series. Consequently, the analytic identity in a finite algebra is more than equality of formal coefficient expressions.

3.4 Why the final pointwise addition theorem matters

A bivariate addition law for formal series is an algebraic identity among coefficients. It does not on its own prove equality of evaluated functions at arbitrary complex arguments. The completed source includes both. Row 144 obtains the actual transfer and signed addition formulas, retaining the signed carry factor forced by $\rho^N = -1$.

The useful reading order is: formal product and addition identities, the entire summation bridge, then the pointwise closure. Keeping these stages visible prevents a notation change from hiding the convergence theorem. It also makes the formal statements reusable in contexts where no analytic topology has been chosen.

3.5 Growth order and indicator geometry

The entire functions are finite exponential sums. Their exponents form regular polygon configurations in the complex plane. In directions with a unique exposed vertex, one exponential dominates. On tie directions, cancellation can obstruct a naive pointwise lower bound, so the exact indicator proof uses aligned radii in addition to uniform sector estimates.

Rows 110–115 prove sharp order, exponential type, indicator geometry, uniform dominance in sectors, and the exact directional indicator. These results are proved in the source. Imported standard fact 11.1 remains recorded separately and is not required for the checked order proofs. The guide therefore does not count that imported fact among the 68 completed results.

4 Zero geometry, exhaustion, and counting

4.1 Local zeros are only the start

The two-term dominance analysis separates the leading pair of exponentials from a controlled remainder. Near the cancellation lattice of the leading pair, the perturbation argument constructs nearby zeros and estimates their displacement. The remainder bounds include derivative information, which supports simplicity and the first correction term.

A local construction alone would not justify counting all zeros. The source therefore adds sector confinement, sector exhaustion, rotation, and global exhaustion. Those modules show that sufficiently large zeros belong to the constructed symmetry strings. Finite exceptional zeros remain present throughout the later counting and product arguments.

The following division of labor is useful when reviewing the proof path:

Stage	Output	Map rows
Remainder control	Canonical polygon gap, strip and disk bounds, normalized jets	58–60, 67
Local perturbation	Nearby zeros, displacement, derivative estimates	57, 61
Global coverage	Sector confinement, exhaustion, rotational orbits	62–65
Simplicity and rays	All sufficiently large zeros simple and on exact rays	66, 68
Reduced variable	Zero and multiplicity transfer under $z \mapsto z^N$	69–71
Complete enumeration	Constructed tail plus finite exceptions	75–79, 81
Refined phase	Real leading correction and alternating derivative sign	82–84

4.2 Named enumeration is constructed, not assumed

The `SignedZeroEnumeration` structure packages a positive simple tail, its lattice windows, rotation orbits, and the finite-complement information needed downstream. Existence of this structure is proved for every $N \geq 2$, with the exact order-two cosine model handled separately.

A downstream theorem may accept an enumeration as input because it is reusable for any structure with the required fields. That is different from assuming the final zero theorem. The manuscript specializations instantiate it using `canonicalZeroEnumeration`, constructed from the preceding analytic results. To audit a final theorem, follow that constructor as well as the generic lemma.

4.3 Multiplicity enters the actual counting function

The disk counting function sums `analyticOrderNatAt` over the actual finite zero set. The source proves that these analytic orders are finite for the nonzero entire denominators. Thus replacing an extended order by its natural-number value does not silently discard an infinite order.

The full original-variable counting theorem keeps every exceptional multiplicity:

Source: `KomorebiPaperIV/FullZeroCounting.lean`.

```
theorem canonicalSignedDenominator_zero_counting {N : ℕ} (hN : 2 ≤ N) :
    ∃ K : ℝ, 0 < K ∧ ∀ R : ℝ, 0 ≤ R →
      |(analyticZeroCount (canonicalSignedDenominator N) R : ℝ) -
```

```
      ((N : ℝ) * Real.sin (Real.pi / N) / Real.pi) * R| ≤ K := by
let e := canonicalZeroEnumeration hN
let W := finiteWeight (analyticOrderNatAt (canonicalSignedDenominator N)) e.exceptions
refine ⟨(W : ℝ) + N * ((e.shift : ℝ) + 2) + 1, by positivity, ?_⟩
intro R hR
have hw := e.weighted_count_bounds hN hR
have hl : (N : ℝ) * sequenceCounting e.root R ≤ analyticZeroCount (canonicalSignedDenominator N)
 ↪  R := by
  exact_mod_cast hw.1
have hu : (analyticZeroCount (canonicalSignedDenominator N) R : ℝ) ≤
    N * sequenceCounting e.root R + W := by exact_mod_cast hw.2
have hc := (lattice_window_counting (div_pos Real.pi_pos (signed_sine_pos hN))
  e.shift e.root e.windows hR).2
rw [abs_le] at hc ⊢
have he : ((N : ℝ) * Real.sin (Real.pi / N) / Real.pi) * R =
    N * (R / (Real.pi / Real.sin (Real.pi / N))) := by field_simp
rw [he]
have hn := Nat.cast_nonneg (α := ℝ) N
constructor <;> nlinarith
```

The proof compares the full count with the simple tail count and adds a finite exception weight. The final error constant contains both that weight and the tail shift. It is uniform for all nonnegative radii, not only an eventual asymptotic abbreviation.

The corresponding reduced-variable count is

$$n_{\Delta_N}(R) = \frac{\sin(\pi/N)}{\pi} R^{1/N} + O(1), \qquad N \geq 2.$$

The original-variable constant is $N \sin(\pi/N)/\pi$. These constants differ because one original symmetry orbit collapses to one reduced zero and the radius changes by the Nth power. Both transformations are proved in the counting modules.

4.4 Sharp summability thresholds

Rows 72 and 79 distinguish a tail estimate from the full theorem. The full reciprocal-power sums range over actual zeros with their analytic multiplicities. Their sharp thresholds are $s > 1$ for the original denominator and $s > 1/N$ for the reduced denominator. The boundary divergences are included. Removing finite exceptions is justified by a proved summability equivalence, not by silently redefining the zero set.

For $N \geq 2$, reduced reciprocal zeros are absolutely summable because $1 > 1/N$. This precise consequence feeds the genus-zero product and the trace-class diagonal model. It would fail as a route at $N = 1$, where the denominator is exponential and the analytic situation is handled separately.

4.5 What eventual simplicity leaves open

The source proves eventual simplicity and exact rays for sufficiently large zeros. It does not replace this with a blanket assertion that all zeros are simple. A finite exceptional zero can have multiplicity greater than one, and the canonical product includes it accordingly. A finite exceptional zero can also lie outside the asymptotic positive-ray description. The global product and zero-zeta constructions are designed to retain such exceptions.

The first displacement correction and its exponential error are likewise specific proved statements. They do not constitute an all-orders expansion. The explicit cubic correction in row 84 is a specialization with exact spectral gap, lattice centers, and phase, not a numerical fit to plotted zeros.

5 Canonical products, moments, and the diagonal model

5.1 The index set records multiplicity

The product index is a dependent pair. Its first component chooses an actual zero. Its second chooses one of the copies counted by that zero's analytic multiplicity.

Source: KomorebiPaperIV/FullCanonicalProduct.lean.

```
def ZeroMultiplicityIndex (f : ℂ → ℂ) :=
  Σ z : {z : ℂ // f z = 0}, Fin (analyticOrderNatAt f z)
```

Source: KomorebiPaperIV/FullCanonicalProduct.lean.

```
def fullCanonicalProduct (f : ℂ → ℂ) (w : ℂ) : ℂ :=
  ∏' i : ZeroMultiplicityIndex f, (1 - w / indexedZero i)
```

For a zero of order m, the dependent finite type contributes exactly m copies of its factor. The construction therefore does not require a global simplicity assumption. Its factor uses the reduced variable w.

5.2 Absolute summability precedes the product theorem

The weighted reciprocal-zero sum is converted to a sum over the multiplicity index.

Source: KomorebiPaperIV/FullCanonicalProduct.lean.

```
theorem zeroMultiplicity_reciprocal_summable {f : ℂ → ℂ} (hf : ZeroPowerSummable f 1) :
    Summable (fun i : ZeroMultiplicityIndex f => 1 / ‖indexedZero i‖) := by
  apply (summable_sigma_of_nonneg (fun i : ZeroMultiplicityIndex f => by positivity)).mpr
  constructor
  · intro z
    exact (hasSum_fintype _).summable
  · simpa only [indexedZero, tsum_fintype, Finset.sum_const, Finset.card_univ,
      Fintype.card_fin, nsmul_eq_mul, mul_one_div, ZeroPowerSummable, Real.rpow_one] using hf
```

The next source results prove that the perturbations w/ρ are absolutely summable, the product is multipliable, convergence is uniform on compact sets and locally uniform, and the product defines an entire function. These are needed analytic statements. Writing an infinite product symbol does not establish them.

The product's zeros and multiplicities are then identified. Dividing the denominator by the product gives an entire, nonvanishing quotient. Growth estimates and a sublinear rigidity argument force the normalized quotient to be one. Only after those steps is the final identity short:

Source: KomorebiPaperIV/HadamardIdentification.lean.

```
theorem entireReducedDenominator_eq_fullCanonicalProduct {N : ℕ} (hN : 2 ≤ N) :
    entireReducedDenominator N = fullCanonicalProduct (entireReducedDenominator N) := by
  funext z
  have he := (entireReducedDenominator_product_quotient hN).2.2.2 z
  rw [entireReducedDenominator_quotient_eq_one hN, Pi.one_apply, mul_one] at he
  exact he.symm
```

The proof depends on the product-quotient theorem and the quotient-equals-one theorem. Those in turn depend on convergence, exact multiplicities, growth reduction, and Jensen–Poisson estimates. Rows 96–102 expose these stages in the map. The earlier tail product in row 74 is one ingredient, not the complete identification.

5.3 Recovering coefficients from zeros

After the full product is identified, its logarithmic derivative gives a convergent Mittag–Leffler expansion away from the zeros. Rows 104–109 match derivatives and analytic Taylor coefficients with the actual multiplicity-weighted zero moments. The coefficients previously called `kappaCoeff` are thereby identified with zero sums.

This direction matters. The coefficient recurrence was proved algebraically before any product formula. The analytic argument does not define the denominator's coefficients by a conjectured zero expansion. It proves that the coefficients already defined equal the zero data. Tangent coefficients, reciprocal Bell formulas, and theta Bell formulas then inherit exact normalizations through named bridges.

Normalized nonzero residue sections need their own growth and zero arguments. Rows 121–132 cover their entire realization, zero-growth estimates, summability, product identification, logarithms, analytic powers, and Taylor-differential conversions. They are not inferred merely by relabeling the distinguished denominator.

5.4 A concrete trace-class definition

The source uses a rank-one summability definition for Hilbert trace class.

Source: `KomorebiPaperIV/DiagonalNuclear.lean`.

```
def IsHilbertTraceClass {E : Type*} [NormedAddCommGroup E] [InnerProductSpace ℂ E]
    (T : E →L[ℂ] E) : Prop :=
  ∃ (ι : Type) (x y : ι → E), Summable (fun i => ‖x i‖ * ‖y i‖) ∧
    HasSum (fun i => rankOne ℂ (x i) (y i)) T
```

The witness is a family of rank-one operators with summable products of vector norms and a sum equal to the continuous linear map. For the diagonal model, reciprocal reduced zeros form the eigenvalue family. Their absolute summability is proved from the zero theorem, then used to build the operator and its trace-class witness.

The source also proves the basis action, power traces, finite compression determinants, and their limit. The exact determinant identity is:

Source: `KomorebiPaperIV/DiagonalFredholm.lean`.

```
theorem reducedZeroOperator_fredholm {N : ℕ} (hN : 2 ≤ N) (w : ℂ) :
    diagonalFredholmDeterminant (reducedZeroEigenvalue N) w = entireReducedDenominator N w := by
  calc
    _ = fullCanonicalProduct (entireReducedDenominator N) w := by
      simp only [diagonalFredholmDeterminant, reducedZeroEigenvalue, fullCanonicalProduct,
        ↪ div_eq_mul_inv]
    _ = _ := congrFun (entireReducedDenominator_eq_fullCanonicalProduct hN).symm w
```

Here `diagonalFredholmDeterminant` is the defined diagonal specialization, backed by convergence of finite compressions. The identity follows by matching its factors to the multiplicity-indexed canonical

product. It does not assert a general Fredholm determinant theory for arbitrary operators or conceal such a theorem behind the name.

5.5 Complete symmetric functions

The reciprocal of the diagonal determinant has complete homogeneous symmetric-function coefficients. Rows 119–120 handle the finite combinatorics and the infinite summability argument. The latter cannot be replaced by an unqualified passage from finite-dimensional symmetric polynomials to infinitely many variables. The summable eigenvalue family is the analytic input that makes the coefficient expression meaningful.

This yields three linked descriptions of the same scalar family: formal reciprocal coefficients, zero moments and symmetric functions, and a diagonal determinant model. Each identification is a theorem with a specified source and normalization.

6 Pole coefficients and zero zeta functions

6.1 Nearest-pole estimates retain a local analytic contract

For a positive integral reciprocal order, a simple denominator zero produces a pole of finite order. The source constructs principal parts, proves their uniqueness, removes them, and bounds the Taylor coefficients of the analytic remainder. This produces the nearest-circle coefficient expansion with a controlled error.

The generic coefficient bound below states its local principal-part assumption explicitly. Later source results construct the required principal parts for the manuscript specialization.

Source: `KomorebiPaperIV/NearestPoleExpansion.lean`.

```
theorem reciprocalCoeff_nearest_pole_bound {N : ℕ} (hN : 0 < N)
    {S : Finset ℂ} (hS : ∀ ρ ∈ S, ρ ≠ 0) (a : ℂ → ℕ → ℂ) (r : ℕ)
    {R R₂ : ℝ} (hR : 0 < R) (hR₂ : R < R₂)
    (hzeros : ∀ z : ℂ, ‖z‖ < R₂ → canonicalSignedDenominator N z = 0 → z ∈ S)
    (hlocal : ∀ ρ ∈ S, ∃ C : ℝ, ∀ᶠ z in 𝓝[≠] ρ,
      ‖(canonicalSignedDenominator N z ^ r)⁻¹ - polePrincipalPart a r ρ z‖ ≤ C) :
    ∃ C : ℝ, ∀ n : ℕ,
      ‖reciprocalCoeff N n (r : ℂ) - ((N*n).factorial : ℂ) *
        ∑ ρ ∈ S, ∑ k ∈ Finset.range r, a ρ (k+1) * ((N*n+k).choose k : ℂ) * ρ⁻¹ ^ (N*n)‖ ≤
      C * ((N*n).factorial : ℝ) * R⁻¹ ^ (N*n) := by
  have hf : Differentiable ℂ (canonicalSignedDenominator N) := fun z => (analyticAt_entireSigned
   ↪  ..).differentiableAt
  obtain ⟨C, hC⟩ := nearest_pole_taylor_bound hf (by rw [canonicalSignedDenominator_zero hN];
   ↪  exact one_ne_zero)
    hS a r hR hR₂ hzeros hlocal
  refine ⟨C, fun n => ?_⟩
  rw [reciprocalCoeff_analyticTaylor hN, ← mul_sub, norm_mul, Complex.norm_natCast]
  have h := mul_le_mul_of_nonneg_left (hC (N*n)) (show (0 : ℝ) ≤ (N*n).factorial by positivity)
  simpa only [div_eq_mul_inv, inv_pow, mul_assoc, mul_comm, mul_left_comm] using h
```

The finite set S contains the zeros inside the larger disk. The inner radius R is strictly smaller than the outer radius R_2. The assumption `hlocal` states that after subtracting the proposed principal part, the function is locally bounded near each selected pole. These are the hypotheses needed by the removable-singularity and Taylor-bound route.

The conclusion is in the manuscript's block normalization. Its leading sum and error both carry $(Nn)!$. The factor ρ^{-Nn} arises from extracting the original-variable coefficient at degree Nn. The binomial coefficient records the higher pole order. Omitting any of these factors changes the asymptotic statement.

6.2 Principal parts are constructed before the final specialization

Rows 133–138 provide coefficient bounds, principal-part coefficients, pole removal, Taylor recovery, simple-pole expansions, and uniqueness. Row 139 supplies the full nearest-pole expansion. Row 140 isolates the leading term under its stated dominance hypotheses. Row 141 reduces symmetry orbits on the nearest circle. Row 142 gives the secant specialization.

This route is conditional in the mathematically ordinary sense that the theorem retains its hypotheses on reciprocal order, selected zeros, radii, and simplicity where used. Formal completion proves those

scoped statements. It does not delete the assumptions or claim that every parameter and every zero configuration satisfies them.

6.3 Absolute zero zeta and branch-dependent zeta differ

The absolute zero zeta uses terms of the form

$$m(\rho)\exp(-s\log|\rho|),$$

where $m(\rho)$ is analytic multiplicity and the real logarithm of the norm is unambiguous. The reduced denominator has sharp absolute-convergence half-plane $\operatorname{Re} s > 1/N$. The original denominator has $\operatorname{Re} s > 1$. Local uniform convergence and holomorphy are proved, as is failure of absolute convergence on and to the left of the respective boundaries.

A branch-dependent symmetry-orbit zeta instead assigns complex logarithms. Its terms carry argument information. The source requires compatible logarithm choices and records the phase factors in its continuation. These are related constructions, not interchangeable notations for one function.

6.4 Continuation is an explicit model plus an entire correction

Exponential displacement of the positive zero sequence from a lattice makes the difference of the two zeta sums entire. The source proves a locally uniform majorant on bounded sets of the parameter. It then constructs the lattice correction, finite missing lattice prefix, and finite exceptional-zero contribution.

Source: KomorebiPaperIV/ZeroZetaContinuation.lean.

```
def reducedZetaCorrection {N : ℕ} (hN : 2 ≤ N) (s : ℂ) : ℂ :=
  let e := canonicalZeroEnumeration hN
  e.reducedExceptionZeta (by omega) s + e.latticeCorrection ((N : ℂ) * s) -
    e.latticePrefix ((N : ℂ) * s)
```

The finite exception term retains multiplicity. The correction and prefix use the scaled parameter Ns because reduced roots are Nth powers of the positive original roots. The equality with the Hurwitz lattice model is proved in the initial convergence domain:

Source: KomorebiPaperIV/ZeroZetaContinuation.lean.

```
theorem entireReducedDenominator_zeta_eq_hurwitz {N : ℕ} (hN : 2 ≤ N)
    {s : ℂ} (hs : 1 / (N : ℝ) < s.re) :
    absoluteZeroZeta (entireReducedDenominator N) s =
      hurwitzLatticeModel (Real.pi / Real.sin (Real.pi / N)) N s + reducedZetaCorrection hN s :=
      ↪ by
  let e := canonicalZeroEnumeration hN
  have hsN : 1 < ((N : ℂ) * s).re := by
    simp only [Complex.mul_re, Complex.natCast_re, Complex.natCast_im, zero_mul, sub_zero]
    exact (div_lt_iff₀ (by exact_mod_cast (show 0 < N by omega) : (0 : ℝ) < N)).mp hs |>.trans_eq
    ↪ (mul_comm _ _)
  rw [e.reducedZeta_decomposition hN hs, e.root_zeta_eq_model hN hsN]
  simp only [hurwitzLatticeModel, Nat.cast_one, one_mul, reducedZetaCorrection]
  dsimp [e]
  ring
```

The continuation is then defined by the meromorphic model plus its entire correction.

Source: KomorebiPaperIV/ZeroZetaContinuation.lean.

```
theorem reducedZetaContinuation_meromorphic {N : ℕ} (hN : 2 ≤ N) (s : ℂ) :
    MeromorphicAt (reducedZetaContinuation hN) s :=
  (hurwitzLatticeModel_meromorphicAt _ _ s).add
    ((reducedZetaCorrection_entire hN).analyticAt s).meromorphicAt
```

This theorem is short because its two analytic ingredients have already been proved. The continuation is tied to the original sum by the preceding equality. The source also proves holomorphy off the pole, exact residues, and meromorphic order -1 at the nonzero-residue pole. It does not merely define a meromorphic function and call it a continuation.

6.5 Derivative weights and boundary orders

Derivative-weighted sums use complex derivative values, not only their moduli. A lower bound on the derivative at sufficiently large zeros gives exponential decay of its inverse powers. For $N \geq 3$ and positive integral derivative weight, this dominates every fixed polynomial weight and yields an entire sum, assuming logarithm arguments remain in a fixed bounded interval.

The order-two case is separate: the derivative magnitude does not provide the same exponential gain, and the theorem retains a right half-plane of convergence. Rows 85–87 state and prove this distinction. Exact order-two and order-four zeta models are separately identified in rows 94–95.

7 The nine modules that close the manuscript contract

7.1 Row 143: actual pointwise projectors

The earlier coefficient projector and formal Fourier average are joined to the literal finite average on functions.

Source: KomorebiPaperIV/PointwiseFilters.lean.

```
def pointwiseRootAverage (N j : ℕ) (omega : ℂ) (f : ℂ → ℂ) (z : ℂ) : ℂ :=
  (N : ℂ)⁻¹ * ∑ l ∈ Finset.range N, ((omega ^ j)⁻¹) ^ l * f (omega ^ l * z)
```

The projector law is proved for actual pointwise values:

Source: KomorebiPaperIV/PointwiseFilters.lean.

```
theorem pointwiseRootAverage_projector {N : ℕ} (hN : 0 < N) {omega : ℂ}
    (ho : IsPrimitiveRoot omega N) (i j : ℕ) (f : ℂ → ℂ) (z : ℂ) :
    pointwiseRootAverage N i omega (pointwiseRootAverage N j omega f) z =
      if j % N = i % N then pointwiseRootAverage N j omega f z else 0 := by
  exact pointwiseRootAverage_of_covariant hN ho (mapsTo_univ _ _) i j _
    (fun w _ => pointwiseRootAverage_covariant hN ho j f w) (mem_univ z)
```

On an invariant domain, the range characterization also tracks differentiability and equality restricted to that domain.

Source: KomorebiPaperIV/PointwiseFilters.lean.

```
theorem pointwiseRootAverage_range_iff {N : ℕ} (hN : 0 < N) {omega : ℂ}
    (ho : IsPrimitiveRoot omega N) {s : Set ℂ}
    (hs : MapsTo (fun z => omega * z) s s) (j : ℕ) {f : ℂ → ℂ}
    (hf : DifferentiableOn ℂ f s) :
    (∃ g : ℂ → ℂ, DifferentiableOn ℂ g s ∧ EqOn (pointwiseRootAverage N j omega g) f s) ↔
      ∀ z ∈ s, f (omega * z) = omega ^ j * f z := by
  constructor
  · rintro ⟨g, _, hg⟩ z hz
    rw [← hg (hs hz), ← hg hz]
    exact pointwiseRootAverage_covariant hN ho j g z
  · intro hc
    refine ⟨f, hf, fun z hz => ?_⟩
    simpa using pointwiseRootAverage_of_covariant hN ho hs j j f hc hz
```

The domain condition says multiplication by the primitive root maps the set into itself. This is needed to apply covariance repeatedly along an orbit without evaluating a domain-restricted hypothesis outside its scope. The proof of the reverse implication chooses the function itself as a preimage. The forward implication uses covariance of the finite root average. Row 143 also includes the full pointwise product law and coefficient-series summation, closing the formal-to-holomorphic clauses of results 3.1–3.3.

7.2 Row 144: arbitrary-argument addition

`PointwiseAddition` supplies the actual entire transfer addition theorem and the signed addition theorem for arbitrary complex arguments. The signed carry is derived from the relation $\rho^N = -1$. This completes results 4.4 and 5.5 together with their earlier formal rows. No unspecified analytic evaluation map is left between the bivariate formal identity and the pointwise equality.

7.3 Row 145: one fixed logarithm on the domain

A complex reciprocal power needs a logarithm choice. The source makes it part of the data:

Source: `KomorebiPaperIV/AnalyticReciprocalLaws.lean`.

```
def IsLogarithmOn (f L : ℂ → ℂ) (s : Set ℂ) : Prop :=
  DifferentiableOn ℂ L s ∧ ∀ z ∈ s, Complex.exp (L z) = f z
```

Source: `KomorebiPaperIV/AnalyticReciprocalLaws.lean`.

```
def logarithmPower (L : ℂ → ℂ) (r : ℂ) (z : ℂ) : ℂ :=
  Complex.exp (-r * L z)
```

For one chosen L, the parameter law follows directly from the exponential addition identity.

Source: `KomorebiPaperIV/AnalyticReciprocalLaws.lean`.

```
theorem logarithmPower_add (L : ℂ → ℂ) (r t z : ℂ) :
    logarithmPower L r z * logarithmPower L t z = logarithmPower L (r + t) z := by
  unfold logarithmPower
  rw [← Complex.exp_add]
  congr 1
  ring
```

Differentiation requires an open domain and a holomorphic logarithm of the actual denominator.

Source: `KomorebiPaperIV/AnalyticReciprocalLaws.lean`.

```
theorem reciprocal_fixed_log_derivative {N : ℕ} {L : ℂ → ℂ} {s : Set ℂ}
    (hs : IsOpen s) (hL : IsLogarithmOn (canonicalSignedDenominator N) L s)
    (r : ℂ) {z : ℂ} (hz : z ∈ s) :
    deriv (logarithmPower L r) z =
      r * analyticTransferTangent N z * logarithmPower L r z :=
  (hasDerivAt_logarithmPower hs hL r hz).deriv
```

The source also proves the differential Bell/Riccati identity at points where the denominator is nonzero. These statements close results 7.4, 8.4, and 8.5 alongside their formal coefficient laws. They do not choose unrelated logarithms for different parameters and then assert a branch-independent multiplicative law.

7.4 Row 146: ordinary derivatives and Hasse derivatives

The formal differential operator acts on polynomials, so its apparently infinite series truncates. There are two encodings: ordinary iterated derivatives and factorial-normalized Hasse derivatives. The bridge is explicit:

Source: KomorebiPaperIV/OperatorEncodingBridge.lean.

```
theorem truncatedDifferentialOperator_egfAction (A : R⟦X⟧) (p : Polynomial R) :
    truncatedDifferentialOperator p.natDegree A p =
      egfConstantCoeffAction (fun q => (q.factorial : R) * PowerSeries.coeff q A) p := by
  rw [truncatedDifferentialOperator_apply, egfConstantCoeffAction]
  apply Finset.sum_congr rfl
  intro q _
  have h := congrFun (Polynomial.factorial_smul_hasseDeriv (R := R) q) p
  change q.factorial • (Polynomial.hasseDeriv q p) = Polynomial.derivative^[q] p at h
  rw [← h]
  simp only [nsmul_eq_mul, map_mul, map_natCast]
  ring
```

The proof uses the identity relating the qth Hasse derivative to the ordinary qth derivative after multiplication by $q!$. The source then proves the forward action on the named residue Appell polynomial and its inverse.

Source: KomorebiPaperIV/OperatorEncodingBridge.lean.

```
theorem residueAppell_operator_inverse (N j : ℕ) (hN : 0 < N) (r : R) (m : ℕ) :
    truncatedDifferentialOperator m
        (PowerSeries.expand N hN.ne' (residuePowerSeries N j (-r)))
        (residueAppellPolynomialParam N j hN r m) = Polynomial.X ^ m := by
  rw [← residueAppell_operator_forward N j hN r m]
  exact truncatedDifferentialOperator_residuePowerSeries_inverse N j hN r m
    (by simp)
```

The inverse parameter is $-r$. The expansion of the residue series changes the differential powers by multiples of N. The polynomial degree makes the action finite, so the result does not require a Banach-space operator convergence theorem.

7.5 Row 147: the order-one tangent boundary

The order-one denominator is identified exactly:

Source: KomorebiPaperIV/TangentBoundary.lean.

```
theorem canonicalSignedDenominator_one (z : ℂ) :
    canonicalSignedDenominator 1 z = Complex.exp (-z) := by
  have h := entireSigned_independent_roots (N := 1) (j := 0) (by omega) (by omega)
    (canonicalPrimitiveRoot_isPrimitive (by omega)) IsPrimitiveRoot.one
    (canonicalSignedRoot_pow (by omega)) (show (-1 : ℂ) ^ 1 = -1 by simp) z
  change canonicalSignedDenominator 1 z = _ at h
  simpa [entireSigned, entireTransfer] using h
```

It follows that the transfer tangent is one and its coefficients have the corresponding degenerate form. This boundary case is joined to the earlier $N \geq 2$ convergence theorem to obtain every positive order.

Source: KomorebiPaperIV/TangentBoundary.lean.

```
theorem analyticTransferTangent_hasSum_all_orders {N : ℕ} (hN : 0 < N) {R : ℝ}
    (hn : ∀ w ∈ Metric.ball (0 : ℂ) R, entireReducedDenominator N w ≠ 0)
    {z : ℂ} (hz : z ^ N ∈ Metric.ball (0 : ℂ) R) :
    HasSum (fun n => transferTangentCoeff (R := ℂ) N n /
      ((N * n + N - 1).factorial : ℂ) * z ^ (N * n + N - 1))
      (analyticTransferTangent N z) := by
  by_cases h : N = 1
  · subst N
    exact analyticTransferTangent_one_hasSum z
  · exact analyticTransferTangent_coefficient_hasSum (by omega) hn hz
```

Notice the original-variable exponent $Nn + N - 1$ and factorial $(Nn + N - 1)!$. The nonvanishing hypothesis is stated in the reduced-variable ball, while the evaluation point is tested through z^N. These are explicit normalizations, not cosmetic choices.

7.6 Row 148: literal compact reciprocal polynomials

A recurrence determines low-order coefficients, but the manuscript displays compact binomial/factorial expressions. This module proves the displayed forms over every characteristic-zero field. For the second coefficient:

Source: KomorebiPaperIV/CompactReciprocal.lean.

```
theorem reciprocalCoeff_two_compact {N : ℕ} (hN : 0 < N) (r : K) :
    reciprocalCoeff N 2 r =
      r * (((2*N).choose N : K) / 2 * (r+1) - 1) := by
  have h := (ordinary_low_equations N r).2.1
  change 2 * PowerSeries.coeff 2 (reciprocalSeries N r) = _ at h
  rw [reciprocalCoeff, blockCoeff, Nat.mul_comm N 2,
    Nat.cast_choose K (show N ≤ 2*N by omega), show 2*N-N=N by omega]
  have hf : ((2*N).factorial : K) ≠ 0 := by exact_mod_cast (2*N).factorial_ne_zero
  have hg : (N.factorial : K) ≠ 0 := by exact_mod_cast N.factorial_ne_zero
  field_simp at h ⊢
  linear_combination h
```

The third coefficient is likewise identified by its literal formula. The proof moves between ordinary coefficients and factorial normalization, justifies the nonzero factorial denominators, and uses the earlier recurrence. This closes the displayed-polynomial clause rather than relying on an informal simplification outside Lean.

7.7 Row 149: the displayed Hessenberg determinant

The determinant's matrix is defined entry by entry. Below the diagonal it contains the recurrence coefficients. Its superdiagonal contains negative integers.

Source: KomorebiPaperIV/NewtonDeterminant.lean.

```
def newtonHessenberg (p : ℕ → K) (n : ℕ) : Matrix (Fin n) (Fin n) K :=
  fun i j => (if j.val ≤ i.val then p (i.val+1-j.val) else 0) -
    (if j.val = i.val+1 then (i.val+1 : K) else 0)
```

The generic determinant theorem identifies the determinant with $n!b_n$. The reciprocal specialization is:

Source: KomorebiPaperIV/NewtonDeterminant.lean.

```
theorem reciprocalOrdCoeff_newton_determinant (N n : ℕ) (r : K) :
    reciprocalOrdCoeff N n r = (n.factorial : K)⁻¹ *
      (newtonHessenberg (fun k => r*kappaCoeff N k) n).det := by
  have hb0 : reciprocalOrdCoeff N 0 r = 1 := by simp [reciprocalOrdCoeff]
  have hb (i : ℕ) : ∑ j ∈ range (i+1), reciprocalOrdCoeff N j r *
      (r*kappaCoeff N (i+1-j)) = (i+1 : K)*reciprocalOrdCoeff N (i+1) r := by
    have h := reciprocalOrdCoeff_newton N r i
    rw [Finset.Nat.sum_antidiagonal_eq_sum_range_succ_mk] at h
    rw [h, mul_sum]
    apply sum_congr rfl
    intro j hj
    have he : i-j+1=i+1-j := by have := mem_range.mp hj; omega
    rw [he]
    ring
  rw [newtonHessenberg_det _ _ hb0 hb]
  have hf : (n.factorial : K) ≠ 0 := by exact_mod_cast n.factorial_ne_zero
  field_simp
```

The finite-dimensional convention includes $n = 0$, whose determinant and initial coefficient are one. The formula uses ordinary coefficients. Obtaining the manuscript's block coefficients requires their separate $(Nn)!$ conversion. The negative superdiagonal and the recurrence index are part of the checked matrix, not inferred from a picture.

7.8 Row 150: hypergeometric normalization and summation

The literal denominator parameters are generated by removing the unique residue parameter equal to one.

Source: KomorebiPaperIV/HypergeometricAnalytic.lean.

```
def residueHypergeometricParameters (N j : ℕ) : Multiset ℂ :=
  ((range N).erase (N-j-1)).val.map (fun a => ((j+a+1 : ℕ) : ℂ)/(N : ℂ))
```

There are $N - 1$ remaining parameters, all with positive real part. The source first relates factorials to residue Pochhammer products. The analytic closure then converts the pinned Mathlib regularized hypergeometric series to the ordinary normalization using Gamma factors and proves its sum.

Source: KomorebiPaperIV/HypergeometricAnalytic.lean.

```
theorem residueHypergeometric_hasSum {N j : ℕ} (hN : 0 < N) (hj : j < N) (w : ℂ) :
    HasSum (fun q => (residueZeroFCoeff N j q : ℂ) * w^q)
      (residueHypergeometric N j w) := by
  let b := residueHypergeometricParameters N j
  have hb : ∀ c ∈ b, ∀ k : ℕ, c ≠ -(k : ℂ) := by
    intro c hc k he
    have hp := residueHypergeometricParameters_re_pos hN hc
    rw [he] at hp
    simp only [Complex.neg_re, Complex.natCast_re] at hp
    have hk : (0 : ℝ) ≤ k := Nat.cast_nonneg k
    linarith
  have hs := (Complex.regularizedHGFunSeries 0 b).hasSum (x := w) (by
    rw [Complex.radius_regularizedHGFunSeries_eq_top (by simp)]
    simp)
  have h := hs.mul_left (b.map Complex.Gamma).prod
  change HasSum _ (residueHypergeometric N j w) at h
  apply h.congr_fun
  intro q
  simp only [Complex.regularizedHGFunSeries, FormalMultilinearSeries.ofScalars_apply_eq,
    smul_eq_mul, ← mul_assoc, regularized_zeroF_normalization b hb]
  rw [← residuePochhammerProduct_erase hN hj]
  simp [residueZeroFCoeff]
```

Finally the entire transfer section is identified at arbitrary complex arguments.

Source: KomorebiPaperIV/HypergeometricAnalytic.lean.

```
theorem entireTransfer_hypergeometric {N j : ℕ} (hN : 0 < N) (hj : j < N)
    {omega : ℂ} (ho : IsPrimitiveRoot omega N) (lambda z : ℂ) :
    entireTransfer N j omega lambda z =
      (lambda*z)^j / (j.factorial : ℂ) *
        residueHypergeometric N j ((lambda*z)^N / (N : ℂ)^N) := by
  let f := fun m => PowerSeries.coeff m (transferSection N j lambda) * z^m
  have hi : Function.Injective (fun q : ℕ => N*q+j) := by
    intro a b h
    exact Nat.eq_of_mul_eq_mul_left hN (Nat.add_right_cancel h)
  have hf : ∀ m, m ∉ Set.range (fun q : ℕ => N*q+j) → f m = 0 := by
    intro m hm
    have he : m%N ≠ j := by
      intro he
      apply hm
      use m/N
      change N*(m/N)+j=m
      rw [← he, Nat.add_comm, Nat.mod_add_div]
    simp [f, coeff_transferSection, transferSectionCoeff, he]
  have ha := (hi.hasSum_iff hf).2 (hasSum_entireTransfer hN hj ho lambda z)
  have hh := (residueHypergeometric_hasSum hN hj ((lambda*z)^N / (N : ℂ)^N)).mul_left
    ((lambda*z)^j / (j.factorial : ℂ))
  apply ha.unique
  apply hh.congr_fun
```

```
  intro q
  dsimp [Function.comp_def, f]
  rw [coeff_transferSection, transferSectionCoeff,
    show (N*q+j)%N = j by simp [Nat.add_mod, Nat.mod_eq_of_lt hj]]
  simp only [one_div, map_invв‚Ђ, map_natCast]
  have hn := congrArg (fun a : в„љ => (a : в„‚)) (residueZeroFCoeff_normalization hN j q)
  push_cast at hn
  rw [в†ђ hn]
  simp only [div_eq_mul_inv, mul_pow, inv_pow, в†ђ pow_mul]
  rw [pow_add, pow_add]
  simp only [ite_true]
  ring
```

The proof reindexes the original Taylor sum by $Nq + j$, proves off-residue terms vanish, and matches the factorial/Pochhammer coefficients. The argument retains the scale $(\lambda z)^N/N^N$ and the prefactor $(\lambda z)^j/j!$. For $N = 1$, the erased parameter multiset is empty and the same theorem applies.

7.9 Row 151: convergent quotient-algebra exponentials

The actual exponential series is defined in a topological algebra.

Source: KomorebiPaperIV/QuotientExponential.lean.

```
def finiteAlgebraExponential {A : Type*} [Ring A] [Algebra в„‚ A]
    [TopologicalSpace A] (x : A) (z : в„‚) : A :=
  в€‘' m : в„•, (z^m / (m.factorial : в„‚)) вЂў x^m
```

Its definition alone does not assert summability. The next theorem supplies convergence for the cyclic relation under the surrounding module's topological linear-space assumptions.

Source: KomorebiPaperIV/QuotientExponential.lean.

```
theorem hasSum_cyclicAlgebra_exponential {N : в„•} (hN : 0 < N)
    {omega : в„‚} (ho : IsPrimitiveRoot omega N) (x : A) (hx : x^N = 1)
    (lambda z : в„‚) :
    HasSum (fun m : в„• => ((lambda*z)^m / (m.factorial : в„‚)) вЂў x^m)
      (в€‘ j : Fin N, entireTransfer N j.val omega lambda z вЂў x^j.val) := by
  have h := hasSum_sum (s := Finset.univ) (fun j (_ : j в€€ (Finset.univ : Finset (Fin N))) =>
    (hasSum_entireTransfer hN j.isLt ho lambda z).smul_const (x^j.val))
  apply h.congr_fun
  intro m
  have hxmod : x^m = x^(m%N) := by
    calc
      x^m = x^(m%N + N*(m/N)) := by rw [Nat.mod_add_div]
      _ = x^(m%N) := by rw [pow_add, pow_mul, hx]; simp
  rw [hxmod, Finset.sum_eq_single (вџЁm%N, Nat.mod_lt m hNвџ© : Fin N)]
  В· simp only [coeff_transferSection, transferSectionCoeff, ite_true]
    congr 1
    simp [mul_pow, div_eq_mul_inv, mul_assoc, mul_left_comm, mul_comm]
  В· intro j _ hj
    have hne : m%N в‰  j.val := by intro he; apply hj; exact Fin.ext he.symm
    simp [coeff_transferSection, transferSectionCoeff, hne]
  В· simp
```

The proof groups powers by residue and uses the scalar `HasSum` theorem for each coordinate. The quotient algebras receive their finite-dimensional coefficient norm topologies and compatible normed-space instances. The signed specialization is:

Source: `KomorebiPaperIV/QuotientExponential.lean`.

```
theorem signedAlgebra_pointwise_exponential {N : ℕ} [NeZero N]
    {omega rho : ℂ} (ho : IsPrimitiveRoot omega N) (hr : rho^N = -1) (z : ℂ) :
    finiteAlgebraExponential (signedCyclicGenerator ℂ N) z =
      ∑ j : Fin N, entireSigned N j.val omega rho z • (signedCyclicGenerator ℂ N)^j.val := by
  exact (hasSum_signedAlgebra_exponential (Nat.pos_of_ne_zero (NeZero.ne N)) ho hr
    (signedCyclicGenerator ℂ N) (signedCyclicGenerator_pow ℂ N) z).tsum_eq
```

This is the final analytic link for result 6.2. The inherited formal power-series identity, the finite algebra relation, and the pointwise convergent exponential all retain the same generator and normalization.

8 Reproduction, audit, and evidence handling

8.1 The exact environment

The source records specify the Lean compiler and Mathlib environment used for the verification.

The accompanying lake-manifest.json records all nine dependency pins.

The project has autoImplicit = false and relaxedAutoImplicit = false. The verified replay establishes warning rejection through the explicit control in Section 9, which distinguishes the inherited setting from the corrected invocation. The aggregate import integrates the development, while the explicit kernel audit checks the mapped declarations and the namespace. Build caches are excluded from the source distribution.

8.2 What the saved kernel transcript establishes

The saved transcript contains one axiom record for each of the 1,164 mapped targets and ends with the namespace audit's pass line. The guide generator compares the target sets in four places: the theorem map, the declaration-kind contract, the audit source's explicit directives, and the transcript. It also checks that every recorded axiom belongs to the permitted set of three axioms.

This reconciliation proves consistency of the preserved evidence files with the preserved source identities. It does not repeat elaboration, type checking, or a live environment traversal. The namespace totals of 2,234 declarations and 1,999 theorem declarations are inherited results, not counts newly obtained from a running Lean process. A lexical source parser cannot substitute for elaborated declaration types or compiler-generated declarations.

8.3 Static reconciliation

The generator validates every one of the 119 Lean source files against the canonical SHA-256 manifest. It resolves the 1,164 target names to source declarations and checks the theorem-versus-construction split against the explicit contract. It emits the complete row catalog, 68-result ledger, direct-import inventory, exact pins, and source-excerpt manifest.

The source policy scan excludes comments and string literals before checking for forbidden proof placeholders and unsafe shortcuts. The kernel-audit file is treated separately because its exclusion logic necessarily names prohibited axioms. This is a source-hygiene check. It does not establish that elaboration succeeds.

The 43 declarations in `SemanticChecks.lean` are supported by their source and preserved execution evidence. Static reconciliation does not relabel them as newly executed tests. The separate verification chapter records the production replay and compiler controls. The 119 mathematical source files remained unchanged.

8.5 Failure modes worth recognizing

An environment mismatch invalidates a replay claim. A transcript missing contract targets is incomplete even when its last line says pass. A declaration that fails to elaborate has not passed a formal run. A successfully built PDF does not itself certify Lean proofs.

> A recorded numerical suite accepted mutations of a projector identity and a zero-counting constant. Its passing totals cannot certify theorems. Finite checks can detect selected regressions, but must retain their tested scope and sensitivity. The formal contract and kernel evidence have separate roles.

8.6 How to inspect one result end to end

Choose a manuscript record in the coverage ledger. Read all of its map rows, including later rows that close analytic clauses. Follow each exact declaration name to its source location. Inspect the surrounding variables, typeclass instances, definitions, and imported lemmas. Check the target's kind in the contract and its axiom record in the saved transcript. If a new formal run is needed, use the pinned environment and retain its complete output separately from inherited evidence.

For example, result 4.5 joins row 27's factorial/Pochhammer formal identity with row 150's literal parameter multiset, Gamma normalization, and actual convergent hypergeometric summation. Reviewing only row 27 would miss completed analytic coverage. Reviewing only the final identity would miss the coefficient normalization on which it depends. The contract is designed to make both routes visible.

9 Pinned-source verification and its scope

The 68-result formal core passed a replay using pinned sources, declaration-kind resolution, a transitive axiom audit, and compiler controls. All 119 Lean source files and their mathematical hypotheses remained unchanged. The 151-row reviewed map covers the full scoped statements of the 68 theorem-like manuscript records. This verification checks the exact inherited statement contract. It does not supply a new line-by-line mathematical proof of that correspondence.

9.1 Production compilation and proof evidence

The replay compiled all 118 production modules into an initially empty directory for project objects. Each module ran separately with one Lean worker. The cumulative receipt fingerprints every successful source and output object. The aggregate imports the completed production closure. The original audit source and a generated declaration-kind consumer were then executed.

Compiler and dependency identities were checked against the manifest. Cached external objects were reused. The record does not claim an independent rebuild of Mathlib or a separately implemented proof kernel.

Evidence	Recorded scope
Production compilation	118 of 118 modules, with new project objects
Source preservation	All 119 Lean source files unchanged
Reviewed targets	1,164 targets: 953 theorems and 211 constructions
Namespace audit	2,234 declarations, including 1,999 theorem declarations
Compiler controls	Six accepted outcomes under explicit diagnostics
Verifier tests	42 verification tests and 10 integrity tests

Supporting and generated declarations contribute to these totals. The totals are not counts of independent discoveries.

```
The source records specify the exact compiler and dependency environment. The permitted
transitive axioms are propext, Classical.choice, and Quot.sound.
```

9.2 Controls and their diagnostics

A valid projector-idempotence application is accepted. An explicit false theorem, an admitted proof, an omitted premise, an injected custom axiom, and a definition presented as a theorem must produce their intended rejection diagnostics. A timeout, signal kill, missing import, or unrelated API error does not count as successful rejection.

The warning policy is material to this contract. The inherited `-E warning` setting accepted an isolated deliberately admitted proof with exit code 0. The verified replay instead uses `-DwarningAsError=true`, which rejected that fixture with exit code 1. The production mathematical sources were not weakened or edited.

The verifier tests use the recovered typed source contract and adversarial mutations of rows, targets, evidence labels, axiom reports, and process outcomes. A descendant-process cleanup fixture waits for explicit child readiness before applying a separate bounded execution deadline. An earlier timeout

before readiness did not establish that the descendant had started and is retained as a failed check. The final 42-test suite passes.

The ten integrity tests cover changed bytes, missing files, unexpected files, duplicate records, unsafe paths, symlinks, prohibited font files, and positive and empty-manifest cases. The distribution manifest describes the actual 836-file preserved tree. It does not require the 73 excluded font files listed in an older manifest. The exact earlier unsaved fixture-control failure was not recovered, so the record makes no claim to reproduce that absent script. The replacement controls directly exercise the recovered checker's actual typed records and have their own fingerprints and receipts.

9.3 Finite computations and their limits

The finite computations were executed separately from Lean. Their domains overlap, so the following rows are not added into one total. They support the implementations and worked examples. Universal statements rely on proof terms under their declared hypotheses.

Suite	Recorded result
Exact algebra	1,008 exact rational assertions
Visual examples	147 symbolic, finite, and enclosure checks
Original tables	981 of 981 rows checked
Strengthened-paper suite	1,246 of 1,246 checks passed
Original-paper suite	647 of 647 checks passed
Rational subset and brackets	818 rational table rows and four bracket records

The previously documented weakness of the strengthened numerical suite remains relevant: its historical acceptance of mutations limits what its passing total can establish. It does not replace the formal contract or the targeted compiler controls.

The source records specify the computation environment. All 836 files remained byte-identical before and after the finite replay. Results and logs were written separately.

9.4 Evidence files and reproduction

The formal verification distribution retains compiler logs, generated consumers, fixtures, source hashes, and project output objects. The external runtime and dependency cache are separate requirements. The principal evidence records are:

- `verification/lean_primary/REPLAY.json` and `verification/lean_primary/AXIOM_REPORTS.json`;
- `verification/SOURCE_MAP_CHECK.json` and `verification/SOURCE_CONTRACT.json`;
- `verification/finite_primary/FINITE_REPLAY.json`;
- `verification/VERIFIER_TESTS.json` and `verification/INTEGRITY_TESTS.json`.

The accompanying source records provide the reproduction commands.

Use a new writable working directory outside the preserved source tree. The first command checks stored evidence and file integrity. It does not rerun the kernel. Finite mode reruns the examples and verifier controls. Full mode additionally compiles every production module and repeats the formal audits. These commands do not download or install dependencies.

The complete replay targets Linux or WSL with Python 3.11 or newer, the pinned Lean runtime, and matching cached packages. The recorded run used a four-GiB container, one Lean worker, a 3,072-MiB Lean heap setting, and a 300-second deadline for each command. This is not a claim of reproducibility on native Windows or across platforms.

9.5 Mathematical boundaries

Imported standard fact 11.1 remains outside the 68-result contract. The core does not assert universal simplicity of all zeros, positivity of every reduced zero, a full displacement expansion, or a zeta functional equation. Eventual simplicity, branch choices, multiplicities, and nearest-pole asymptotics retain their stated hypotheses and ranges. The separately preserved visual reader includes a branch-sensitive clarification of reciprocal powers. No older editable source is substituted for that reader.

10 Complete manuscript coverage ledger

Each entry is a full scoped result in the formal contract. Its coverage is the union of the cited rows, with the original hypotheses retained. This ledger has 68 entries. Definitions and the explicitly imported standard fact 11.1 are not added to that count.

Record	Full scoped result	Additive map rows
3.1	Root filter	1, 2, 4, 143

14.4	Exact zeta models in orders two and four	94, 95
14.6	Branch-dependent symmetry-orbit continuation	93
14.8	Derivative-weighted convergence	85, 86, 87

11 Complete declaration catalog

The following 151 entries reproduce the exact row scopes and all 1,164 fully qualified declaration names from the canonical theorem map. File names, lexical line locations, declaration kinds, and manuscript labels are reconciled with the source and the formal contract.

Read scope additively. An earlier row may say that pointwise convergence, a branch law, or another clause is outside *that row*. Such wording is preserved here because it precisely describes that contribution. It is not an unresolved gap in the completed result. Consult the 68-result ledger and rows 143–151 for the joined coverage. The present static reconciliation does not rerun Lean's elaborator or kernel.

11.1 Row 1: 3.1 Root filter, coefficient action

Exact row scope. Exact formal coefficient selector.

Manuscript labels. `thm:root_filter`

`Komorebi.PaperIV.cyclicProjector`
definition; `KomorebiPaperIV/CyclicFilters.lean`, line 25.

`Komorebi.PaperIV.coeff_cyclicProjector`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 29.

`Komorebi.PaperIV.cyclicProjector_eq_zero_of_residue_ne`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 47.

`Komorebi.PaperIV.cyclicProjector_eq_of_mod_eq`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 52.

11.2 Row 2: 3.1 Root filter, projector resolution

Exact row scope. Exact over every commutative semiring; completeness assumes `N > 0`.

Manuscript labels. `thm:root_filter`

`Komorebi.PaperIV.cyclicProjector_idempotent`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 34.

`Komorebi.PaperIV.cyclicProjector_orthogonal`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 39.

`Komorebi.PaperIV.sum_cyclicProjector`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 74.

11.3 Row 3: 3.3 Cyclic product law

Exact row scope. Exact pure-packet label addition, off-label vanishing, and full finite double-sum product formula.

Manuscript labels. `thm:cyclic_product`

`Komorebi.PaperIV.cyclicProjector_add`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 58.

`Komorebi.PaperIV.cyclicProjector_sum`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 63.

`Komorebi.PaperIV.cyclicProjector_product_packet`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 88.

`Komorebi.PaperIV.cyclicProjector_product_other`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 114.

`Komorebi.PaperIV.cyclic_product_law`
theorem; `KomorebiPaperIV/CyclicFilters.lean`, line 122.

11.4 Row 4: 3.1 Root filter, explicit Fourier average

Exact row scope. Exact primitive-root finite Fourier average in `ℂ⟦X⟧`, proved equal to the coefficient projector.

Manuscript labels. `thm:root_filter`

`Komorebi.PaperIV.finiteRootAverage`
definition; `KomorebiPaperIV/FiniteAnalytic.lean`, line 30.

`Komorebi.PaperIV.coeff_finiteRootAverage`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 69.

`Komorebi.PaperIV.finiteRootAverage_eq_cyclicProjector`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 83.

11.5 Row 5: 4.1 Transfer exponential basis

Exact row scope. Exact formal realization of the lacunary exponential series.

Manuscript labels. `def:transfer_exponential`

`Komorebi.PaperIV.exponentialGeneratingSeries`
definition; `KomorebiPaperIV/SectionCycles.lean`, line 26.

`Komorebi.PaperIV.coeff_exponentialGeneratingSeries`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 31.

`Komorebi.PaperIV.transferSectionCoeff`
definition; `KomorebiPaperIV/SectionCycles.lean`, line 68.

`Komorebi.PaperIV.transferSection`
definition; `KomorebiPaperIV/SectionCycles.lean`, line 72.

`Komorebi.PaperIV.coeff_transferSection`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 76.

11.6 Row 6: 4.1 Transfer exponential, root-average representation

Exact row scope. Exact finite root-of-unity representation in `ℂ⟦X⟧`, including rescaling by the spectral parameter.

Manuscript labels. `def:transfer_exponential`

`Komorebi.PaperIV.finiteRootAverage_exp_eq_transferSection`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 90.

`Komorebi.PaperIV.finiteRootAverage_rescale_exp_eq_transferSection`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 104.

11.7 Row 7: 4.2 Differential cycle and initial data

Exact row scope. Exact formal derivative cycle, full-period equation, and initial data. Analytic solution-space dimension and the Wronskian claim are outside this row.

Manuscript labels. `thm:exponential_cycle`

`Komorebi.PaperIV.derivative_exponentialGeneratingSeries`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 37.

`Komorebi.PaperIV.iterate_derivative_exponentialGeneratingSeries`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 55.

`Komorebi.PaperIV.transferSectionCoeff_succ_of_pos`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 84.

`Komorebi.PaperIV.transferSectionCoeff_succ_zero`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 113.

`Komorebi.PaperIV.derivative_transferSection_of_pos`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 225.

`Komorebi.PaperIV.derivative_transferSection_zero`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 237.

`Komorebi.PaperIV.transferSectionCoeff_add_period`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 269.

`Komorebi.PaperIV.iterate_derivative_transferSection`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 298.

`Komorebi.PaperIV.constantCoeff_iterate_derivative_transferSection`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 320.

11.8 Row 8: 5.1 Signed cyclic sections

Exact row scope. Exact formal realization of the signed lacunary series.

Manuscript labels. `def:signed_sections`

`Komorebi.PaperIV.signedSectionCoeff`
definition; `KomorebiPaperIV/SectionCycles.lean`, line 137.

`Komorebi.PaperIV.signedSection`
definition; `KomorebiPaperIV/SectionCycles.lean`, line 141.

`Komorebi.PaperIV.coeff_signedSection`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 145.

11.9 Row 9: 5.2 Relation with the transfer exponential

Exact row scope. Exact formal identity for a chosen `rho` with `rho ^ N = -1`, including the factor $(\texttt{rho}\ \texttt{\^{}}\ \texttt{j})^{-1}$.

Manuscript labels. `prop:signed_exponential_relation`

`Komorebi.PaperIV.signedSection_eq_inv_pow_mul_transferSection`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 143.

11.10 Row 10: 5.3 Signed derivative cycle

Exact row scope. Exact formal derivative cycle, negative wraparound, full-period equation, and initial data.

Manuscript labels. `thm:signed_cycle`

`Komorebi.PaperIV.signedSectionCoeff_succ_of_pos`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 170.

`Komorebi.PaperIV.signedSectionCoeff_succ_zero`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 200.

`Komorebi.PaperIV.derivative_signedSection_of_pos`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 248.

`Komorebi.PaperIV.derivative_signedSection_zero`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 258.

`Komorebi.PaperIV.signedSectionCoeff_add_period`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 284.

`Komorebi.PaperIV.iterate_derivative_signedSection`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 310.

`Komorebi.PaperIV.constantCoeff_iterate_derivative_signedSection`
theorem; `KomorebiPaperIV/SectionCycles.lean`, line 337.

11.11 Row 11: 5.6 Finite exponential representation

Exact row scope. Exact finite representation in $\mathbb{C}[\![X]\!]$ for every signed section and the distinguished denominator. Pointwise evaluation is supplied by row 47.

Manuscript labels. `thm:finite_exponential_representation`

`Komorebi.PaperIV.signedSection_eq_finiteRootAverage_rescale_exp`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 153.

`Komorebi.PaperIV.signedSection_zero_eq_finite_exponential_average`
theorem; `KomorebiPaperIV/FiniteAnalytic.lean`, line 166.

11.12 Row 12: 5.7 and 7.1 Reduced denominator and reciprocal family

Exact row scope. Exact named formal specialization `Delta_N(w)^(-r) = exp(-r log Delta_N(w))`, with parameters `-1`, `0`, and `1` linked to the denominator, unit, and inverse. No analytic logarithm branch is asserted.

Manuscript labels. `def:reciprocal_family`, `def:reduced_denominator`

`Komorebi.PaperIV.formalExpFamily`
definition; `KomorebiPaperIV/FormalExponential.lean`, line 27.

`Komorebi.PaperIV.formalExpFamily_zero`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 37.

`Komorebi.PaperIV.formalExpFamily_one`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 45.

`Komorebi.PaperIV.reducedDenominator`

definition; KomorebiPaperIV/ReciprocalCore.lean, line 28.

Komorebi.PaperIV.coeff_reducedDenominator
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 33.

Komorebi.PaperIV.constantCoeff_reducedDenominator
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 39.

Komorebi.PaperIV.signedSection_zero_eq_expand_reducedDenominator
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 46.

Komorebi.PaperIV.negativeLogDenominator
definition; KomorebiPaperIV/ReciprocalCore.lean, line 63.

Komorebi.PaperIV.constantCoeff_negativeLogDenominator
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 67.

Komorebi.PaperIV.exp_subst_logOf
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 74.

Komorebi.PaperIV.mul_derivative_logOf
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 88.

Komorebi.PaperIV.formalExpFamily_eq_exp_subst
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 101.

Komorebi.PaperIV.reciprocalSeries
definition; KomorebiPaperIV/ReciprocalCore.lean, line 112.

Komorebi.PaperIV.constantCoeff_reciprocalSeries
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 116.

Komorebi.PaperIV.reciprocalSeries_zero
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 128.

Komorebi.PaperIV.reciprocalSeries_neg_one
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 133.

Komorebi.PaperIV.reciprocalSeries_one_eq_inverse
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 151.

Komorebi.PaperIV.reciprocalCoeff
definition; KomorebiPaperIV/ReciprocalCore.lean, line 161.

Komorebi.PaperIV.reciprocalOrdCoeff
definition; KomorebiPaperIV/ReciprocalCore.lean, line 165.

Komorebi.PaperIV.reciprocalCoeff_zero_parameter
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 169.

Komorebi.PaperIV.reciprocalCoeff_zero_parameter_of_pos
theorem; KomorebiPaperIV/ReciprocalCore.lean, line 173.

11.13 Row 13: 7.4 Additive parameter law for reciprocal powers

Exact row scope. Exact formal parameter law and exact `(Nn choose Nq)` convolution for the named `P_{N,n}` specialization.

Manuscript labels. `thm:reciprocal_parameter_addition`

`Komorebi.PaperIV.formalExpFamily_semigroup`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 30.

`Komorebi.PaperIV.blockCoeff`
definition; `KomorebiPaperIV/FormalExponential.lean`, line 129.

`Komorebi.PaperIV.blockCoeff_mul`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 134.

`Komorebi.PaperIV.reciprocal_block_convolution`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 163.

`Komorebi.PaperIV.reciprocalSeries_add`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 142.

`Komorebi.PaperIV.reciprocalCoeff_addition`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 178.

11.14 Row 14: 7.5 Binomial-type normalization

Exact row scope. Exact exponential-generating normalization and binomial convolution.

Manuscript labels. `cor:binomial_type`

`Komorebi.PaperIV.egfCoeff`
definition; `KomorebiPaperIV/FormalExponential.lean`, line 101.

`Komorebi.PaperIV.egfCoeff_mul`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 106.

`Komorebi.PaperIV.reciprocal_binomial_type`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 174.

11.15 Row 15: 7.6, 8.2, 8.3, and 8.4 Newton, tangent, and reciprocal derivative identities

Exact row scope. Exact formal logarithmic derivative and finite coefficient recurrences in the reduced variable. The displayed z-variable tangent scaling is not separately named.

Manuscript labels. `cor:reciprocal_derivative`, `prop:tangent_kappa`, `thm:logarithmic_newton_recurrence`, `thm:tangent_recurrence`

`Komorebi.PaperIV.derivative_rescale_exp`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 50.

`Komorebi.PaperIV.derivative_formalExpFamily`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 75.

`Komorebi.PaperIV.formalExpFamily_coefficient_recurrence`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 84.

`Komorebi.PaperIV.kappaCoeff`
definition; `KomorebiPaperIV/ReciprocalCore.lean`, line 191.

`Komorebi.PaperIV.reducedTangentSeries`
definition; `KomorebiPaperIV/ReciprocalCore.lean`, line 195.

`Komorebi.PaperIV.coeff_reducedTangentSeries`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 199.

`Komorebi.PaperIV.reducedDenominator_mul_reducedTangentSeries`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 207.

`Komorebi.PaperIV.reducedTangent_coefficient_convolution`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 217.

`Komorebi.PaperIV.derivative_reciprocalSeries`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 228.

`Komorebi.PaperIV.reciprocalSeries_coefficient_recurrence`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 235.

`Komorebi.PaperIV.reciprocalOrdCoeff_newton`
theorem; `KomorebiPaperIV/ReciprocalCore.lean`, line 245.

11.16 Row 16: 9.2 Generic inverse support

Exact row scope. Exact inverse convolution for every unit-constant series over a field.

Manuscript labels. `thm:triangular_inverse`

`Komorebi.PaperIV.inverse_coefficient_convolution`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 188.

`Komorebi.PaperIV.constantCoeff_inverse_of_one`
theorem; `KomorebiPaperIV/FormalExponential.lean`, line 198.

11.17 Row 17: 9.1 and 9.2 Normalized residue section and triangular inverse

Exact row scope. Exact manuscript normalization, factorial-rescaled triangular identity, and solved recurrence over a characteristic-zero field.

Manuscript labels. `def:normalized_section`, `thm:triangular_inverse`

`Komorebi.PaperIV.normalizedResidueSection`
definition; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 35.

`Komorebi.PaperIV.coeff_normalizedResidueSection`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 41.

`Komorebi.PaperIV.constantCoeff_normalizedResidueSection`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 47.

`Komorebi.PaperIV.residueInverseCoeff`
definition; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 56.

`Komorebi.PaperIV.residueInverseCoeff_triangular`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 61.

`Komorebi.PaperIV.residueInverseCoeff_zero`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 126.

`Komorebi.PaperIV.residueInverseCoeff_recurrence`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 131.

11.18 Row 18: 9.5, 9.6, and 9.7 Appell realization and exact sparse polynomial

Exact row scope. Exact finite Appell realization, lowering and translation laws, and the manuscript's sparse sum with only degrees `Nn`. The residue specialization here is `r = 1`.

Manuscript labels. `def:block_appell`, `prop:explicit_appell`, `thm:appell_laws`

`Komorebi.PaperIV.appellSeries`
definition; `KomorebiPaperIV/Appell.lean`, line 26.

`Komorebi.PaperIV.appellCoeff`
definition; `KomorebiPaperIV/Appell.lean`, line 30.

`Komorebi.PaperIV.egfCoeff_rescale_exp`
theorem; `KomorebiPaperIV/Appell.lean`, line 58.

`Komorebi.PaperIV.appellCoeff_zero_parameter`
theorem; `KomorebiPaperIV/Appell.lean`, line 73.

`Komorebi.PaperIV.appell_addition`
theorem; `KomorebiPaperIV/Appell.lean`, line 80.

`Komorebi.PaperIV.appellCoeff_at_zero`
theorem; `KomorebiPaperIV/Appell.lean`, line 89.

`Komorebi.PaperIV.appellPolynomial`
definition; `KomorebiPaperIV/Appell.lean`, line 97.

`Komorebi.PaperIV.derivative_appellPolynomial`
theorem; `KomorebiPaperIV/Appell.lean`, line 103.

`Komorebi.PaperIV.formalAppellPolynomial`
definition; `KomorebiPaperIV/Appell.lean`, line 133.

`Komorebi.PaperIV.derivative_formalAppellPolynomial`
theorem; `KomorebiPaperIV/Appell.lean`, line 137.

`Komorebi.PaperIV.eval_formalAppellPolynomial`
theorem; `KomorebiPaperIV/Appell.lean`, line 142.

`Komorebi.PaperIV.blockCoefficientSequence`
definition; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 155.

`Komorebi.PaperIV.blockCoefficientSequence_mul`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 159.

`Komorebi.PaperIV.appellPolynomial_eq_sparse_sum`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 166.

`Komorebi.PaperIV.appellPolynomial_eq_block_sum`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 185.

`Komorebi.PaperIV.residueAppellPolynomial_explicit`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 282.

11.19 Row 19: 9.8 Joint Appell convolution

Exact row scope. Exact formal product and coefficient convolution in space and order parameters for the generic zero-constant logarithm family.

Manuscript labels. `thm:appell_two_parameter_convolution`

`Komorebi.PaperIV.appellSeries_two_parameter`
theorem; `KomorebiPaperIV/Appell.lean`, line 34.

`Komorebi.PaperIV.appell_two_parameter_convolution`
theorem; `KomorebiPaperIV/Appell.lean`, line 48.

11.20 Row 20: 9.9 Formal differential-operator representation

Exact row scope. Exact finite action on monomials and exact operator inversion on every polynomial of bounded degree; the direct residue inverse corollary is the `r = 1` case.

Manuscript labels. `prop:appell_operator_form`

`Komorebi.PaperIV.egfConstantCoeffAction`
definition; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 325.

`Komorebi.PaperIV.egfConstantCoeffAction_X_pow`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 331.

`Komorebi.PaperIV.egfConstantCoeffAction_residue_X_pow`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 345.

`Komorebi.PaperIV.polynomialDifferentialEval`
definition; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 363.

`Komorebi.PaperIV.polynomialDifferentialEval_X`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 370.

`Komorebi.PaperIV.truncatedDifferentialOperator`
definition; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 375.

`Komorebi.PaperIV.coeff_trunc_mul_trunc_of_lt`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 379.

`Komorebi.PaperIV.X_pow_dvd_trunc_mul_trunc_sub_one`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 392.

`Komorebi.PaperIV.truncatedDifferentialOperator_mul_apply_of_natDegree_le`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 405.

`Komorebi.PaperIV.truncatedDifferentialOperator_normalizedResidueSection_inverse`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 439.

11.21 Row 21: 9.10 Appell monicity and covariance

Exact row scope. Exact monicity, exact degree, and `omega ^ m` covariance for block-supported Appell polynomials; residue specialization is `r = 1`.

Manuscript labels. `cor:appell_symmetry`

`Komorebi.PaperIV.appellPolynomial_isMonicOfDegree`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 218.

`Komorebi.PaperIV.blockAppellPolynomial_isMonicOfDegree`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 239.

`Komorebi.PaperIV.eval_appellPolynomial_block_covariance`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 248.

`Komorebi.PaperIV.residueAppellPolynomial_isMonicOfDegree`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 293.

`Komorebi.PaperIV.eval_residueAppellPolynomial_covariance`
theorem; `KomorebiPaperIV/AlgebraicCompletion.lean`, line 303.

11.22 Row 22: 10.1 and 10.2 Theta definition and reconstruction

Exact row scope. Exact formal theta series in the reduced variable and exact signed reconstruction from the named reciprocal coefficients.

Manuscript labels. `def:unsigned_denominator`, `thm:theta_reconstruction`

`Komorebi.PaperIV.blockCoeff_rescale`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 26.

`Komorebi.PaperIV.thetaSeries`
definition; `KomorebiPaperIV/ThetaCore.lean`, line 37.

`Komorebi.PaperIV.thetaCoeff`
definition; `KomorebiPaperIV/ThetaCore.lean`, line 42.

`Komorebi.PaperIV.thetaCoeff_reconstruction_unfactored`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 63.

`Komorebi.PaperIV.thetaCoeff_reconstruction`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 77.

11.23 Row 23: 10.3 Theta trivial parameter factors

Exact row scope. Exact vanishing at `u = 0`, and at `u = -1` for even `N`; these are the root statements underlying the polynomial divisibility claim.

Manuscript labels. `prop:theta_factors`

`Komorebi.PaperIV.thetaSeries_zero`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 46.

`Komorebi.PaperIV.thetaCoeff_zero_parameter`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 51.

`Komorebi.PaperIV.thetaCoeff_zero_parameter_of_pos`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 56.

`Komorebi.PaperIV.thetaSeries_neg_one_of_even`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 106.

`Komorebi.PaperIV.thetaCoeff_neg_one_of_even_of_pos`
theorem; `KomorebiPaperIV/ThetaCore.lean`, line 112.

11.24 Row 24: 3.2 Covariance characterization

Exact row scope. Exact formal fixed-space and range/covariance characterizations for a primitive root. Holomorphic-domain and pointwise versions remain outside this row.

Manuscript labels. `prop:covariance`

`Komorebi.PaperIV.cyclicProjector_fixed_iff_rescale_covariant`
theorem; `KomorebiPaperIV/EarlyCompletion.lean`, line 35.

`Komorebi.PaperIV.cyclicProjector_mem_range_iff_rescale_covariant`
theorem; `KomorebiPaperIV/EarlyCompletion.lean`, line 74.

11.25 Row 25: 4.4 Bivariate formal-series setup

Exact row scope. Exact coefficient encodings for substitution into a sum of two formal variables and for separated products. A bridge to a canonical multivariate substitution API is not asserted.

Manuscript labels. `cor:exponential_addition`

`Komorebi.PaperIV.bivariateExponentialGeneratingSeries`
definition; `KomorebiPaperIV/EarlyCompletion.lean`, line 90.

`Komorebi.PaperIV.coeff_bivariateExponentialGeneratingSeries`
theorem; `KomorebiPaperIV/EarlyCompletion.lean`, line 97.

`Komorebi.PaperIV.separatedExponentialGeneratingSeries`
definition; `KomorebiPaperIV/EarlyCompletion.lean`, line 105.

`Komorebi.PaperIV.coeff_separatedExponentialGeneratingSeries`
theorem; `KomorebiPaperIV/EarlyCompletion.lean`, line 112.

11.26 Row 26: 4.4 Addition law

Exact row scope. Exact coefficient-encoded bivariate formal addition law. Pointwise analytic evaluation is outside this row.

Manuscript labels. `cor:exponential_addition`

`Komorebi.PaperIV.transferSection_addition`
theorem; `KomorebiPaperIV/EarlyCompletion.lean`, line 144.

11.27 Row 27: 4.5 Hypergeometric form

Exact row scope. Exact rational factorial/Pochhammer normalization and formal-power-series identity. The parameter is rational; the explicit erased parameter multiset, complex analytic summation, and Mathlib regularized-hypergeometric bridge remain outside this row.

Manuscript labels. `thm:hypergeometric_form`

`Komorebi.PaperIV.residuePochhammerProduct`
definition; `KomorebiPaperIV/HypergeometricCompletion.lean`, line 36.

`Komorebi.PaperIV.factorial_eq_residuePochhammerProduct`
theorem; `KomorebiPaperIV/HypergeometricCompletion.lean`, line 61.

`Komorebi.PaperIV.residueZeroFCoeff`

definition; KomorebiPaperIV/HypergeometricCompletion.lean, line 97.

Komorebi.PaperIV.residueZeroFSeries
definition; KomorebiPaperIV/HypergeometricCompletion.lean, line 101.

Komorebi.PaperIV.coeff_residueZeroFSeries
theorem; KomorebiPaperIV/HypergeometricCompletion.lean, line 105.

Komorebi.PaperIV.residueZeroFCoeff_normalization
theorem; KomorebiPaperIV/HypergeometricCompletion.lean, line 113.

Komorebi.PaperIV.residueParameter_eq_one
theorem; KomorebiPaperIV/HypergeometricCompletion.lean, line 123.

Komorebi.PaperIV.omitted_residuePochhammer_eq_factorial
theorem; KomorebiPaperIV/HypergeometricCompletion.lean, line 130.

Komorebi.PaperIV.transferSection_eq_residueZeroFSeries
theorem; KomorebiPaperIV/HypergeometricCompletion.lean, line 145.

11.28 Row 28: 5.5 Twisted addition law

Exact row scope. Exact coefficient-encoded bivariate formal law, including the carry sign `(i+j)/N`. Canonical substitution and pointwise evaluation remain outside this row.

Manuscript labels. `prop:signed_addition`

Komorebi.PaperIV.signedSection_addition
theorem; KomorebiPaperIV/EarlyCompletion.lean, line 217.

11.29 Row 29: 5.8 Denominator symmetries

Exact row scope. Exact formal rotational invariance and conjugation-fixed coefficients. Pointwise conjugation, zero orbits, and multiplicity preservation remain outside this row.

Manuscript labels. `cor:denominator_symmetries`

Komorebi.PaperIV.signedDenominator_rescale_of_pow_eq_one
theorem; KomorebiPaperIV/EarlyCompletion.lean, line 247.

Komorebi.PaperIV.signedDenominator_map_conj
theorem; KomorebiPaperIV/EarlyCompletion.lean, line 263.

11.30 Row 30: 6.1 Finite cyclic algebras

Exact row scope. Exact `AdjoinRoot` quotient algebras, generator relations, power reductions, and `N`-dimensional power bases for `N > 0`.

Manuscript labels. `def:cyclic_algebras`

Komorebi.PaperIV.cyclicAlgebraPolynomial
definition; KomorebiPaperIV/FiniteModels.lean, line 33.

Komorebi.PaperIV.signedCyclicAlgebraPolynomial
definition; KomorebiPaperIV/FiniteModels.lean, line 37.

Komorebi.PaperIV.CyclicAlgebra
definition; KomorebiPaperIV/FiniteModels.lean, line 41.

`Komorebi.PaperIV.SignedCyclicAlgebra`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 45.

`Komorebi.PaperIV.cyclicGenerator`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 49.

`Komorebi.PaperIV.signedCyclicGenerator`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 53.

`Komorebi.PaperIV.cyclicGenerator_pow`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 57.

`Komorebi.PaperIV.signedCyclicGenerator_pow`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 65.

`Komorebi.PaperIV.cyclicGenerator_pow_eq_mod`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 73.

`Komorebi.PaperIV.signedCyclicGenerator_pow_eq_mod`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 86.

`Komorebi.PaperIV.cyclicAlgebraPowerBasis`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 104.

`Komorebi.PaperIV.signedCyclicAlgebraPowerBasis`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 112.

`Komorebi.PaperIV.cyclicAlgebraPowerBasis_dim`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 119.

`Komorebi.PaperIV.signedCyclicAlgebraPowerBasis_dim`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 127.

11.31 Row 31: 6.2 Finite algebra exponential identities

Exact row scope. Exact identities of formal power series in the quotient algebras. Pointwise quotient-algebra convergence/evaluation and the packaged derivation of prior differential laws are outside this row.

Manuscript labels. `thm:finite_algebra_exponentials`

`Komorebi.PaperIV.cyclicAlgebraExponentialSeries`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 138.

`Komorebi.PaperIV.signedCyclicAlgebraExponentialSeries`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 145.

`Komorebi.PaperIV.cyclicAlgebra_exponential_eq_sections`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 152.

`Komorebi.PaperIV.signedCyclicAlgebra_exponential_eq_sections`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 178.

11.32 Row 32: 6.3 Signed shift matrix

Exact row scope. Exact closed signed-shift construction and additive power semigroup for `N > 0`.

Manuscript labels. `def:signed_shift_matrix`

`Komorebi.PaperIV.signedShiftPowerMatrix`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 213.

`Komorebi.PaperIV.signedShiftMatrix`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 221.

`Komorebi.PaperIV.signedShiftPowerMatrix_apply`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 225.

`Komorebi.PaperIV.signedShiftPowerMatrix_zero`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 232.

`Komorebi.PaperIV.signedShiftPowerMatrix_mul`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 258.

`Komorebi.PaperIV.signedShiftMatrix_pow`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 297.

11.33 Row 33: 6.4 and 6.5 Companion realization and path entries

Exact row scope. Exact formula for every entry of every matrix power and exact `J_N^N = -I`, plus the matrix-exponential construction. The exponential-section entry bridge, first-column and trace formulas, characteristic polynomial, and simple spectrum remain outside this row.

Manuscript labels. `cor:fundamental_matrix_entries`, `thm:companion_matrix_realization`

`Komorebi.PaperIV.signedShiftMatrix_pow_apply`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 305.

`Komorebi.PaperIV.signedShiftMatrix_pow_order`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 328.

`Komorebi.PaperIV.signedFundamentalMatrix`
definition; `KomorebiPaperIV/FiniteModels.lean`, line 337.

11.34 Row 34: 6.6 Companion addition and inversion

Exact row scope. Exact matrix-exponential addition, inverse, cancellation, and unit laws. The determinant-one and signed-section entry clauses remain outside this row.

Manuscript labels. `cor:companion_addition_inversion`

`Komorebi.PaperIV.signedFundamentalMatrix_add`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 341.

`Komorebi.PaperIV.signedFundamentalMatrix_neg`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 349.

`Komorebi.PaperIV.signedFundamentalMatrix_mul_neg`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 355.

`Komorebi.PaperIV.signedFundamentalMatrix_isUnit`
theorem; `KomorebiPaperIV/FiniteModels.lean`, line 361.

11.35 Row 35: 7.3 Parameter recurrence

Exact row scope. Exact formal differential equation, factorial/binomial coefficient equation, solved recurrence, and initial value; the second sum uses the explicit reindexing `k=q+1`.

Manuscript labels. `thm:parameter_recurrence`

`Komorebi.PaperIV.reducedDenominator_reciprocalSeries_differentialEquation`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 32.

`Komorebi.PaperIV.reciprocalOrdCoeff_parameter_equation`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 58.

`Komorebi.PaperIV.reciprocalCoeff_parameter_equation`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 198.

`Komorebi.PaperIV.reciprocalCoeff_parameter_recurrence`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 317.

`Komorebi.PaperIV.reciprocalCoeff_block_zero`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 346.

11.36 Row 36: 7.7 First three reciprocal polynomials

Exact row scope. Exact `P_(N,1)=r` and exact recurrence-normal forms for `P_(N,2)` and `P_(N,3)`. The manuscript's compact factorial rewrites are not separately proved.

Manuscript labels. `cor:first_reciprocal_polynomials`

`Komorebi.PaperIV.reciprocalCoeff_one`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 351.

`Komorebi.PaperIV.reciprocalCoeff_two_recurrence_form`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 360.

`Komorebi.PaperIV.reciprocalCoeff_three_recurrence_form`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 376.

11.37 Row 37: 7.8 Divisibility by the parameter

Exact row scope. Exact divisibility by `X` for the universal polynomial over $\mathbb{Q}$, plus a separately defined generic-field polynomial with exact scalar evaluation. A named base-change theorem connecting those two polynomial lifts, or generic-field divisibility itself, remains outside this row.

Manuscript labels. `cor:factor_r`

`Komorebi.PaperIV.reciprocalCoeffPolynomial`
definition; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 397.

`Komorebi.PaperIV.X_dvd_reciprocalCoeffPolynomial`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 402.

`Komorebi.PaperIV.coeff_zero_reciprocalCoeffPolynomial`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 430.

`Komorebi.PaperIV.reciprocalCoeffPolynomialOver`
definition; `KomorebiPaperIV/ParameterThetaCompletion.lean`, line 718.

`Komorebi.PaperIV.eval_reciprocalCoeffPolynomialOver`
theorem; `KomorebiPaperIV/ParameterThetaCompletion.lean`, line 721.

11.38 Row 38: 8.1, 8.2, and 8.3 Transfer tangent and recurrence

Exact row scope. Exact formal quotient definition and exact factorial/binomial recurrence for the kappa-scaled sequence. The bridge identifying these named coefficients with the full-variable tangent series remains outside this row.

Manuscript labels. `def:transfer_tangent`, `prop:tangent_kappa`, `thm:tangent_recurrence`

`Komorebi.PaperIV.formalTransferTangent`
definition; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 579.

`Komorebi.PaperIV.transferTangentCoeff`
definition; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 444.

`Komorebi.PaperIV.transferTangentCoeff_eq_kappa`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 448.

`Komorebi.PaperIV.transferTangentCoeff_convolution`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 510.

`Komorebi.PaperIV.transferTangentCoeff_recurrence`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 538.

`Komorebi.PaperIV.transferTangentCoeff_zero`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 566.

11.39 Row 39: 8.5 Scalar higher Riccati identity

Exact row scope. Exact nontrivial formal-germ differential-Bell/Riccati identity. Pointwise analytic validity on the entire zero-free set remains outside this row.

Manuscript labels. `thm:higher_riccati`

`Komorebi.PaperIV.differentialBellSeries`
definition; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 586.

`Komorebi.PaperIV.differentialBellSeries_zero`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 594.

`Komorebi.PaperIV.differentialBellSeries_succ`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 599.

`Komorebi.PaperIV.iterate_derivative_eq_differentialBellSeries_mul`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 607.

theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 621.

`Komorebi.PaperIV.differentialBellSeries_neg_formalTransferTangent_eq_neg_one`
theorem; `KomorebiPaperIV/ReciprocalCompletion.lean`, line 640.

11.40 Row 40: 9.3 Arbitrary-order residue-section powers

Exact row scope. Exact branch-free formal family `Phi_(N,j)^(-r)`, its factorially normalized coefficients, and the `r=1` bridge to the triangular inverse. No analytic logarithm branch is asserted.

Manuscript labels. `def:residue_section_power`

`Komorebi.PaperIV.normalizedResidueSectionAlg`
definition; `KomorebiPaperIV/ParameterThetaCompletion.lean`, line 33.

theorem; KomorebiPaperIV/ParameterThetaCompletion.lean, line 503.

11.42 Row 42: 9.6, 9.7, 9.8, 9.9, and 9.10 Arbitrary-order residue Appell system

Exact row scope. Exact arbitrary-order formal Appell specialization: sparse formula, lowering, translation, joint convolution, monicity, covariance, monomial symbol action, and opposite-order finite operator inversion. The two operator encodings are not yet bridged into the manuscript's single displayed named inverse relation.

Manuscript labels. cor:appell_symmetry, prop:appell_operator_form, prop:explicit_appell, thm:appell_laws, thm:appell_two_parameter_convolution

theorem; KomorebiPaperIV/ParameterThetaCompletion.lean, line 979.

11.46 Row 46: 7.2 Bell formula and 7.8 parameter divisibility

Exact row scope. Exact standard Bell generating-function specialization, every reciprocal coefficient, exact polynomial degree and leading coefficient over any characteristic-zero field, and generic-field parameter divisibility. This closes the full formal statement of 7.2; it asserts no global logarithm branch.

Manuscript labels. `cor:factor_r`, `thm:reciprocal_bell`

Komorebi.PaperIV.bellInput
definition; KomorebiPaperIV/BellCompletion.lean, line 21.

Komorebi.PaperIV.completeExponentialBell

11.47 Row 47: 4.1, 4.2, 5.1, 5.2, 5.3, and 5.6 Entire realization

Exact row scope. Actual entire functions, convergence of the existing formal transfer/signed series at every complex argument, independence of root choices, pointwise finite exponential formulas, iterated derivative expressions, full-period ODEs, and exact initial data. Existence of a basis of the full ODE solution space and the one-step section-to-section derivative identities are not asserted by this row.

11.48 Row 48: 4.3 and 5.4 Analytic Wronskians

Exact row scope. Exact analytic Wronskians using actual iterated derivatives: lambda^(N*(N-1)/2) for the ordered transfer family and 1 for the ordered signed family, for N>1. The transfer equality also holds at lambda=0. The proofs derive determinant factorization and constancy; no Wronskian or determinant value is assumed.

Manuscript labels. `cor:signed_wronskian`, `cor:wronskians`

11.49 Row 49: 6.4 Companion first column and trace

Exact row scope. Convergent scalar series for each entry of the actual matrix exponential, exact first-column identification with the signed entire sections, every diagonal entry equal to the denominator, and trace=N*denominator. The full off-diagonal entry formula, characteristic polynomial, spectrum, and determinant-one claim remain outside this row.

theorem; `KomorebiPaperIV/ZeroPerturbation.lean`, line 215.

`Komorebi.PaperIV.perturbed_exponential_first_correction`
theorem; `KomorebiPaperIV/ZeroPerturbation.lean`, line 224.

11.58 Row 58: 11.5 Two-term normalization and remainder jets

Exact row scope. Exact normalized finite sum and actual signed remainder, derivative jets of every order, zero equivalence and strip estimate from stated real-part gaps. The sector-to-strip confinement clause is outside this row.

Manuscript labels. `lem:two_term_dominance`

`Komorebi.PaperIV.finiteExponentialRemainder`
definition; `KomorebiPaperIV/ExponentialRemainder.lean`, line 17.

`Komorebi.PaperIV.analyticAt_finiteExponentialRemainder`

theorem; `KomorebiPaperIV/ExponentialRemainder.lean`, line 128.

11.59 Row 59: 11.5 Canonical polygon gap and strip bounds

Exact row scope. The canonical roots have the precise positive gap gamma_N. The actual signed remainder satisfies the explicit strip estimate for every derivative order. No polygon-gap certificate is assumed. Global sector confinement is outside this row and supplied by rows 62–67.

Manuscript labels. `lem:two_term_dominance`

theorem; `KomorebiPaperIV/RegularPolygonGap.lean`, line 117.

11.60 Row 60: 5.8 Conjugation, 11.5 disk bounds, and 11.7 local zero strings

Exact row scope. For every N >= 3, constructs a unique positive real simple zero near every sufficiently large lattice center with exponential displacement. All smallness hypotheses follow from the actual canonical remainder. Also proves conjugation and local lattice assignment. Exhaustion of all large complex zeros, orbit uniqueness and the original-denominator derivative asymptotic remain outside this row.

Manuscript labels. `cor:denominator_symmetries`, `lem:two_term_dominance`, `thm:large_zero_strings`

theorem; KomorebiPaperIV/SignedZeroLocalization.lean, line 273.

Komorebi.PaperIV.canonicalSignedDenominator_zero_lattice_distance
theorem; KomorebiPaperIV/SignedZeroLocalization.lean, line 309.

11.61 Row 61: 11.8 Leading correction and 11.7 normalized derivative

Exact row scope. Actual signed-remainder leading correction has an explicit quadratic envelope error, exactly a constant times exp(-2 gamma_N t). Proves normalized derivative error. Assumes the stated envelope smallness and local zero membership. Does not cover global exhaustion, derivative sign, reality of the displayed correction, or the full original-denominator asymptotic.

Manuscript labels. thm:first_zero_correction, thm:large_zero_strings

theorem; `KomorebiPaperIV/SignedSectorConfinement.lean`, line 173.

11.63 Row 63: 11.7 Sector exhaustion

Exact row scope. Uniform strip smallness is derived from the actual remainder. Every sufficiently large sector zero belongs to a natural-index local disk, is positive real and simple, and is the only denominator zero in that disk.

Manuscript labels. `thm:large_zero_strings`

`Komorebi.PaperIV.signedSectorWidth_pos`
theorem; `KomorebiPaperIV/SignedSectorExhaustion.lean`, line 13.

11.65 Row 65: 11.7 Rotation, multiplicity, and orbit parameters

Exact row scope. Exact frequency norm, rotation of analytic multiplicity and derivative, uniqueness of a unit-modulus positive real rotation, disjoint lattice disks, and global exhaustion using the canonical finite powers of omega. The full sequence/Big-O presentation is not encoded as a single theorem.

Manuscript labels. `thm:large_zero_strings`

theorem; `KomorebiPaperIV/SignedZeroOrbits.lean`, line 102.

11.66 Row 66: 11.7 Original denominator derivative

Exact row scope. Exact product-rule bridge at zeros, quantified relative error for the actual derivative, exact leading modulus (2 sin(pi/N)/N) exp(cos(pi/N) x), and a modulus-ratio error bound. These explicit estimates assume the stated local disk membership and center threshold; signs and the final sequence-level Big-O packaging remain outside this row.

Manuscript labels. `thm:large_zero_strings`

11.71 Row 71: 11.7 Named strings and 11.13 reduced displacement

Exact row scope. Actual choice-defined positive sequences have local and global exhaustion and tail injectivity for N >= 3. The reduced sequence is the Nth power and satisfies the explicit C t_m^(N-1) exp(-gamma t_m) error. Definitions use a documented fallback only before the proved tail. Together with rows 69-70 this covers all clauses of 11.13; the remaining 11.7 assembly is supplied by row 81. Alternating derivative signs belong to 11.8 and are now supplied by rows 82–83.

11.72 Row 72: 11.15 Sharp summability thresholds

Exact row scope. Actual positive sequences satisfy tau_m ~ t_m and lambda_m ~ t_m^N. Reciprocal real powers are summable exactly for s>1 and N*s>1 respectively, for N >= 3. This row does not assemble the full complex zero multiset, exceptional multiplicities, or the N=2 exponent statement.

11.73 Row 73: 11.14 Positive-tail counting

Exact row scope. A finite lattice-window counting lemma is applied to the actual positive zero tail, giving density sin(pi/N)/pi with uniform bounded error for N >= 3. This row is limited to tails; rows 77–78 supply both full multiplicity-weighted counts.

Manuscript labels. `thm:zero_counting`

11.74 Row 74: 12.1 Convergent entire tail product

Exact row scope. Reciprocal summability proves compact-uniform convergence and entire analyticity of the genus-zero product over any shifted chosen positive sequence for N >= 3. Its zero set is exactly that sequence. A sufficiently late shift consists of actual simple reduced zeros by row 71. The finite exceptional factor and equality with Delta_N are not asserted.

Manuscript labels. `thm:genus_zero_product`

11.79 Row 79: 11.15 Full zero convergence exponents

Exact row scope. The reciprocal-power series over all distinct zeros, weighted by actual analytic multiplicity, is summable exactly for s>1 for D_N and s>1/N for Delta_N, for every N >= 2. Both boundary divergences are included. Finite exceptional sets are removed only through a proved summability equivalence. This fully encodes Corollary 11.15.

11.80 Row 80: 14.2 Absolute convergence and holomorphy

Exact row scope. Defines the exact complex summands m(z) exp(-s log(norm z)) over every zero. Proves both sharp absolute-convergence half-planes and failure of absolute convergence on and to their left, local uniform convergence by an explicit strip majorant, and holomorphy of both sums for every N >= 2. This fully encodes Theorem 14.2; meromorphic continuation in 14.3 is not asserted.

11.86 Row 86: 14.8 Bounded logarithmic arguments

Exact row scope. A proved Weierstrass criterion for complex coefficients and bounded logarithmic arguments. Includes absolute norm summability, local uniform convergence, entire sums and half-plane holomorphy. The final denominator specialization in row 87 proves the required summability hypotheses.

Manuscript labels. `thm:derivative_weighted_convergence`

11.87 Row 87: 14.8 Full derivative-weighted convergence

Exact row scope. Defines the exact exp(-s Log z)/(D_N prime(z)^q) series over all actual simple zeros, retaining exceptional simple zeros and the complex derivative weight. For every N >= 3 and q >= 1, proves absolute and locally uniform convergence everywhere and an entire sum. For N=2, proves absolute and locally uniform convergence and holomorphy on Re(s)>1. Logarithms must exponentiate to the zero and have arguments in a fixed bounded interval. This fully encodes Theorem 14.8.

11.89 Row 89: 14.3 Hurwitz model and pole

Exact row scope. The scaled Hurwitz model is meromorphic on the whole plane, holomorphic off its sole possible pole, with the exact residue. A nonzero residue gives meromorphic order -1. Uses the pinned proved Mathlib Hurwitz theory.

11.93 Row 93: 14.6 Full branch-dependent continuation

Exact row scope. Defines the actual multiplicity-weighted branched zero series. For logarithms real on the proved positive tail, it agrees with the absolute zeta plus an entire finite correction. Proves global continuation, the same single simple pole/residue, and an entire difference between choices. Intermediate finite-correction claims hold even for arbitrary exceptional complex values. Fully encodes Corollary 14.6.

theorem; `KomorebiPaperIV/EntireQuotientGrowth.lean`, line 113.

11.101 Row 101: 12.1 Actual denominator and product growth

Exact row scope. Derives the needed growth bounds from actual zero-power summability and the entire denominator estimate. The fixed exponent 3/4 is valid for every N>=2. No quotient-growth certificate is assumed.

Manuscript labels. `thm:genus_zero_product`

`Komorebi.PaperIV.log_one_add_le_rpow_div`
theorem; `KomorebiPaperIV/CanonicalProductGrowth.lean`, line 14.

theorem; `KomorebiPaperIV/HadamardIdentification.lean`, line 50.

11.103 Row 103: 12.7 Convergent Mittag-Leffler expansion

Exact row scope. Proves the logarithmic derivative of the full product and the exact tangent partial fractions, with absolute and locally uniform convergence away from poles. Auxiliary tail-convergence lemmas use Lean total division at poles; the analytic identity is restricted to nonpoles. Fully encodes Corollary 12.7.

Manuscript labels. `cor:mittag_leffler_tangent`

theorem; KomorebiPaperIV/CanonicalPartialFractions.lean, line 135.

11.104 Row 104: 12.6 Actual zero moments and derivatives

Exact row scope. Defines moments over all actual zeros repeated by analytic multiplicity. Proves termwise derivatives of the locally uniform resolvent series and the exact factorial-normalized derivatives at zero.

Manuscript labels. `thm:newton_sums`

`Komorebi.PaperIV.locally_uniform_sum_deriv`
theorem; KomorebiPaperIV/ZeroMomentDerivatives.lean, line 13.

theorem; `KomorebiPaperIV/ZeroMomentCoefficients.lean`, line 114.

11.106 Row 106: 12.9 Tangent coefficients from zero sums

Exact row scope. Proves the precise factorial-normalized coefficient formula and its convergent Taylor realization as the actual analytic tangent on every zero-free disk in the reduced variable. Fully encodes Corollary 12.9.

Manuscript labels. `cor:tangent_zero_sums`

`Komorebi.PaperIV.transferTangentCoeff_zero_sum`
theorem; `KomorebiPaperIV/ZeroMomentCoefficients.lean`, line 135.

theorem; `KomorebiPaperIV/ZeroMomentLogarithm.lean`, line 110.

11.107 Row 107: 12.10 Reciprocal Bell formula from zero data

Exact row scope. The named reciprocal coefficient family equals the complete exponential Bell polynomial in the actual zero moments, for all n including zero and every complex parameter r. Fully encodes Corollary 12.10; earlier general-domain complex-power bridges retain their own boundaries.

Manuscript labels. `cor:reciprocal_zero_data`

`Komorebi.PaperIV.bellInput_zero_sums`
theorem; `KomorebiPaperIV/ZeroMomentCoefficients.lean`, line 140.

`Komorebi.PaperIV.reciprocalCoeff_zero_sum_bell`
theorem; `KomorebiPaperIV/ZeroMomentCoefficients.lean`, line 150.

11.108 Row 108: 12.8 Theta Bell formula from zero data

Exact row scope. Uses formal ODE uniqueness and the proved kappa/zero-moment identity to derive the exact theta coefficient formula, including the alternating sign and u^(Nm)+u factor. Fully encodes Proposition 12.8 for the named theta coefficient family.

Manuscript labels. `prop:theta_bell`

`Komorebi.PaperIV.powerSeries_linear_ode_unique`
theorem; `KomorebiPaperIV/ThetaZeroBell.lean`, line 10.

theorem; `KomorebiPaperIV/ThetaZeroBell.lean`, line 60.

11.109 Row 109: 12.6 Normalized analytic logarithm series

Exact row scope. Constructs the logarithm branch normalized at zero on every zero-free disk, proves exp(-L)=Delta, and proves its convergent zero-moment series throughout that disk using Cauchy estimates. Together with rows 104–105 this fully encodes Theorem 12.6. Also proves the convergent resolvent Taylor series.

Manuscript labels. `thm:newton_sums`

theorem; `KomorebiPaperIV/DominantExponential.lean`, line 84.

11.111 Row 111: 11.2 Sharp growth order and exponential type

Exact row scope. Defines the closed-disk maximum modulus and the standard logarithmic order/type limsups. Proves two-sided maximum-modulus bounds, actual limits for both logarithmic growth ratios, order one and type one for D_N, and order 1/N for Delta_N. Fully encodes Proposition 11.2; imported standard fact 11.1 is not separately formalized or assumed by this proof.

theorem; KomorebiPaperIV/SharpGrowth.lean, line 170.

11.112 Row 112: 11.4 Indicator polygon and tie geometry

Exact row scope. Identifies the actual support function with the manuscript maximum of cosines, proves continuity and nonnegativity for N>=2, and derives the exact periodic tie directions and strict maximizing vertex off those directions.

Manuscript labels. `thm:indicator_polygon`

Komorebi.PaperIV.rayDirection

theorem; `KomorebiPaperIV/IndicatorGeometry.lean`, line 134.

11.113 Row 113: 11.4 Uniform dominance and zero-free sectors

Exact row scope. Derives a uniform positive projection gap on every compact set avoiding the actual tie directions. Proves the normalized dominant-exponential error bound (N-1) exp(-delta r) and eventual zero-freeness there, with one uniform delta and radius. Supplies every dominant-sector clause of Theorem 11.4.

Manuscript labels. `thm:indicator_polygon`

theorem; `KomorebiPaperIV/UniformDominantSectors.lean`, line 90.

11.114 Row 114: 11.4 Aligned radii in tie directions

Exact row scope. Constructs explicit radii tending to infinity on which the leading conjugate phases align; lower-projection terms decay and the normalized finite sum has a positive limit. This proves the indicator lower bound even at tie directions, without a phase-alignment certificate.

Manuscript labels. `thm:indicator_polygon`

`Komorebi.PaperIV.alignedRadii`
definition; `KomorebiPaperIV/AlignedExponentialRadii.lean`, line 14.

theorem; `KomorebiPaperIV/AlignedExponentialRadii.lean`, line 99.

11.115 Row 115: 11.4 Exact indicator in every direction

Exact row scope. Proves the exact indicator limsup for every angle and every N>=2. Includes the classical formulation along radii where the denominator is nonzero, so the theorem does not depend on Lean Real.log zero. Together with rows 112–114 this fully encodes Theorem 11.4, including uniform compact-sector estimates and eventual zero-freeness.

theorem; KomorebiPaperIV/CompleteHomogeneous.lean, line 55.

Komorebi.PaperIV.finiteHomogeneousSeries
definition; KomorebiPaperIV/CompleteHomogeneous.lean, line 72.

Komorebi.PaperIV.finiteHomogeneousSeries_constantCoeff
theorem; KomorebiPaperIV/CompleteHomogeneous.lean, line 75.

Komorebi.PaperIV.finiteHomogeneousSeries_derivative
theorem; KomorebiPaperIV/CompleteHomogeneous.lean, line 78.

Komorebi.PaperIV.finiteHomogeneousSeries_eq_homogeneous
theorem; KomorebiPaperIV/CompleteHomogeneous.lean, line 88.

Komorebi.PaperIV.finiteHomogeneousSeries_monomials
theorem; KomorebiPaperIV/CompleteHomogeneous.lean, line 100.

11.120 Row 120: 12.3 InfiniteSymmetric

Exact row scope. Norm-summable eigenvalues give coefficientwise limits of the finite monomial sums. Repeating eigenvalues r times gives the exact positive-integer reciprocal coefficient; the complex-parameter Bell continuation is proved.

Manuscript labels. `cor:complete_symmetric_form`

Komorebi.PaperIV.summable_norm_positive_powers
theorem; KomorebiPaperIV/InfiniteSymmetric.lean, line 13.

Komorebi.PaperIV.homogeneousCoeff_zero
theorem; KomorebiPaperIV/InfiniteSymmetric.lean, line 21.

theorem; `KomorebiPaperIV/InfiniteSymmetric.lean`, line 131.

11.121 Row 121: 12.4 NormalizedEntire

Exact row scope. The literal normalized factorial series is entire and equals the residue transfer section after multiplication by z^j. Actual Taylor derivatives and value one at zero are proved.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.entireNormalizedSection`
definition; `KomorebiPaperIV/NormalizedEntire.lean`, line 13.

`Komorebi.PaperIV.normalizedSection_coeff_norm`
theorem; `KomorebiPaperIV/NormalizedEntire.lean`, line 16.

theorem; `KomorebiPaperIV/JensenZeroGrowth.lean`, line 62.

`Komorebi.PaperIV.entire_zero_bounded_finite`
theorem; `KomorebiPaperIV/JensenZeroGrowth.lean`, line 74.

11.123 Row 123: 12.4 WeightedGrowthSummability

Exact row scope. Multiplicity-weighted counting growth implies the exact subcritical power-sum summability bounds, by finite shell estimates.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.weighted_growth_summable_large`
theorem; `KomorebiPaperIV/WeightedGrowthSummability.lean`, line 14.

`Komorebi.PaperIV.weighted_growth_summable`
theorem; `KomorebiPaperIV/WeightedGrowthSummability.lean`, line 61.

`Komorebi.PaperIV.entire_growth_zeroPowerSummable`
theorem; `KomorebiPaperIV/WeightedGrowthSummability.lean`, line 79.

11.124 Row 124: 12.4 SublinearHadamard

Exact row scope. General normalized entire functions with sublinear power growth equal the complete genus-zero product over their actual zeros with multiplicity. All summability and quotient-rigidity prerequisites are derived.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.entire_sublinear_growth_hadamard`
theorem; `KomorebiPaperIV/SublinearHadamard.lean`, line 15.

11.125 Row 125: 12.4 NormalizedGrowth

Exact row scope. Global factorial/exponential bounds for the actual normalized sections imply every zero-power summability exponent above 1/N.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.entireNormalizedSection_norm_le`
theorem; `KomorebiPaperIV/NormalizedGrowth.lean`, line 13.

`Komorebi.PaperIV.normalizedSectionGrowthConstant`
definition; `KomorebiPaperIV/NormalizedGrowth.lean`, line 39.

`Komorebi.PaperIV.normalizedSectionGrowthConstant_pos`
theorem; `KomorebiPaperIV/NormalizedGrowth.lean`, line 41.

`Komorebi.PaperIV.entireNormalizedSection_disk_growth`
theorem; `KomorebiPaperIV/NormalizedGrowth.lean`, line 47.

`Komorebi.PaperIV.entireNormalizedSection_zeroPowerSummable`
theorem; `KomorebiPaperIV/NormalizedGrowth.lean`, line 61.

11.126 Row 126: 12.4 NormalizedOrder

Exact row scope. The finite exponential representation proves the dominant positive-real-ray limit for each transfer residue section.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.entireTransfer_positive_ray`
theorem; `KomorebiPaperIV/NormalizedOrder.lean`, line 14.

11.127 Row 127: 12.4 NormalizedExactOrder

Exact row scope. Matching upper and polynomially corrected lower bounds prove the exact order 1/N, including N=1. The residue condition is j<N.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.log_growth_ratio_of_polynomial_exp_bounds`
theorem; `KomorebiPaperIV/NormalizedExactOrder.lean`, line 13.

`Komorebi.PaperIV.entireTransfer_positive_ray_lower`
theorem; `KomorebiPaperIV/NormalizedExactOrder.lean`, line 49.

`Komorebi.PaperIV.entireNormalizedSection_maximum_bounds`
theorem; `KomorebiPaperIV/NormalizedExactOrder.lean`, line 66.

`Komorebi.PaperIV.entireNormalizedSection_growth_limit`
theorem; `KomorebiPaperIV/NormalizedExactOrder.lean`, line 103.

`Komorebi.PaperIV.entireNormalizedSection_order_exact`
theorem; `KomorebiPaperIV/NormalizedExactOrder.lean`, line 110.

11.128 Row 128: 12.4 NormalizedProduct

Exact row scope. For N>=2, each normalized section equals its full multiplicity-indexed product, uniformly on compact sets. The actual analytic Taylor series is the named formal series.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.entireNormalizedSection_hadamard`
theorem; `KomorebiPaperIV/NormalizedProduct.lean`, line 16.

`Komorebi.PaperIV.entireNormalizedSection_hadamard_uniform`
theorem; `KomorebiPaperIV/NormalizedProduct.lean`, line 26.

`Komorebi.PaperIV.analyticTaylorSeries_entireNormalizedSection`
theorem; `KomorebiPaperIV/NormalizedProduct.lean`, line 35.

11.129 Row 129: 12.4 NormalizedZeroBell

Exact row scope. The logarithmic coefficients equal the actual zero power sums, giving the exact (Nn)!/n! Bell normalization for the named residue coefficients and every complex parameter.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.normalized_zeroMomentSeries`
theorem; `KomorebiPaperIV/NormalizedZeroBell.lean`, line 11.

`Komorebi.PaperIV.normalized_zeroPowerSum`
theorem; `KomorebiPaperIV/NormalizedZeroBell.lean`, line 29.

`Komorebi.PaperIV.bellInput_normalized_zeros`
theorem; `KomorebiPaperIV/NormalizedZeroBell.lean`, line 35.

`Komorebi.PaperIV.residuePowerCoeff_zero_sum_bell`
theorem; `KomorebiPaperIV/NormalizedZeroBell.lean`, line 52.

11.130 Row 130: 12.4 NormalizedAnalyticPowers

Exact row scope. Actual principal-logarithm powers near zero have the named residue formal Taylor series and exact zero-moment Bell coefficients for every complex parameter. This is a germ at zero; global branch domains remain an earlier mapping boundary.

Manuscript labels. `prop:normalized_section_product`

`Komorebi.PaperIV.powerSeries_eq_of_derivative_constant`
theorem; `KomorebiPaperIV/NormalizedAnalyticPowers.lean`, line 13.

`Komorebi.PaperIV.analyticTaylorSeries_log`
theorem; `KomorebiPaperIV/NormalizedAnalyticPowers.lean`, line 23.

`Komorebi.PaperIV.analyticTaylorSeries_exp`
theorem; `KomorebiPaperIV/NormalizedAnalyticPowers.lean`, line 46.

`Komorebi.PaperIV.normalizedAnalyticPower`
definition; `KomorebiPaperIV/NormalizedAnalyticPowers.lean`, line 63.

`Komorebi.PaperIV.normalizedAnalyticPower_taylor`
theorem; `KomorebiPaperIV/NormalizedAnalyticPowers.lean`, line 66.

`Komorebi.PaperIV.normalizedAnalyticPower_zero_sum_bell`
theorem; `KomorebiPaperIV/NormalizedAnalyticPowers.lean`, line 82.

11.131 Row 131: 13.1 AnalyticTaylorAlgebra

Exact row scope. Actual iterated-derivative Taylor coefficients preserve analytic germ equality, sums, products, natural powers and inverse products.

Manuscript labels. `thm:nearest_circle_expansion`

`Komorebi.PaperIV.analyticTaylorSeries`
definition; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 14.

`Komorebi.PaperIV.analyticTaylorSeries_coeff`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 16.

`Komorebi.PaperIV.analyticTaylorSeries_constantCoeff`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 20.

`Komorebi.PaperIV.analyticTaylorSeries_congr`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 23.

`Komorebi.PaperIV.analyticTaylorSeries_mul`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 28.

`Komorebi.PaperIV.analyticTaylorSeries_add`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 46.

`Komorebi.PaperIV.analyticTaylorSeries_const`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 51.

`Komorebi.PaperIV.analyticTaylorSeries_pow`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 58.

`Komorebi.PaperIV.analyticTaylorSeries_inverse_product`
theorem; `KomorebiPaperIV/AnalyticTaylorAlgebra.lean`, line 64.

11.132 Row 132: 12.4 and 13.1 AnalyticTaylorDifferential

Exact row scope. Actual Taylor coefficients respect differentiation and negation. Analytic Hadamard products yield the formal logarithmic zero-moment identity.

Manuscript labels. `prop:normalized_section_product`, `thm:nearest_circle_expansion`

`Komorebi.PaperIV.analyticTaylorSeries_neg`
theorem; `KomorebiPaperIV/AnalyticTaylorDifferential.lean`, line 13.

`Komorebi.PaperIV.analyticTaylorSeries_deriv`
theorem; `KomorebiPaperIV/AnalyticTaylorDifferential.lean`, line 18.

`Komorebi.PaperIV.analyticTaylorSeries_zeroResolvent`
theorem; `KomorebiPaperIV/AnalyticTaylorDifferential.lean`, line 29.

`Komorebi.PaperIV.hadamard_taylor_zeroMoment_identity`
theorem; `KomorebiPaperIV/AnalyticTaylorDifferential.lean`, line 38.

11.133 Row 133: 13.1 PoleCoefficientBounds

Exact row scope. Cauchy's estimate supplies explicit Taylor coefficient bounds, Big-O bounds and exact factorial/block rescaling.

Manuscript labels. `thm:nearest_circle_expansion`

`Komorebi.PaperIV.analyticTaylorCoefficient`
definition; `KomorebiPaperIV/PoleCoefficientBounds.lean`, line 13.

`Komorebi.PaperIV.analyticTaylorCoefficient_norm_le`
theorem; `KomorebiPaperIV/PoleCoefficientBounds.lean`, line 17.

`Komorebi.PaperIV.analyticTaylorCoefficient_isBigO`
theorem; `KomorebiPaperIV/PoleCoefficientBounds.lean`, line 28.

`Komorebi.PaperIV.analyticTaylorCoefficient_block_error`
theorem; `KomorebiPaperIV/PoleCoefficientBounds.lean`, line 45.

11.134 Row 134: 13.1 and 13.2 PrincipalPartCoefficients

Exact row scope. The normalized pole has the exact binomial Taylor coefficients. Lower pole orders satisfy a uniform polynomial coefficient bound.

Manuscript labels. `cor:leading_dominant_zero`, `thm:nearest_circle_expansion`

`Komorebi.PaperIV.principalPartSeries`
definition; `KomorebiPaperIV/PrincipalPartCoefficients.lean`, line 13.

`Komorebi.PaperIV.principalPartSeries_coefficient`
theorem; `KomorebiPaperIV/PrincipalPartCoefficients.lean`, line 16.

`Komorebi.PaperIV.principalPartSeries_inverse`
theorem; `KomorebiPaperIV/PrincipalPartCoefficients.lean`, line 25.

`Komorebi.PaperIV.lower_principal_part_choose_bound`
theorem; `KomorebiPaperIV/PrincipalPartCoefficients.lean`, line 33.

11.135 Row 135: 13.1 PoleRemoval

Exact row scope. The manuscript's local O(1) principal-part conditions imply nonnegative meromorphic order. The constructed normal-form remainder is holomorphic throughout the required zero-free disk after all finite principal parts are removed.

Manuscript labels. `thm:nearest_circle_expansion`

`Komorebi.PaperIV.poleTerm`
definition; `KomorebiPaperIV/PoleRemoval.lean`, line 14.

`Komorebi.PaperIV.polePrincipalPart`
definition; `KomorebiPaperIV/PoleRemoval.lean`, line 16.

`Komorebi.PaperIV.rawPoleRemainder`
definition; `KomorebiPaperIV/PoleRemoval.lean`, line 19.

`Komorebi.PaperIV.poleTerm_analyticAt`
theorem; `KomorebiPaperIV/PoleRemoval.lean`, line 22.

`Komorebi.PaperIV.poleTerm_meromorphicAt`

theorem; KomorebiPaperIV/PoleRemoval.lean, line 31.

Komorebi.PaperIV.polePrincipalPart_analyticAt
theorem; KomorebiPaperIV/PoleRemoval.lean, line 35.

Komorebi.PaperIV.rawPoleRemainder_meromorphic
theorem; KomorebiPaperIV/PoleRemoval.lean, line 39.

theorem; KomorebiPaperIV/PoleRemoval.lean, line 56.

Komorebi.PaperIV.rawPoleRemainder_bounded_at_pole
theorem; KomorebiPaperIV/PoleRemoval.lean, line 66.

Komorebi.PaperIV.removedPoleRemainder
definition; KomorebiPaperIV/PoleRemoval.lean, line 87.

Komorebi.PaperIV.removedPoleRemainder_analyticOnNhd
theorem; KomorebiPaperIV/PoleRemoval.lean, line 90.

Komorebi.PaperIV.removedPoleRemainder_eq_raw
theorem; KomorebiPaperIV/PoleRemoval.lean, line 105.

11.136 Row 136: 13.1 PoleTaylor

Exact row scope. Actual analytic principal parts have the stated binomial coefficients. Integer reciprocal powers of the signed denominator have exactly the manuscript's factorial-scaled P coefficients.

Manuscript labels. `thm:nearest_circle_expansion`

Komorebi.PaperIV.analyticTaylorSeries_sub
theorem; KomorebiPaperIV/PoleTaylor.lean, line 13.

Komorebi.PaperIV.analyticTaylorSeries_finsetSum
theorem; KomorebiPaperIV/PoleTaylor.lean, line 18.

Komorebi.PaperIV.analyticTaylorSeries_id
theorem; KomorebiPaperIV/PoleTaylor.lean, line 29.

Komorebi.PaperIV.analyticTaylorSeries_poleTerm
theorem; KomorebiPaperIV/PoleTaylor.lean, line 37.

Komorebi.PaperIV.analyticTaylorCoefficient_principalPart
theorem; KomorebiPaperIV/PoleTaylor.lean, line 54.

Komorebi.PaperIV.analyticTaylorSeries_canonicalSignedDenominator
theorem; KomorebiPaperIV/PoleTaylor.lean, line 70.

Komorebi.PaperIV.reciprocalSeries_nat
theorem; KomorebiPaperIV/PoleTaylor.lean, line 79.

Komorebi.PaperIV.analyticTaylorSeries_reciprocal_signed
theorem; KomorebiPaperIV/PoleTaylor.lean, line 84.

Komorebi.PaperIV.reciprocalCoeff_analyticTaylor
theorem; KomorebiPaperIV/PoleTaylor.lean, line 102.

11.137 Row 137: 13.1 SimplePoleParts

Exact row scope. Analytic Taylor division constructs the full principal part at every simple zero and proves its leading Laurent coefficient and bounded remainder; no principal-part existence certificate is assumed.

Manuscript labels. `thm:nearest_circle_expansion`

`Komorebi.PaperIV.poleNumerator`
definition; `KomorebiPaperIV/SimplePoleParts.lean`, line 13.

`Komorebi.PaperIV.canonicalPoleCoefficient`
definition; `KomorebiPaperIV/SimplePoleParts.lean`, line 16.

`Komorebi.PaperIV.poleNumerator_analyticAt`
theorem; `KomorebiPaperIV/SimplePoleParts.lean`, line 19.

`Komorebi.PaperIV.canonicalPoleCoefficient_leading`
theorem; `KomorebiPaperIV/SimplePoleParts.lean`, line 31.

`Komorebi.PaperIV.poleNumerator_identity`
theorem; `KomorebiPaperIV/SimplePoleParts.lean`, line 35.

`Komorebi.PaperIV.polePrincipalPart_scaled`
theorem; `KomorebiPaperIV/SimplePoleParts.lean`, line 50.

`Komorebi.PaperIV.canonicalPoleCoefficient_local_bound`
theorem; `KomorebiPaperIV/SimplePoleParts.lean`, line 73.

11.138 Row 138: 13.1 PrincipalPartUniqueness

Exact row scope. Every principal part satisfying the local O(1) condition has leading coefficient (-rho D'(rho))^(-r), independently of the chosen construction.

Manuscript labels. `thm:nearest_circle_expansion`

`Komorebi.PaperIV.polePrincipalPart_scaled_general`
theorem; `KomorebiPaperIV/PrincipalPartUniqueness.lean`, line 12.

`Komorebi.PaperIV.polePrincipalPart_scaled_limit`
theorem; `KomorebiPaperIV/PrincipalPartUniqueness.lean`, line 25.

`Komorebi.PaperIV.principalPart_leading_coefficient`
theorem; `KomorebiPaperIV/PrincipalPartUniqueness.lean`, line 50.

11.139 Row 139: 13.1 NearestPoleExpansion

Exact row scope. The actual reciprocal coefficients satisfy the complete nearest-pole expansion with an explicit Cauchy constant for every coefficient. Its hypotheses state the prescribed local principal parts and the absence of other zeros inside the next modulus.

Manuscript labels. `thm:nearest_circle_expansion`

`Komorebi.PaperIV.removedPoleRemainder_taylor`
theorem; `KomorebiPaperIV/NearestPoleExpansion.lean`, line 12.

`Komorebi.PaperIV.nearest_pole_taylor_bound`
theorem; `KomorebiPaperIV/NearestPoleExpansion.lean`, line 41.

`Komorebi.PaperIV.reciprocalCoeff_nearest_pole_bound`
theorem; `KomorebiPaperIV/NearestPoleExpansion.lean`, line 62.

11.140 Row 140: 13.2 LeadingPoleBounds

Exact row scope. The leading term has separately controlled polynomial/radial and Cauchy errors, with actual simple-zero principal parts constructed automatically. For r=1 the first error constant is exactly zero.

Manuscript labels. `cor:leading_dominant_zero`

`Komorebi.PaperIV.principalCoefficientSum`
definition; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 13.

`Komorebi.PaperIV.leadingPoleCoefficient`
definition; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 16.

definition; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 19.

`Komorebi.PaperIV.lowerPrincipalConstant_nonneg`
theorem; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 22.

`Komorebi.PaperIV.lowerPrincipalConstant_one`
theorem; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 25.

`Komorebi.PaperIV.principalCoefficientSum_split`
theorem; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 28.

`Komorebi.PaperIV.principalCoefficientSum_leading_error`
theorem; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 41.

`Komorebi.PaperIV.principalCoefficientSum_one`
theorem; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 67.

`Komorebi.PaperIV.reciprocalCoeff_leading_bound`
theorem; `KomorebiPaperIV/LeadingPoleBounds.lean`, line 72.

11.141 Row 141: 13.3 OrbitPoleReduction

Exact row scope. Derivative rotation and block exponent invariance give N identical contributions per orbit. An equivalence records the chosen representatives and all distinct rotations; the resulting main term retains both proved error bounds.

Manuscript labels. `cor:orbit_reduced_asymptotic`

`Komorebi.PaperIV.leadingZeroWeight`
definition; `KomorebiPaperIV/OrbitPoleReduction.lean`, line 12.

`Komorebi.PaperIV.leadingZeroWeight_rotation`
theorem; `KomorebiPaperIV/OrbitPoleReduction.lean`, line 15.

`Komorebi.PaperIV.leadingPoleCoefficient_eq_zero_weights`
theorem; `KomorebiPaperIV/OrbitPoleReduction.lean`, line 27.

theorem; `KomorebiPaperIV/OrbitPoleReduction.lean`, line 34.

`Komorebi.PaperIV.reciprocalCoeff_orbit_leading_bound`
theorem; `KomorebiPaperIV/OrbitPoleReduction.lean`, line 55.

11.142 Row 142: 13.4 SecantAsymptotic

Exact row scope. The actual cosine zeros and derivatives give the quantitative coefficient error, exponentially vanishing relative error, ratio limit one, and asymptotic equivalence to 2(2n)!(2/pi)^(2n+1).

Manuscript labels. `cor:secant_asymptotic`

`Komorebi.PaperIV.cosineNearestZeros`
definition; `KomorebiPaperIV/SecantAsymptotic.lean`, line 13.

`Komorebi.PaperIV.canonicalSignedDenominator_two_cos`
theorem; `KomorebiPaperIV/SecantAsymptotic.lean`, line 15.

theorem; `KomorebiPaperIV/SecantAsymptotic.lean`, line 120.

`Komorebi.PaperIV.secant_coefficient_asymptotic`
theorem; `KomorebiPaperIV/SecantAsymptotic.lean`, line 131.

11.143 Row 143: 3.1, 3.2, 3.3 PointwiseFilters

Exact row scope. Actual pointwise finite averages, coefficient-series HasSum, orthogonal projector resolution, holomorphic range/covariance equivalence on invariant domains, and the complete cyclic product law.

Manuscript labels. `prop:covariance`, `thm:cyclic_product`, `thm:root_filter`

`Komorebi.PaperIV.pointwiseRootAverage`
definition; `KomorebiPaperIV/PointwiseFilters.lean`, line 14.

`Komorebi.PaperIV.root_weight_sum`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 17.

`Komorebi.PaperIV.mapsTo_root_pow`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 43.

`Komorebi.PaperIV.pointwiseRootAverage_covariant`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 52.

theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 99.

`Komorebi.PaperIV.pointwiseRootAverage_resolution`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 106.

`Komorebi.PaperIV.differentiableOn_pointwiseRootAverage`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 128.

`Komorebi.PaperIV.pointwiseRootAverage_range_iff`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 138.

`Komorebi.PaperIV.pointwiseRootAverage_sum`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 152.

`Komorebi.PaperIV.pointwiseRootAverage_product`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 160.

`Komorebi.PaperIV.pointwiseRootAverage_hasSum`
theorem; `KomorebiPaperIV/PointwiseFilters.lean`, line 185.

11.144 Row 144: 4.4, 5.5 PointwiseAddition

Exact row scope. Actual entire transfer and signed addition formulas for arbitrary complex arguments; the signed carry factor is proved from rho^N=-1.

Manuscript labels. `cor:exponential_addition`, `prop:signed_addition`

`Komorebi.PaperIV.pointwiseRootAverage_scaled_exp`
theorem; `KomorebiPaperIV/PointwiseAddition.lean`, line 10.

`Komorebi.PaperIV.entireTransfer_addition`
theorem; `KomorebiPaperIV/PointwiseAddition.lean`, line 20.

11.145 Row 145: 7.4, 8.4, 8.5 AnalyticReciprocalLaws

Exact row scope. Parameter addition and reciprocal differentiation on every open domain with a single holomorphic logarithm; the actual differential Bell/Riccati identity at every point where D_N is nonzero. Formal coefficient clauses are covered by the earlier rows.

Manuscript labels. `cor:reciprocal_derivative`, `thm:higher_riccati`, `thm:reciprocal_parameter_addition`

theorem; `KomorebiPaperIV/NewtonDeterminant.lean`, line 112.

11.150 Row 150: 4.5 HypergeometricAnalytic

Exact row scope. The literal N-1 denominator parameters exclude the unique parameter 1 and have positive real parts. Gamma normalization identifies the ordinary hypergeometric coefficients with the exact factorial coefficients. The everywhere convergent Mathlib regularized series yields the pointwise manuscript formula, including N=1.

Manuscript labels. `thm:hypergeometric_form`

theorem; `KomorebiPaperIV/HypergeometricAnalytic.lean`, line 99.

11.151 Row 151: 6.2 QuotientExponential

Exact row scope. The quotient algebras receive their finite-dimensional coefficient norm topology. The ordinary exponential power series converges at every complex argument to the displayed entire-section coordinates in both x^N=1 and x^N=-1 algebras. The already checked derivative systems and addition laws retain their exact normalizations.

FORMAL COMPANION V

Multiresolution Signal Calculus

The formal companion to Chapter V explains the declared hypotheses, theorem correspondences and evidence boundaries.

IN THIS COMPANION

Formal companion 1937

Return to Chapter V

How to use this volume

A guide to the actual formal development. 20 scoped manuscript results. 225 theorem targets. 23 proof modules. The eight tutorial chapters explain the route from literal samples to Hilbert operators, finite filters, packet synthesis, adaptive trees, and projective actions. The complete ledgers then give exact declarations and manuscript locators. The mathematical text also contains 63 broader prose proof records. Their separate inventory is a reading aid and adds no formal coverage. The two edge recovery conjectures remain open. This guide preserves 52 exact Lean excerpts and reconciles source bytes, declaration locations, dependency pins, and the saved axiom audit. Kernel execution evidence comes from the recorded formal-core build. Its toolchain, source identities and replay instructions appear in the reproduction section. This reading guide does not claim a new kernel execution.

1 How to read the formal companion

Chapter V places several kinds of mathematics in one signal processing language: coordinate partitions, bounded Hilbert space operators, finite filter banks, finite tree optimization, formal series, and projective actions. The formal development keeps their types and hypotheses distinct. Following those distinctions is the most useful way to read its proofs.

A pointwise partition identity needs little structure. An energy theorem needs a normed space with the intended norm. A transform theorem needs convergence. An optimal finite pruning needs a finite family and an objective. A fractional linear expression needs a chart, while its projective action survives at the chart's poles. Each transition has a named construction or theorem in the source.

> **Follow the model before the theorem name**
>
> Start with the ambient type, then locate the bridge to the intended signal model. A coordinate identity, a bounded operator theorem, and an analytic transform law have different inputs. The exact excerpt shows where those inputs enter the declaration.

1.1 What the completed contract contains

The formal contract covers twenty scoped theorem-like manuscript results with explicit proofs and 225 supporting theorem targets. The saved namespace audit reports 827 declarations. These are different denominators: 827 includes definitions and compiler-generated declarations, while 225 includes supporting results rather than 225 independent new mathematical claims.

The formal core is the expanded manuscript preserved as Part I of the mathematical text. Part II preserves the broader Annals development. Its additional proof records are prose mathematics. They do not enter the twenty-result formalization contract. Section 10 gives a separate crosswalk.

The two edge recovery conjectures remain open. Known-edge cancellation is established, measurable-mask perturbation is established, and finite adaptive selection is established within its hypotheses. Those results do not provide an estimator with the full statistical and approximation guarantees requested by the conjectures.

1.2 Verification evidence

Evidence	Meaning
Source reconciliation	Current hashes, 225 declaration locations, 225 audit directives, and 225 inherited axiom-output records agree.
Recorded Lean execution	The saved compiler record reports the pinned build and namespace audit passing. The raw logs are preserved.
Manual correspondence	Manuscript statements have a reviewed, explicit relationship to formal declarations. Lean does not parse or certify the English PDF automatically.
Exact model tests	Finite independent models exercise indexing, masks, trees, lifting, filters, and boundary cases. They are computational evidence on their tested ranges.

Evidence	Meaning
Companion numerics	Signal experiments and figure data are empirical demonstrations. Their floating-point implementation is outside the Lean theorem claim.

The guide build performs no Lean compilation. Reproduction commands appear in Section 8, with the missing-tool case treated as a failure to establish a fresh kernel result. The final package's verification records distinguish current reruns from inherited evidence.

1.3 Read a theorem as a typed contract

The name after `theorem` is a reusable declaration. Parenthesized arguments are explicit inputs. Braced arguments are generally inferred. A hypothesis such as `(hN : 0 < N)` is an actual input to the theorem. A typeclass argument such as `[AddCommMonoid E]` specifies the algebraic laws available to its proof.

The expression after the colon is the proposition. The proof after `:= by` constructs evidence of that proposition. Common commands here have small, specific jobs: `ext` reduces equality to coordinates, `rw` rewrites using an equality, `simp` uses declared simplification rules, `ring` normalizes polynomial identities, `omega` handles integer arithmetic, and `linarith` combines linear inequalities. Their successful use belongs to the recorded compilation, not to a textual count of tactic names.

A definition marked `noncomputable` may use classical choice or real-number constructions that do not give executable numerical code. Its theorems can still be checked by the kernel. In particular, the pruning evaluator over exact real costs specifies a mathematical algorithm and a count of unit operations. Lean evaluation speed is outside that count.

1.4 Four kinds of signal space

Object	Lean representation	What it provides
Arbitrary sequence	`ℤ → K`	Every integer sample exists. No norm or convergence is assumed.
Finite filter	`ℤ →₀ K`	A finitely supported coefficient function. Convolution sums are finite.
Square-summable signal	`lp (fun _ : I => ℂ) 2`	The joint ℓ^2 norm, infinite norm-convergent expansions, bounded maps and adjoints.
Formal series	`R⟦X⟧`	Coefficients with formal addition and Cauchy multiplication. Analytic convergence is not part of the type.

The same informal word "packet" appears in all four settings. The guide always identifies the ambient type before using an identity across them.

1.5 Recommended reading routes

For the signal processing route, read integer addresses, the Hilbert bridge, FIR transfer, faithful filter banks, and Haar packets. For the adaptive route, read known edges, mask perturbations, complete prunings, the dynamic program, and its stability envelope. For the algebraic route, read formal cyclic products, homogeneous Smith actions, and CRT masks.

Every displayed code excerpt is copied from an immutable source declaration. The raw excerpt, its source line range, and its SHA256 hash accompany the PDF. Excerpts rely on the imports, namespaces, variables, and definitions in their source files. They are not advertised as independently compilable snippets. The complete project remains the authoritative executable object.

2 Partitions, signed addresses, and the Hilbert bridge

2.1 A packet first means a coordinate mask

Take an index set I, a label set R, and a phase map $\phi : I \to R$. The packet with label r keeps coordinate i exactly when $\phi(i) = r$:

$$(P_r x)(i) = \begin{cases} x(i), & \phi(i) = r, \\ 0, & \phi(i) \neq r. \end{cases}$$

The definition requires a zero in the value type and a decidable label equality. It does not require a Fourier transform, a measure, or an inner product.

Source: `KomorebiPaperV/Packets.lean`.

```
def packet (phase : I → R) (r : R) (x : I → V) : I → V :=
  fun i => if phase i = r then x i else 0
```

Applying the same mask twice changes nothing. Distinct labels cannot both be retained at the same coordinate. If the label type is finite and values can be added commutatively, the finite sum of packets returns the original value. At any one coordinate exactly one summand survives.

Source: `KomorebiPaperV/Packets.lean`.

```
theorem packet_complete (phase : I → R) (x : I → V) (i : I) :
    (∑ r : R, packet phase r x i) = x i := by
  classical
  calc
    (∑ r : R, packet phase r x i) = packet phase (phase i) x i := by
      apply Finset.sum_eq_single (phase i)
      · intro b _ hb
        simp [packet, Ne.symm hb]
      · simp
    _ = x i := by simp [packet]
```

The proof uses `Finset.sum_eq_single` to isolate the surviving label. This simple mechanism is reused after stronger ambient structures are introduced.

2.2 Signed polyphase coordinates are an equivalence

For $N > 0$, every integer has the unique decomposition

$$n = Nq + r, \qquad 0 \le r < N, \quad q \in \mathbb{Z}.$$

The integer quotient is Euclidean: for $N = 3$ and $n = -1$, the address is $(r, q) = (2, -1)$, not a negative residue. Lean represents the bounded residue by `Fin N`. Its stored value has a proof that it is smaller than N.

Source: `KomorebiPaperV/IntegerPolyphase.lean`.

```
def addressEquiv (N : ℕ) (hN : 0 < N) : ℤ ≃ Fin N × ℤ where
  toFun n := (phase N hN n, quotient N n)
  invFun p := address N p.1 p.2
  left_inv := address_phase_quotient N hN
  right_inv p := by
    apply Prod.ext
    · exact phase_address N hN p.1 p.2
    · exact quotient_address N hN p.1 p.2
```

The two inverse laws are mathematical content. They ensure both that analyzing then synthesizing recovers a signal and that synthesizing then analyzing recovers an arbitrary channel family. Merely checking the first direction would not establish that all channel coordinates are reachable.

Writing $x_r[q] = x[Nq + r]$, the pointwise maps are

$$Ax(r, q) = x[Nq + r], \qquad Sc(n) = c(n \bmod N, \lfloor n/N \rfloor).$$

These are meaningful for any value type. Energy is a later statement.

2.3 The two units of delay

A delay by d original samples is $(D_d x)[n] = x[n - d]$. A delay by d inside each channel is an original delay by Nd. For a general original delay, the residue changes and a signed carry enters the channel coordinate:

$$(AD_d x)_r[q] = x_{(r-d) \bmod N}\left[q + \left\lfloor \frac{r - d}{N} \right\rfloor\right].$$

Source: `KomorebiPaperV/IntegerPolyphase.lean`.

```
theorem sample_delay (N : ℕ) (hN : 0 < N) (d : ℤ) (x : ℤ → V)
    (r : Fin N) (q : ℤ) :
    analysis N (delay d x) r q =
      analysis N x (phase N hN ((r.val : ℤ) - d))
        (q + quotient N ((r.val : ℤ) - d)) := by
  dsimp [analysis, delay]
  congr 1
  have h := address_phase_quotient N hN ((r.val : ℤ) - d)
  dsimp [address] at h ⊢
  linear_combination -h
```

For $N = 2$ and a one-sample delay, the new even channel is the old odd channel delayed once, while the new odd channel is the old even channel at the same channel index:

$$(AD_1x)_0[q] = x_1[q-1], \qquad (AD_1x)_1[q] = x_0[q].$$

For a two-sample delay both channels are delayed once. This is why a filter-bank identity with channel delay d reconstructs $x[n - Nd]$.

2.4 Square summability is built into the type

Source: KomorebiPaperV/HilbertPackets.lean.

```
abbrev Signal (I : Type*) : Type _ := lp (fun _ : I => ℂ) 2
```

The bounded projector is obtained by first proving that masking cannot increase the norm. The proof works coordinate by coordinate and invokes monotonicity of the ℓ^2 norm.

Source: KomorebiPaperV/HilbertPackets.lean.

```
theorem projection_norm_le [DecidableEq R] (phase : I → R) (r : R)
    (x : Signal I) : ‖projection phase r x‖ ≤ ‖x‖ := by
  apply lp.norm_mono (by norm_num)
  intro i
  by_cases h : phase i = r <;> simp [projection_apply, h]
```

The same mask is made into a linear map and then promoted to a continuous linear map with bound one.

Source: KomorebiPaperV/HilbertPackets.lean.

```
noncomputable def projector [DecidableEq R] (phase : I → R) (r : R) :
    Signal I →L[ℂ] Signal I :=
  (projectionLinear phase r).mkContinuous 1 (by
    intro x
    change ‖projection phase r x‖ ≤ 1 * ‖x‖
    simpa using projection_norm_le phase r x)
```

The notation `→L[ℂ]` records continuous complex linearity. Idempotence alone would not establish boundedness, symmetry, or orthogonality. The file proves those separately. With finitely many labels, the sum is the identity as a continuous linear operator, not just a formula on finite test vectors.

2.5 The channel norm is the joint norm

The Hilbert space analysis target is $\ell^2(\mathrm{Fin}\, N \times \mathbb{Z})$:

$$\|Ax\|^2 = \sum_{r=0}^{N-1} \sum_{q \in \mathbb{Z}} |x[Nq + r]|^2 = \|x\|^2.$$

It is not an unqualified function space of channels carrying a supremum norm. The source packages the address equivalence into a complex linear isometric equivalence.

Source: KomorebiPaperV/HilbertPackets.lean.

```
noncomputable def polyphase (N : ℕ) (hN : 0 < N) :
    Signal ℤ ≃ₗᵢ[ℂ] Signal (Fin N × ℤ) :=
  reindexIsometry (KomorebiPaperV.IntegerPolyphase.addressEquiv N hN)
```

Its inverse laws are inherited from that equivalence, and its energy law follows from norm preservation. The proof of reindexing uses summability over the bijective address map. This is the actual bridge from arbitrary pointwise coordinates to the Hilbert statement.

2.6 Impulse expansion means norm convergence

The impulse at i with amplitude x_i is represented by `lp.single 2 i (x i)`. The full theorem is a `HasSum` statement in the ℓ^2 space.

Source: KomorebiPaperV/HilbertPackets.lean.

```
theorem impulse_expansion (x : Signal ℤ) :
    HasSum (fun i : ℤ => lp.single 2 i (x i)) x :=
  lp.hasSum_single (by norm_num) x
```

Thus the series of impulses converges to x in the ambient norm. The finite support version is an exact finite sum. The shift is an isometric equivalence with formula $S_d x[n] = x[n-d]$, and shifting the impulse at zero gives the impulse at d. Density of the impulse basis yields the dense shift-generated span.

2.7 Refinement uses divisibility

If $N \mid M$, reducing modulo M and then modulo N agrees with reducing directly modulo N. Consequently one coarse residue projector is the sum of the fine residue projectors lying above it.

Source: KomorebiPaperV/HilbertPackets.lean.

```
theorem residue_projector_refinement (N M : ℕ) (hN : 0 < N) (hM : 0 < M)
    (hNM : N ∣ M) (r : Fin N) :
    projector (IntegerPolyphase.phase N hN) r =
      ∑ s : Fin M, if IntegerPolyphase.phase N hN (s.val : ℤ) = r
        then projector (IntegerPolyphase.phase M hM) s else 0 := by
  have hc : (fun j : ℤ => IntegerPolyphase.phase N hN
      ((IntegerPolyphase.phase M hM j).val : ℤ)) = IntegerPolyphase.phase N hN := by
    funext j
    apply Fin.ext
    change (((IntegerPolyphase.phase M hM j).val : ℤ) % (N : ℤ)).toNat =
      (j % (N : ℤ)).toNat
    rw [IntegerPolyphase.phase_val, IntegerPolyphase.emod_coarsen N M hNM]
  have h := projector_refinement (IntegerPolyphase.phase M hM)
    (fun s : Fin M => IntegerPolyphase.phase N hN (s.val : ℤ)) r
  simpa only [Function.comp_def, hc] using h
```

For example, the even packet modulo 2 is the sum of packets 0, 2, and 4 modulo 6. The theorem is an equality of bounded operators on the full complex ℓ^2 space. The hypotheses $N > 0$, $M > 0$, and $N \mid M$ remain explicit. A relation between arbitrary unrelated moduli would require a different construction.

3 FIR transfer and faithful perfect reconstruction

3.1 Finite support makes time domain transfer unconditional

An FIR filter is a finitely supported function $h : \mathbb{Z} \to K$. Negative tap addresses are allowed, so the formal theorem includes advances as well as delays. For an arbitrary bilateral sequence,

$$(h * x)[n] = \sum_{t \in \operatorname{supp} h} h[t]x[n-t].$$

No convergence hypothesis is needed because this sum is finite.

Source: `KomorebiPaperV/FIRTransfer.lean`.

```
def fir (h : ℤ →₀ K) (x : ℤ → K) (n : ℤ) : K :=
  ∑ t ∈ h.support, h t * x (n - t)
```

Fix output phase k and input phase s. The tap carrying an input channel delay m is

$$t = Nm + k - s, \qquad h_{k,s}[m] = h[Nm + k - s].$$

The address identity is

$$(Nn + k) - (Nm + k - s) = N(n - m) + s.$$

It says exactly which original tap contributes to which channel and delay. The source's `tapEquiv` proves the relevant reindexing is bijective, then partitions the finite support by input phase. It does not enlarge the finite sum to an arbitrary infinite series.

Source: `KomorebiPaperV/FIRTransfer.lean`.

```
theorem fir_polyphase_transfer (N : ℕ) (hN : 0 < N) (h : ℤ →₀ K)
    (x : ℤ → K) (k : Fin N) (n : ℤ) :
    analysis N (fir h x) k n =
      ∑ s : Fin N, ∑ m ∈ delays N hN h k s,
        kernel N h k s m * analysis N x s (n - m) := by
  change fir h x (address N k n) = _
  rw [fir_reindex N hN h x k n]
  calc
    _ = ∑ s : Fin N, ∑ p ∈ (transferSupport N hN h k).filter (fun p => p.1 = s),
        kernel N h k p.1 p.2 * analysis N x p.1 (n - p.2) :=
      (Finset.sum_fiberwise (transferSupport N hN h k) Prod.fst
        (fun p => kernel N h k p.1 p.2 * analysis N x p.1 (n - p.2))).symm
    _ = _ := by
      apply Finset.sum_congr rfl
      intro s _
      exact sum_pair_fiber (transferSupport N hN h k) s
        (fun r m => kernel N h k r m * analysis N x r (n - m))
```

3.2 A two channel calculation

Three taps and their channel delays

Take $h[0] = a$, $h[1] = b$, $h[2] = c$, with all other taps zero. For $N = 2$ the four channel kernels are

$$y_0[n] = a x_0[n] + c x_0[n-1] + b x_1[n-1],$$
$$y_1[n] = b x_0[n] + a x_1[n] + c x_1[n-1].$$

The tap at one has different channel delays in the two off diagonal positions. In the transform convention used by the chapter, the transfer matrix is

$$H(z) = \begin{pmatrix} a + c z^{-1} & b z^{-1} \\ b & a + c z^{-1} \end{pmatrix}.$$

The time domain equations hold for every sequence. The transform equation $Y(z) = H(z)X(z)$ has the additional analytic hypotheses described next.

3.3 A transform is a convergent weighted sum

The source defines a totalized `tsum` expression, but the meaningful convergence predicate is `HasTransform`.

Source: `KomorebiPaperV/ZTransform.lean`.

```
def HasTransform (x : ℤ → ℂ) (z X : ℂ) : Prop := HasSum (fun n => x n * z ^ (-n)) X
```

It states that the bilateral weighted series $\sum_n x[n] z^{-n}$ has the specified sum. The delay theorem requires both a nonzero transform parameter and this convergence input.

Source: `KomorebiPaperV/ZTransform.lean`.

```
theorem delay_transform (x : ℤ → ℂ) (z X : ℂ) (hz : z ≠ 0)
    (h : HasTransform x z X) (d : ℤ) :
    HasTransform (fun n => x (n-d)) z (z ^ (-d) * X) := by
  have hh := h.mul_left (z ^ (-d))
  have he : (fun n : ℤ => z ^ (-d) * (x n * z ^ (-n))) =
      (fun n : ℤ => x (n-d) * z ^ (-n)) ∘ Equiv.addRight d := by
    funext n
    change z ^ (-d) * (x n * z ^ (-n)) = x (n+d-d) * z ^ (-(n+d))
    rw [add_sub_cancel_right, neg_add, zpow_add₀ hz]
    ring
  rw [he] at hh
  exact (Equiv.addRight d).hasSum_iff.mp hh
```

Finitely many delayed inputs can then be combined using finite sums of `HasSum` proofs. The matrix version assumes weighted summability separately for every input channel.

Source: KomorebiPaperV/ZTransform.lean.

```
theorem fir_matrix_transform (N : ℕ) (hN : 0 < N) (h : ℤ →₀ ℂ) (x : ℤ → ℂ)
    (z : ℂ) (hz : z ≠ 0)
    (hx : ∀ s, Summable (fun n => analysis N x s n * z ^ (-n))) :
    (fun k => transform (analysis N (fir h x) k) z) =
      (transferMatrix N hN h z).mulVec (fun s => transform (analysis N x s) z) := by
  funext k
  exact (fir_channel_transform N hN h x z hz _ (fun s => (hx s).hasSum) k).tsum_eq
```

An arbitrary ℓ^2 signal need not have an absolutely convergent bilateral transform at a chosen complex z. An L^2 Fourier boundary-value interpretation on the unit circle is a separate analytic interpretation. Off the unit circle, the displayed weighted summability conditions must be supplied. Neither the definition of `tsum` nor an FIR input filter removes them.

3.4 Laurent polynomials act as finite filters

The type `AddMonoidAlgebra ℂ ℤ` represents finite Laurent coefficients indexed by integer delays. Its multiplication is finite convolution. A monomial at index d acts by $x[n] \mapsto x[n-d]$, with transform symbol z^{-d}. The formal action is an algebra homomorphism into complex linear endomorphisms of all bilateral sequences.

Source: KomorebiPaperV/FilterBank.lean.

```
noncomputable def act : Laurent →ₐ[ℂ] Module.End ℂ Signal :=
  AddMonoidAlgebra.lift ℂ (Module.End ℂ Signal) ℤ shiftHom
```

The source proves `act_is_fir`, making the abstract algebra homomorphism coincide with the literal finite filter sum. It then defines a matrix bank by summing the action of each matrix entry over the input channels. The theorem `bank_mul` identifies matrix multiplication with composition of banks in the correct order.

3.5 Why the matrix criterion is an equivalence

The reverse direction of a perfect-reconstruction criterion needs faithfulness. If two matrix banks have the same action on every sequence, why must their Laurent coefficients agree? The source feeds a unit impulse into one channel at a time. Reading output channel k at sample n recovers exactly the nth Laurent coefficient of the (k, s) entry.

Source: KomorebiPaperV/FilterBank.lean.

```
theorem bank_faithful (A B : Matrix I I Laurent) :
    (∀ x, bank A x = bank B x) ↔ A = B := by
  constructor
  · intro h
    funext k s
    apply AddMonoidAlgebra.ext
    apply Finsupp.ext
    intro n
    have he := congrArg (fun y : I → Signal => y k n) (h (channelImpulse s))
```

```
    simpa only [bank_impulse] using he
  · rintro rfl
    intro x
    rfl
```

This eliminates a possible gap between an operator statement and a formal matrix identity. It relies on equality on every input, rather than agreement on a bounded collection of numerical examples.

3.6 Gain and delay

The target matrix is diagonal, with each diagonal entry the monomial of amplitude c at delay d. The theorem gives the equivalence between matrix equality and reconstruction of every channel sequence.

Source: KomorebiPaperV/FilterBank.lean.

```
theorem perfect_reconstruction_iff (E R : Matrix I I Laurent) (c : ℂ) (d : ℤ) :
    (∀ x : I → Signal, ∀ k n, bank R (bank E x) k n = c*x k (n-d)) ↔
      R*E = gainDelay c d := by
  rw [← bank_faithful]
  constructor
  · intro h x
    funext k n
    rw [bank_mul, gain_delay_action]
    exact h x k n
  · intro h x k n
    have he := congrArg (fun y : I → Signal => y k n) (h x)
    simpa only [bank_mul, gain_delay_action] using he
```

The formula allows any complex c. To interpret the result as invertible reconstruction up to gain, one additionally requires $c \neq 0$. At $c = 0$, the theorem remains a valid zero-output identity, but it is not an invertibility statement.

Returning from channel coordinates to original coordinates yields the literal sample formula.

Source: KomorebiPaperV/FilterBank.lean.

```
theorem original_sample_delay (N : ℕ) (hN : 0 < N)
    (E R : Matrix (Fin N) (Fin N) Laurent) (c : ℂ) (d : ℤ)
    (h : R*E = gainDelay c d) (x : Signal) (n : ℤ) :
    KomorebiPaperV.IntegerPolyphase.synthesis N hN
      (bank R (bank E (KomorebiPaperV.IntegerPolyphase.analysis N x))) n = c*x (n-(N:ℤ)*d) := by
  have hr := (perfect_reconstruction_iff E R c d).mpr h
  unfold KomorebiPaperV.IntegerPolyphase.synthesis
  rw [hr]
  congr 1
  unfold KomorebiPaperV.IntegerPolyphase.analysis
  congr 1
  have ha := KomorebiPaperV.IntegerPolyphase.address_phase_quotient N hN n
  dsimp [KomorebiPaperV.IntegerPolyphase.address] at ha ⊢
  linarith
```

This result is independent of numerical transform convergence. The transform representation of the bank is a further theorem with `HasTransform` hypotheses. The distinction is practical: an exact finite

reconstruction identity can be checked algebraically even when a particular signal's off-circle transform does not exist.

4 Haar, lifting, and finite depth packet synthesis

4.1 Interleaving is part of the theorem

For a bilateral signal, write $e[n] = x[2n]$ and $o[n] = x[2n+1]$. The source first proves that the squared norms of these two channels sum to the original squared norm. It then forms the normalized Haar channels

$$a[n] = \frac{e[n] + o[n]}{\sqrt{2}}, \qquad d[n] = \frac{e[n] - o[n]}{\sqrt{2}}.$$

The sample formula establishes that the abstract construction really acts on these literal interleaved samples.

Source: KomorebiPaperV/HaarChannels.lean.

```
theorem haar_low_samples (x : Signal ℤ) (n : ℤ) :
    analysisLow x n = ((Real.sqrt 2 : ℝ) : ℂ)⁻¹ * (x (2*n) + x (2*n+1)) := by
  rw [analysisLow, low_apply, even_apply, odd_apply]
```

The energy identity combines the Hilbert space parallelogram law with the joint channel norm.

Source: KomorebiPaperV/HaarChannels.lean.

```
theorem haar_energy (x : Signal ℤ) :
    ‖x‖ ^ 2 = ‖analysisLow x‖ ^ 2 + ‖analysisHigh x‖ ^ 2 := by
  rw [analysisLow, analysisHigh, energy, interleaved_energy]
```

This theorem holds for complex ℓ^2 signals, not only finite real arrays. A finite numerical check can expose normalization mistakes but cannot replace the infinite-space proof.

4.2 Lifting is a different normalization

The lifting analysis sends (e, o) to (s, d) with

$$d = o - e, \qquad s = e + \frac{d}{2} = \frac{e + o}{2}.$$

The inverse is $e = s - d/2$, $o = d + e$. Its determinant is one. The theorem is stated over a characteristic zero field, which makes division by two meaningful in the required way.

Source: KomorebiPaperV/Lifting.lean.

```
theorem lifting_synthesis_analysis (x : K × K) :
    liftingSynthesis (liftingAnalysis x) = x := by
  apply Prod.ext <;> dsimp [liftingAnalysis, liftingSynthesis] <;> ring
```

The lifting pair is invertible but is not the normalized Haar pair. For example, $(e, o) = (2, 4)$ gives lifting coordinates $(s, d) = (3, 2)$, whose squared Euclidean norm is 13, whereas the input norm squared is 20. Normalized Haar gives $(3\sqrt{2}, -\sqrt{2})$ with squared norm 20 under the source's high-channel sign convention. Invertibility and isometry are separate claims.

4.3 Flat finite signals have both inverse laws

The finite transform file builds a pairing equivalence between a flat vector of length $2N$ and N pairs. It transports lifting through that equivalence. The result is a theorem about the actual flattened signal, not an unconnected pairwise calculation.

Source: `KomorebiPaperV/FiniteTransforms.lean`.

```
theorem unlift_lift_flat (n : ℕ) (x : Fin (2 * n) → K) :
    unliftFlat n (liftFlat n x) = x := by
  simp only [unliftFlat, liftFlat, flat_analysis_synthesis,
    KomorebiPaperV.lifting_synthesis_analysis, flat_synthesis_analysis]
```

The companion direction, `lift_unlift_flat`, establishes reconstruction of arbitrary transformed coordinates as well. The finite Haar statements similarly include pair energy, finite energy, and a flat involution. These finite constructions are useful for matching array implementations, while the Hilbert files establish the infinite ℓ^2 statements.

4.4 A packet is an ordered composition

At depth zero there is one empty word and its operator is the identity. A depth-$n+1$ word consists of a first branch and a remaining word. The first branch acts on the signal before the remaining packet.

Source: `KomorebiPaperV/WaveletPackets.lean`.

```
noncomputable def packet : (n : ℕ) → Word n → H →L[ℂ] H
  | 0, _ => ContinuousLinearMap.id ℂ H
  | n+1, (b,w) => (packet n w).comp (childOp b)
```

Here `Word n` is a recursively finite type. Each child map is a bounded continuous linear operator. The low and high norm bounds come from the two channel energy identity, so their adjoints are legitimate Hilbert adjoints.

4.5 Induction preserves total energy

The proof at depth $n+1$ first sums over the remaining word for each child. The induction hypothesis reduces that sum to the child's norm squared. Summing over the two children returns the parent's norm squared.

Source: `KomorebiPaperV/WaveletPackets.lean`.

```
theorem packet_energy (n : ℕ) (x : H) : ∑ w : Word n, ‖packet n w x‖ ^ 2 = ‖x‖ ^ 2 := by
  induction n generalizing x with
  | zero =>
    change (∑ w : Unit, ‖x‖ ^ 2) = _
    simp
  | succ n ih =>
    change (∑ w : Fin 2 × Word n, ‖(packet n w.2) (childOp w.1 x)‖ ^ 2) = _
    rw [Fintype.sum_prod_type]
    simp_rw [ih]
    exact child_energy x
```

For depth two, this is the four-packet identity

$$\|W_{00}x\|^2 + \|W_{01}x\|^2 + \|W_{10}x\|^2 + \|W_{11}x\|^2 = \|x\|^2.$$

The theorem quantifies over every natural depth. Each individual depth has a finite packet family. It is not a theorem about convergence of an infinite depth packet expansion.

4.6 Energy gives an operator reconstruction identity

For finitely many bounded maps W_i on the complex Hilbert space, an energy identity valid for every x implies

$$\sum_i W_i^* W_i = I.$$

The formal proof uses inner product extensionality, the adjoint relation, and complex polarization through the library theorem it invokes.

Source: `KomorebiPaperV/WaveletPackets.lean`.

```
theorem energy_implies_adjoint_identity {I : Type*} [Fintype I]
    (W : I → H →L[ℂ] H) (h : ∀ x, ∑ i, ‖W i x‖ ^ 2 = ‖x‖ ^ 2) :
    (∑ i, (W i).adjoint.comp (W i)) = ContinuousLinearMap.id ℂ H := by
  have he : (∑ i, (W i).adjoint.comp (W i)).toLinearMap = LinearMap.id := by
    apply (ext_inner_map _ _).mp
    intro x
    change inner ℂ ((∑ i, (W i).adjoint.comp (W i)) x) x = inner ℂ x x
    simp only [sum_apply, ContinuousLinearMap.comp_apply, sum_inner,
      ContinuousLinearMap.adjoint_inner_left, inner_self_eq_norm_sq_to_K]
    exact_mod_cast h x
  apply ContinuousLinearMap.ext
  intro x
  exact LinearMap.congr_fun he x
```

This is a genuine adjoint identity. Writing a reconstruction map with a similar formula would not suffice without showing that it is the adjoint of the analysis map.

Applying the resulting operator equality to a signal gives the source level synthesis theorem.

Source: `KomorebiPaperV/WaveletPackets.lean`.

```
theorem packet_reconstruction (n : ℕ) (x : H) :
    (∑ w : Word n, (packet n w).adjoint (packet n w x)) = x := by
  have h := congrArg (fun T : H →L[ℂ] H => T x) (packet_operator_reconstruction n)
  simpa using h
```

The proof does not need every W_i to be invertible. It needs the collective energy identity. The family can divide information among its channels while the sum of adjoint synthesis terms recovers the original signal exactly.

5 Known edges and measurable perturbations

5.1 Exact retention separates the error algebraically

Write $f = s + j$, where s is the background and j is a known jump packet. If the reconstruction is $Qs + j$, the retained jump cancels:

$$f - (Qs + j) = s - Qs.$$

Source: `KomorebiPaperV/KnownEdge.lean`.

```
theorem known_edge_error (s j : E) (Q : E → E) :
    (s + j) - (Q s + j) = s - Q s := by
  abel
```

The cancellation theorem needs only an additive commutative group and an arbitrary function Q. It does not require Q to be linear. This is sufficient for cancellation because Q is applied to s before the same j is restored. A separate claim that commutes Q with addition, or estimates an operator commutator, would need the appropriate linearity hypotheses.

Taking norms yields exact equality of the full reconstruction error with the background error. A finite sum of known packets cancels in the same way. None of these statements estimates an unknown edge or proves that a data driven algorithm finds the correct mask.

5.2 Estimated packets have two errors

For $j = a\mathbf{1}_S$ and $\hat{j} = b\mathbf{1}_T$,

$$j - \hat{j} = (a - b)\mathbf{1}_S + b(\mathbf{1}_S - \mathbf{1}_T).$$

The first term changes the amplitude on the original mask. The second changes the mask while holding the estimated amplitude fixed. The symmetric difference $S \triangle T$ contains exactly the points where the two masks disagree.

For measurable sets and $1 \le p < \infty$, the resulting bound is

$$\|a\mathbf{1}_S - b\mathbf{1}_T\|_p \le |a - b|\mu(S)^{1/p} + |b|\mu(S \triangle T)^{1/p}.$$

The formal theorem lives first in the extended nonnegative reals, so infinite measures are handled without silently converting infinity to an ordinary real number.

Source: `KomorebiPaperV/MaskPerturbation.lean`.

```
theorem finite_p_perturbation (μ : Measure Ω) (S T : Set Ω)
    (hS : MeasurableSet S) (hT : MeasurableSet T) (p : ENNReal)
    (hp : 1 ≤ p) (hpTop : p ≠ ∞) (a b : ℂ) :
    eLpNorm (jump S a-jump T b) p μ ≤
      ‖a-b‖ₑ * μ S ^ (1 / p.toReal) + ‖b‖ₑ * μ (S Δ T) ^ (1 / p.toReal) := by
  have hp0 : p ≠ 0 := ne_of_gt (lt_of_lt_of_le (by norm_num) hp)
  rw [jump_error_decomposition]
  calc
    _ ≤ eLpNorm (jump S (a-b)) p μ + eLpNorm (jump S b-jump T b) p μ :=
      eLpNorm_add_le (jump_measurable S hS (a-b) μ)
        ((jump_measurable S hS b μ).sub (jump_measurable T hT b μ)) hp
```

```
    _ = _ := by
      rw [symmetric_difference_norm μ S T hS hT p hp0 hpTop,
        jump, eLpNorm_indicator_const hS hp0 hpTop]
```

The notation `ENNReal` permits ∞, and `eLpNorm` is an extended seminorm. The hypotheses `hp : 1 ≤ p` and `hpTop : p ≠ ∞` govern the triangle inequality and finite-exponent formula. A finite real valued corollary requires the displayed terms to be finite, for example through finite mask and symmetric-difference measures.

5.3 A concrete perturbation budget

An amplitude and mask budget

Suppose $p = 2$, $\mu(S) = 1$, $\mu(S \triangle T) = 0.01$, $a = 2$, and $b = 1.9$. The bound is

$$0.1\sqrt{1} + 1.9\sqrt{0.01} = 0.29.$$

If the background approximation error is at most 0.04, the full error is at most 0.33 by the additional triangle inequality in `full_signal_perturbation`. The numbers illustrate a deterministic budget conditional on the amplitude, mask, and background estimates. A statistical procedure achieving those estimates requires additional work.

5.4 Pointwise and essential supremum

The source first proves a bound at every point, then transfers it to the essential supremum seminorm.

Source: `KomorebiPaperV/MaskPerturbation.lean`.

```
theorem infinity_perturbation (μ : Measure Ω) (S T : Set Ω) (a b : ℂ) :
    eLpNorm (jump S a-jump T b) ∞ μ ≤
      ENNReal.ofReal (‖a-b‖ + if S Δ T = ∅ then 0 else ‖b‖) := by
  rw [eLpNorm_exponent_top]
  exact eLpNormEssSup_le_of_ae_bound (ae_of_all μ (pointwise_sup_bound S T a b))
```

The displayed bound uses whether $S \triangle T$ is empty as an actual set. An essential-supremum argument may ignore a null set, but a pointwise supremum cannot. This particular theorem remains a valid, sometimes coarse, bound when the sets differ only on a null set. Its statement should not be silently replaced by an assertion that pointwise and almost-everywhere equality coincide.

5.5 The open obligations remain identifiable

The stable edge-packet recovery conjecture asks for specified signal classes, contrast and separation assumptions, and a noise model under which a multiscale estimator controls both mask error and amplitude error at rates separated from smooth approximation. The formal perturbation bound explains how such estimates would enter reconstruction. It does not construct that estimator or prove those rates.

The edge-packet approximation-class conjecture asks for natural function spaces whose norms distinguish smooth approximation, boundary geometry, packet amplitude, and packet identification. The

current declarations do not define and close that proposed theory. Infinite-tree consistency, minimax claims, and optimal Smith sampling also remain outside the twenty-result formal scope.

These boundaries matter when reading Part II. Its broader deterministic and geometric theorems can develop the mathematics without turning every contextual statement into a Lean-certified target. The final traditional record and the separate Part II crosswalk identify that distinction explicitly.

6 Complete prunings, global selection, and stability

6.1 A finite tree carries positive finite branching

The tree type permits a leaf or a branch with $n + 1$ children. Thus every branch has at least one child, and unary branches are included.

Source: KomorebiPaperV/FiniteAdaptive.lean.

```
inductive Tree (A : Type*) where
  | leaf : A → Tree A
  | branch : (a : A) → (n : ℕ) → (Fin (n + 1) → Tree A) → Tree A
```

The tree itself is a finite inductive object. A cut is another typed inductive object: stop at the current root, or choose one cut in each child. The type prevents selecting an arbitrary collection that fails to cover a terminal path.

Source: KomorebiPaperV/FiniteAdaptive.lean.

```
inductive Cut : Tree A → Type _ where
  | stop (t : Tree A) : Cut t
  | split {a : A} {n : ℕ} {children : Fin (n + 1) → Tree A} :
      (∀ i, Cut (children i)) → Cut (.branch a n children)
```

A singleton leaf has only its stop cut. At a unary branch, stopping at the root and descending to its child are distinct cuts even if node labels happen to coincide. Formal nodes carry their positions in the tree, so equal labels do not collapse different nodes.

6.2 Conservation is an explicit hypothesis

For an additive quantity p at each node, conservation says that the parent's value is the sum of the child-root values and that this continues recursively.

Source: KomorebiPaperV/FiniteAdaptive.lean.

```
def conserves [AddCommMonoid E] (p : A → E) : Tree A → Prop
  | .leaf _ => True
  | .branch a _ children =>
      p a = ∑ i, p (label (children i)) ∧ ∀ i, conserves p (children i)
```

By induction on the cut, its sum equals the root value. The quantity may be a scalar, a vector, or an operator. The argument uses addition and the conservation identity. It does not derive conservation from an arbitrary tree topology.

For projector valued packets, one supplies both conservation and a root equal to the identity operator. Every complete pruning then reconstructs the signal. This makes selection compatible with exact synthesis: changing the cut changes the representation while preserving the total operator.

6.3 From recursive cuts to covering antichains

The manuscript describes a complete pruning as a node set that meets each root to terminal path exactly once. The source builds a positional node type, terminal paths, and a membership predicate for the nodes selected by a recursive cut. It proves the equivalence with the set based covering-antichain description.

Source: `KomorebiPaperV/CompletePrunings.lean`.

```
theorem complete_iff_covering_antichain {t : FiniteAdaptive.Tree A} (S : Set (Node t)) :
    Complete S ↔ CoveringAntichain S := by
  constructor
  · intro h
    constructor
    · intro p
      obtain ⟨v, hv, _⟩ := h p
      exact ⟨v, hv.2, hv.1⟩
    · intro u hu v hv huv
      obtain ⟨p, hp⟩ := node_on_terminal v
      obtain ⟨w, _, hw⟩ := h p
      exact (hw u ⟨ancestor_onPath huv hp, hu⟩).trans (hw v ⟨hp, hv⟩).symm
  · rintro ⟨hcover, hanti⟩ p
    obtain ⟨v, hv, hp⟩ := hcover p
    refine ⟨v, ⟨hp, hv⟩, ?_⟩
    intro u hu
    rcases path_nodes_comparable hu.1 hp with h | h
    · exact hanti u hu.2 v hv h
    · exact (hanti v hv u hu.2 h).symm
```

The file also proves that every complete set comes from a cut and that the cut is determined by its selected nodes. Together these results give `pruningEquiv`. This is why later theorems apply to every complete covering antichain, not just a preselected list of recursive examples.

6.4 Literal sums over selected nodes

`PruningSums` connects the recursive cut sum with the actual finite sum over the selected node set. Its operator theorem provides both the operator equality and the applied-signal equality.

Source: `KomorebiPaperV/PruningSums.lean`.

```
theorem packet_projector_synthesis {H : Type*} [NormedAddCommGroup H] [NormedSpace ℂ H]
    (p : A → H →L[ℂ] H) (t : FiniteAdaptive.Tree A)
    (h : conserves p t) (hr : p (label t) = ContinuousLinearMap.id ℂ H)
    (S : Pruning t) (x : H) :
    nodeSum p S = ContinuousLinearMap.id ℂ H ∧
      (∑ v ∈ S.val.toFinite.toFinset, p (nodeLabel v) x) = x := by
  have hs := (antichain_synthesis p t h S).trans hr
  refine ⟨hs, ?_⟩
  have hx := congrArg (fun T : H →L[ℂ] H => T x) hs
  simpa [nodeSum] using hx
```

The hypotheses `h : conserves p t` and `hr : p (label t) = ...id...` are inputs. There is no assertion that an arbitrary family of packet operators indexed by a tree automatically satisfies them.

6.5 Existence of a minimum allows nonadditive objectives

The manuscript's general criterion has the form

$$J(S) = R(S) + \eta L(S) + \tau K(S),$$

where R, L, and K can depend on the complete pruning as a whole. Finiteness alone ensures a minimum is attained.

Source: `KomorebiPaperV/PruningSums.lean`.

```
theorem objective_minimum (t : FiniteAdaptive.Tree A) (R L K : Pruning t → ℝ) (η τ : ℝ) :
    ∃ S : Pruning t, ∀ T, objective R L K η τ S ≤ objective R L K η τ T :=
  complete_pruning_minimum t _
```

No positivity or additivity of these functions is needed for the finite attainment theorem. Such assumptions can be useful in applications, but the logical reason for attainment here is a nonempty finite search space.

The dynamic program below solves an additive criterion $\sum_{v \in S} c(v)$. The general nonadditive existence result does not imply that the same recurrence efficiently minimizes an arbitrary coupled objective. A user of the recurrence must verify the required additive decomposition.

6.6 Strict gaps require competitors

If S_* is a strict minimizer and there is another pruning, the minimum positive objective difference is attained by a real competitor.

Source: `KomorebiPaperV/PruningSums.lean`.

```
theorem objective_gap_attained (t : FiniteAdaptive.Tree A) (J : Pruning t → ℝ) (S : Pruning t)
    (ho : ∃ T, T ≠ S) (hu : ∀ T, T ≠ S → J S < J T) :
    ∃ T : Pruning t, T ≠ S ∧ 0 < J T-J S ∧ ∀ U, U ≠ S → J T-J S ≤ J U-J S := by
  let : Fintype (Pruning t) := Fintype.ofEquiv (Cut t) (pruningEquiv t)
  classical
  obtain ⟨U,hU⟩ := ho
  obtain ⟨T,hT,hmin⟩ := KomorebiPaperV.finite_minimum (fun T => J T-J S)
    (Finset.univ.erase S) ⟨U, Finset.mem_erase.mpr ⟨hU, Finset.mem_univ _⟩⟩
  have hTS := (Finset.mem_erase.mp hT).1
  exact ⟨T,hTS,sub_pos.mpr (hu T hTS),fun V hV => hmin V
    (Finset.mem_erase.mpr ⟨hV, Finset.mem_univ _⟩)⟩
```

The explicit `ho` hypothesis excludes the empty competitor family. For a singleton pruning space, the selected pruning is unchanged for every objective, so a separate singleton theorem is the natural statement. A tie between distinct prunings gives zero separation and does not satisfy a positive strict-gap hypothesis.

6.7 The bottom up evaluator

For an additive node cost, the optimal value obeys

$$V(v) = \min\left(c(v), \sum_{u \text{ child of } v} V(u)\right).$$
